Upon this subject, Dr. Gusserow says:¹ "If the tumor represents mainly a simple hyperplasia of uterine tissue (such as is normally witnessed in pregnancy), there is a preponderance of muscular over connective tissue-elements. In that case, the growth approaches the type of pure myoma. On the other hand, if from the very incipiency of the new formation the connective tissue predominates, or if it does so secondarily, by a process of fibrous induration, the muscular tissue being held in abeyance, as it were, we get an almost pure fibroma. Nevertheless, it would not be in accordance with histological principles to divide these tumors into myomata and fibromata, since, as already stated, both varieties of tissue invariably coexist in them."

A separation of uterine fibroids into two classes was made by Mr. Tait in 1874. The one he designated as "soft oedematous myoma," the other, as "nodular myoma." This classification in one way is as objectionable as the preceding, for there is no distinct line of division between the soft and the hard myomata. Clinically we find them all the way from those that have the hard feel of a rock and cut like cartilage, to those that are so soft that they give a doubtful sense of fluctuation through the abdominal walls, and upon

¹ *Cyclopedia of Obstetrics in Gynecology*, vol. ix, p. 186.

section have very much the appearance of lipomata. In another way this division is important, for in many instances it is possible to distinguish the very soft myoma from the firm nodular one. The former variety is more richly supplied with blood; its growth is usually continuous, rapid and unaffected by the meno-pause, while it is more liable to dangerous degenerations than the latter. Therefore, the recognition of a soft myoma, as will be shown elsewhere, will modify greatly our prognosis and treatment.

Making use for the moment of that somewhat arbitrary division of uterine fibroids, with reference to their direction of growth, into subserous, interstitial and submucous myomata, we shall omit all consideration of the last class. They are pedunculated growths in the uterine cavity, and their treatment by removal through the vagina is established beyond all question. The same is true of a portion of the interstitial growths. Those that invade mainly the cavity of the uterus can best be reached by the same route as the submucous, and removed by enucleation. Therefore, one of these classes, the submucous, and a part of the second class, the interstitial, need not further engage our attention with reference to treatment.

The fact seems well settled, that the development of these neoplasms never begins before the establishment of the menstrual function, nor after its cessation. Still I have seen one case in which a rapidly growing fibroid was first found many years after the meno-pause; and I think several other similar examples have been recorded. Yet it is very probable that these tumors may have begun during the menstrual life of their possessors.

They commence in the muscular or connective tissue structure of the body of the uterus, exceptionally in the cervix, and, as a rule, grow very slowly at first. They are single growths in about one-half the cases, and in the other half, multiple. The multiple fibromata, or multinodular, as Mr. Tait calls them, are much more likely to grow slowly and never to reach any very great size, and to complete their growth at or before the time of the meno-pause. They are almost certain, at an early period of their existence, to give rise to menorrhagia. For the rule is that one or more of them will extend towards the uterine mucous membrane and produce in it those changes that are usually the cause of hemorrhage. The single fibromata generally grow more rapidly and often in the direction of the abdominal cavity. Like the multiple fibroids in the early period of their progress, they cause profuse menorrhagia. But as they ascend into the abdomen and become, as often happens, more or less pedunculated, the hemorrhage becomes less, or entirely ceases. There are, however, frequent exceptional cases in which the menorrhagia continues when the subserous fibroma has a location somewhat remote from the endometrium. This symptom is then probably due to a general hyperemic condition of the uterus.

It is not a very unusual occurrence in cases of multinodular myomata for one of them to advance steadily and invade the abdominal cavity, while the others remain stationary in size. The case then becomes one which practically follows the course of single subserous myomata.

In tracing the natural history of uterine fibromata, the one question of paramount importance that arises, is this: Are we dealing with a self-limited

disease? That is, does the development of these neoplasms end with the establishment of the meno-pause? Again, if their growth does stop at this time, a second question presents itself, as to what extent their after-history of retrogression is free from suffering or danger.

The mode of treatment, whether palliative or radical, that should be chosen, will depend greatly upon the answers to these questions. The first one has been answered so often and so positively in the affirmative, that it never has occurred to any one to question or investigate the correctness of the answer. It has been laid down and accepted as a rule, that the progress of uterine fibroids of all classes ended with the cessation of the menses, and that, after that time, they gradually disappeared or diminished in size, or at least, became harmless. The exceptions to this rule have been regarded as so rare as to merit but little attention.

Mr. Tait, however, says of the "soft edematous myoma": "It is no regarder of age. The largest I ever removed — over sixty pounds — grew almost entirely after the meno-pause; patient's age, sixty-three." He further remarks that the hard, multinodular myoma is a disease of menstrual life, and the soft, edematous myoma certainly is not; that is, Mr. Tait makes an exception to the rule in the latter class of myomata, whose relative frequency is certainly great enough to go a long way in invalidating it.

The observations that my own small experience has permitted me, are in accord with those of Mr. Tait in regard to soft myomata and small multiple fibroids. But in three instances I have removed by abdominal section nodular fibromata, that were growing rapidly at a period of from one to three years after the meno-pause had been completely established. In another case I attempted the removal of a large fibroid in a patient sixty-nine years of age, because it was growing very fast, and had doubled in size within the preceding two years. This tumor could not be classed as a soft nor as a hard nodular myoma. In density of structure it seemed to be about half-way between the two.

Of sixteen abdominal hysterectomies that I have made, I have operated in seven, after the time of the climacteric period, either because the tumors were growing or were otherwise dangerous to the life of the patient. Thus of my sixteen cases, one-half of them lacking one, developed the formidable symptoms necessitating hysterectomy after the meno-pause. This seems to me a sufficient answer to the second question, namely: Do uterine myomata become harmless when the climacteric is passed? Therefore, from the facts that have been given, I submit that the rule, that the development of uterine fibromyomata ceases at the time of the meno-pause, and that ever after they become innocuous, has so many exceptions that it becomes almost valueless as a guide to treatment.

I do not for a moment doubt that most of the hard-multiple myomata and many of the small single ones, particularly those that have existed for a long time, complete their development with the advent of the meno-pause, and afterwards entirely disappear or become much diminished in size, and of no further inconvenience to the patient. On the other hand, I am very certain that those subserous and interstitial myomata, whether soft or hard, that have attained already a considerable size and have encroached to quite an extent upon the abdominal cavity, are not

much influenced in their progress by the cessation of the menstrual function.

Furthermore, a careful study of the natural history of uterine myomata in a large number of cases, cannot fail to convince one that the three or four years preceding and following the menopause are especially disastrous to patients suffering from this disease.

Out of sixteen hysterectomies by abdominal section ten of them became necessary during this period. Keith, a few months since, published a book in which he reported 106 cases treated by electrolysis. Omitting from this number twelve, in which the existence of a fibroid was doubtful or in which it was submucous, we have remaining 94 cases; 43 of these, or almost one-half, first went to him for treatment between the ages of forty-two and fifty inclusive.

According to a table of 798 cases prepared by Schröder,² 407 of the number, or fifty-one per cent., first sought medical aid between the ages of forty and fifty.

Again, the method of treatment to be selected will depend, to a considerable extent, upon the severity of the disease, the amount of suffering, and the infirmity it occasions, and the danger to life with which it is attended. There can be no doubt of the very frequent occurrence of uterine fibromata; and that in quite a proportion of cases no serious inconvenience results, and no treatment is necessary. But we have no reliable data upon which to base any conclusion as to their frequency; nor are we interested in that indefinite number that do not require treatment. What will be said, therefore, of the seriousness of the affection, will have reference only to that class of cases in which some kind of treatment is indispensable.

Passing in review as hastily as possible some of the symptoms, complications and degenerations attendant upon fibroids, that constitute their gravity and danger, we have first, hemorrhage and pain. Both occur, as a rule, with interstitial tumors, and exceptionally with the subserous. All will agree that both are prominent factors in making invalids of patients with myomata, just in proportion to their severity and persistence.

Pressure within the pelvis upon ureters, bladder and rectum, often gives rise to very serious symptoms other than pain. Both interstitial and subserous fibroids, on account of the great size they attain, frequently become a distressing and dangerous disease. Parenthetically, it may be said of these large tumors that they have formed adhesions to surrounding structures, especially the omentum, and thence derive a rich blood-supply. In eight laparotomies that I have made for myomata that nearly filled the abdominal cavity, this condition existed.

As complications, I have in four instances found cystic ovaries; and in one, pus in the pelvic cavity, probably from a ruptured pyosalpinx. Dr. Wyllie³ says, "In the majority of cases in which I have removed the tubes and ovaries to stop the growth of fibroids there has been salpingitis, and in many of these I have found large quantities of pus in or about the tubes and ovaries." Mr. Tait also says that in a large number of operations he found the myoma complicated by double pyosalpinx.

Most important of all are the degenerations to

² *Krankheiten der Weiblichen Geschlechtsorgane*, Leipzig, 1884, p. 216.

³ *Transactions of the American Gynecological Society*, vol. xiv, p. 119.

which these growths are liable. The whole class of so-called fibro-cystic tumors of the uterus are, undoubtedly, degenerate myomata. They sometimes suppurate, and contain pus cavities. Their structure becomes necrotic, wholly or in part, from interference with the blood-supply; or softened and broken down, from the effects of inflammation or serous effusion. It has been demonstrated, too, beyond all question, that they degenerate into sarcomata. Under these circumstances the uterine fibroid becomes as certainly fatal as a degenerating ovarian cystoma.

The observations of Dr. Martin upon this subject, as quoted by Dr. Cushing, have so important a bearing that I append them: "Of the 205 myomata of the corpus, therefore, only ten showed pronounced conditions of involution; 32 were undergoing a transformation which must be designated as very serious for the women afflicted with them; six were malignant degenerations; and nine showed a fatal complication with carcinoma. If we leave the latter cases out of consideration, as being accidental complications, the fact remains, that yet 38 out of 196, or out of 186 (if we subtract the cases of involution of the tumor), 38, that is, 20.4 per cent. showed changes, which certainly represented the opposite of that which was called benign."

If this brief and very imperfect presentation of the development and complications of uterine fibromata be accepted as substantially correct, it must be concluded that we are considering the treatment of a disease, that is not self-limited, and that is formidable and dangerous both to the health and life of the woman thus afflicted. For the management of this grave affection we have, on the one hand, as has already been said, the radical method of treatment, hysterectomy, and on the other, certain palliative methods. First among the latter stands Tait's operation for the removal of the uterine appendages; the object of which is two-fold, first to arrest hemorrhage by inducing an artificial menopause, and secondly, to stop the growth of the tumor. In those cases where the myoma is small, and where hemorrhage is a prominent symptom, and is likely to continue to be so for several years, this operation is especially indicated. Also when the growth is recent, small, and steadily growing, and the patient is young, it so often completely terminates the affection, so far as any further symptoms are concerned, that it becomes a resource of treatment of very great value. When employed in the limited range of cases that I have indicated, removal of the uterine appendages has rarely failed to relieve the hemorrhage, and has usually been successful in arresting the growth of the tumor. In spite of some failures, its measure of success has been great enough to make it a method of treatment with which we could not well dispense. But when uterine fibromata (subserous and interstitial) have reached a large, or even medium size, and have extended considerably into the abdominal cavity, removal of tubes and ovaries becomes a very difficult, and sometimes an impossible operation. In comparison with hysterectomy, it is fully as formidable and dangerous. At the same time it is merely palliative. It is true that it may stop hemorrhage, but this is a serious matter only exceptionally in these cases. Again, it often fails to arrest their growth, and certainly fails to remove the other attendant dangers of degeneration, that are a constant menace. Therefore this operation can, in no way, take the place

of hysterectomy. It rather supplements the latter, in that it is especially applicable to small bleeding fibroids in young patients, where hysterectomy would be particularly difficult to do, and would be a procedure of greater danger than the existing gravity of the disease would warrant.

The second palliative mode of treatment that we have to compare with the radical, hysterectomy, is electricity by the method of Apostoli. Some of the advocates of this treatment, notably Keith, have claimed for it, in the cure of fibroids, an efficacy so great as to obviate all further necessity for the operation of hysterectomy. Apostoli himself, however, has never made for it any such claim. I have never made trial of Apostoli's method, and therefore know nothing of it from actual experience. So I am forced to draw my conclusions in regard to its value, and consequent relation to hysterectomy, from the testimony of others. Fortunately there is no lack of witnesses; but unfortunately, the evidence they give is conflicting almost to contradiction. Keith, in the publication referred to above, reports 106 cases treated by him with electricity, but does not give any summary of the results of his treatment. Yet following through the cases in detail as recorded by this writer, it would appear that electricity, often after a long-continued use, relieved the hemorrhage in most cases, but failed to do so in some; that a few very small tumors were made to disappear entirely; and that many others were diminished somewhat in size. This diminution, however, was noted principally in those that did not extend to the umbilicus. For the most part, there was no decrease in the size of the larger ones. Mr. Keith lays special stress, in reporting these cases, upon the claim that most of these patients felt better after the use of the electricity than before; they suffered less pain, and were less invalids. In one instance the treatment gave a fatal result. In several very successful cases the existence of a tumor, to say the least, was doubtful.

Dr. Chadwick,⁴ after reporting the cases in which he had employed Apostoli's method, says: "It will be seen from these brief records that the only favorable results were in diminishing menorrhagia (Cases I, V), and once (Case III), in temporarily relieving dysmenorrhea. In no case did the fibroid decrease, during or subsequent to treatment. In three cases (II, X, XI), metro-peritonitis was caused, one of which terminated fatally. In one case (IX), septicæmia set in, resulting fatally. In two cases (VI, VII), menorrhagia was increased. With the experience that I have had, I feel warranted in insisting that the method is a dangerous one; that its claims to diminish the bulk or even arrest the growth of fibroids is questionable and unproved. Its alleged effects in arresting hemorrhage of the uterus, through its caustic action upon the lining membrane of the uterus, has *a priori* considerations and a preponderance of experience in its favor. Whether it is the safest and most efficient agent to achieve this end, seems to me open to question."

Dr. Homans says, "The curative action of the electrolysis à la Apostoli, is very problematical, and it hardly even diminishes the size of the tumors."

Dr. Martin, of Chicago, says, "Fibroid tumors of small size can be completely absorbed by the proper currents of galvanism."

⁴ Transactions of the American Gynecological Association, vol. xiv, pp. 132, 133.

Dr. Doléris, of Paris, through his assistant, Dr. D. Angel Villa, says, "After a thorough and extended trial of Apostoli's methods, no disappearance or marked diminution of the tumors was noted."

In the summary of a report of thirty cases treated by the method of Apostoli at St. Bartholomew's Hospital, the operator concludes with the following words: "The results of the cases reported are not as brilliant as could be wished, and the treatment is not entirely free from danger, as shown by the fatal case; but compared with other methods, it is probably the best short of actual removal by operation. Whether the advantage, which is small, is worth the extra trouble and time involved, it is difficult to say. This point can possibly only be decided by reference to the circumstances connected with each case. It would seem that Dr. Apostoli has not found it so uniformly successful as he at first believed, for he has recently advocated the treatment of uterine fibroids by the interrupted current. The tumors do not decrease much in size, but in the thirty cases only two have increased. Hemorrhagic myomata are those most favorably influenced by the treatment."

Whatever else the above testimony may show, it incontestably demonstrates (even that portion of it most favorable to this method) that electricity is no direct substitute for hysterectomy. It has signally failed, even as a palliative procedure, exactly in those cases where the radical operation is indicated, namely, the very large interstitial and subperitoneal tumors. In short, whatever value it has, is shown principally in the treatment of small bleeding myomata, precisely as is the case with the first palliative removal of the uterine appendages. The only way that either of them can be claimed in any manner to restrict the application of hysterectomy in the treatment of fibroids is by stopping the growth of small tumors, and thus preventing the necessity of the latter operation at some future time.

There remains to be mentioned as briefly as possible the third palliative method — use of the sharp curette for treatment of the endometrium. This procedure is directed solely to the relief of hemorrhage, and is usually successful when the uterine cavity is not too much distorted to prevent the operation from being thoroughly done. It is more reliable means of treating menorrhagia than electrolysis. It may also, with advantage, take the place of the comparatively grave operation — removal of the uterine appendages — when hemorrhage is the principal symptom requiring treatment.

Finally, abdominal hysterectomy, the treatment for radical cure, remains to be considered. From our deductions in regard to palliative methods, it follows that this operation, in large interstitial and subserous myomata, is our only resource. That the disease is one of very great gravity with reference to the health and life of the patient has, I think, been clearly shown. In view of this fact, has the danger of the operation become sufficiently small to warrant its general employment in these cases? The operation may be said to have commenced its legitimate existence about the year 1865. During the following twenty years, that is up to 1885, there was something over six hundred recorded cases of laparotomy for the removal of uterine fibroids, with a mortality of about thirty-three per cent. This great fatality is partly explained by the fact that these cases represented the early experience of the

operators, but in much greater degree by the additional fact that most of them were simply operations of last resort. And from this, we may again infer that a fatal tendency often attaches to uterine myomata. The results of hysterectomy during this period are not at all surprising when we recall that the death rate of ovariotomy was almost as great when it occupied a similar position as a last resort procedure. The great fatality of the operation, which prevailed until lately, explains also the eagerness with which any palliative means of treatment was welcomed by surgeons, and the exaggerated praise accorded to it in every supposed case of success.

Since 1885, and especially during the past two or three years, the operation has made very rapid progress in point of success. While it had a fatality of thirty-three per cent. five years ago, now the proportion of failures has become so small in comparison, that the advisability of hysterectomy in any given case has become an entirely different question. The percentage of success that is attained at the present time can only be approximately determined.

My own cases of hysterectomy are too few in number to be of the least value, so far as their percentage of deaths or recoveries is concerned. My last six in succession have recovered. Looking back over the failures of my earlier work, and seeing how many of them were due to preventable causes, I feel very certain that in the future my unfavorable results after hysterectomy will not exceed ten per cent. Dr. Holmes has recently reported ten successive recoveries.

In a total of about one hundred cases, Dr. Bantock has had not far from a ten per cent. loss. His later operations, I believe, give a mortality considerably less than this. On the whole, it is probable that ten per cent. approximately represents the present mortality of the operation.

Again recurring to the many dangers that attend the large interstitial and subserous fibromata, and recalling the many ways in which they kill, and especially (of the several degenerations to which they are liable) those of malignant character, that Dr. Martin found in twenty per cent. of 186 cases, I feel warranted in insisting that hysterectomy, which entirely cures nine out of every ten of the patients, is urgently indicated. I claim, too, that apart from the dangers mentioned, the operation, with its present small fatality, is perfectly justifiable for the cure of the hopeless physical and mental suffering that these large tumors often inflict. When its mortality is still further decreased by its prompt employment, and, by the consequent elimination of many cases that have become desperate by delay, abdominal hysterectomy will take its place among the great surgical procedures of the half-century, second only to ovariotomy in its brilliant success.

— A correspondent writing to an English contemporary throws a light upon the dark side of the subject of purchasing medical practices, when he says: "About nine months ago I bought a practice, which, to say the least, has not turned out altogether an unequalled financial success. When I mention (with a blush) that one of the names given to me belonged to a patient who died four years ago, and that several others had been previously, as I subsequently ascertained, handed over to a neighboring practitioner, it will be readily understood that it was not the practice alone that was sold."

ADENOID GROWTHS IN THE NASO-PHARYNX: RESULTS OF THEIR REMOVAL IN SEVENTY CASES OF MIDDLE-EAR DISEASE.

BY FREDERICK L. JACK, M.D.,
Assistant Aural Surgeon to the Massachusetts Charitable Eye and Ear Infirmary.

THE importance of nasal and post-nasal obstructions in their relation to diseases of the middle ear has recently received careful consideration in the admirable paper of Dr. Franklin Hooper on "Adenoid Vegetations in Children," and also in the article written by Dr. Clarence J. Blake on the "Relation of Adenoid Growths in the Naso-Pharynx to the Production of Middle-Ear Disease in Children." In reading a brief report of seventy cases, I offer nothing original, but wish to emphasize what has already been said as to the encouraging results obtained by removal.

For the opportunity of operating on many of the patients, I am indebted to the aural surgeons of the Infirmary. Observations on these, together with private ones, extending through a period of eighteen months, warrant the belief that the relief from ear trouble in many is permanent. A hundred or more children were examined for adenoids, and if found in small amounts and soft, attempts were made at their removal with the finger. These cases have no value in statistics. I regret that notes of these were not made for comparison with those receiving more thorough interference.

In only a few of the seventy cases was nasal breathing especially interfered with. A number were heavy breathers from obstruction of the nasal passages by the growths, but in a few, the condition of the drum membranes, or the middle ear, aroused the first suspicion of post-nasal growths. That even a small amount of vegetations is frequently found in children suffering from deafness and otorrhoea, or both, is a frequent experience. If these cause or aggravate the ear trouble, in what way do they act? Is it mechanically by pressure near the orifice of the Eustachian tubes, preventing their opening, or is it rather by the changed direction of the inspired air, preventing the normal interchange of air with the middle ear, or is it by inflammation of the tubes by extension from the pharynx of a catarrh induced by the growths?

In spite of what has been written, the importance of the relation between the vegetations and ear diseases seems not to be appreciated by all. Let me briefly cite the following case as a rare example of the distressing condition induced by these tumors:

T. A., age five, was brought to the Infirmary in July, 1888, for deafness. Examination showed the drum membranes reddened and completely collapsed. The hearing power for the voice was very defective, and not improved after attempts to inflate the ears. The mouth was wide open, and the lips cracked and bleeding. Breathing through the nose was impossible. This condition was of a year's duration, and had caused the patient many sleepless nights and the parents much alarm. All the symptoms described by various writers on this subject were painfully exaggerated in this child. The post-nasal space was found, on examination, completely filled with growths. Operation was performed in July, 1888, and though rather long, nothing unusual happened. Immediately after the operation she could blow through the nose and could also use it for breathing. On inflation a day or two after, air entered the middle ears freely. Low

voice was heard at sixteen feet. She made an uninterrupted convalescence.

March 24, 1890, nearly one year and nine months afterwards, the mother reports the child's condition as excellent. Has had no trouble about hearing, and only at times, while suffering from a cold, has the breathing been interfered with.

FIG. 1.
From a photograph taken just before the operation, the child holding her breath.

FIG. 2.
From a photograph taken one year after the operation.

Of the seventy cases operated on, forty-three were males and twenty-seven females. The ages varied as follows:

Under five years	7
Five to ten years	41
Over ten years	22
Total	—
	70

The diseases of the middle ear were the following:

Otitis catarrhalis mucosa chronica	20
" " serosa	8
" media acuta simplex	18
" " suppurativa acuta	6
" " " chronicus	15
" " " cum granulations tympani	3
Total	—
	70

The instruments employed in operating were Hooper's modification of Löwenberg's forceps, but with larger blades, a rubber palate retractor, and the O'Dwyer mouth-gag. Patients were completely etherized and placed in an upright position.

In regard to sequelæ, it may be well to mention that seven experienced a sore throat after the operation, but in three only was it serious enough to cause discomfort. Of the seven, three had acute otitis. I experienced no trouble from haemorrhage, although at times it seemed a good deal. Drs. Bryant and Plummer kindly assisted in most of the operations.

It occurred to me to note the situation of the growths in relation to the kind of ear trouble. In fifty-one cases the vegetations were located chiefly on the posterior wall of the pharynx. Of this number, forty-six had non-purulent otitis. In nineteen the development was more extensive in the vault, and was associated with purulent disease in ten. From this it would appear that the location of the growths had little to do with the nature of the ear disturbance. In forty-four cases both middle ears were affected, fifteen experienced trouble in the left only, and eleven in the right ear. Among the number were two deaf mutes. In the case of one the growths offered an almost com-

plete obstacle to the entrance of air through the Eustachian tubes. This operation entirely removed, and the ears could be inflated with ease. Improvement in hearing was hardly expected, for in this case, as in the other, the labyrinth was already affected. I might mention incidentally that there was nervous twitching in one of the mutes, which suggested chorea. This quite disappeared after the operation, and when last seen, nine months afterwards, was barely noticeable. The faecal tonsils were hypertrophied in seven cases, and removed in two.

In considering the question of recurrence, I regret that the opportunity of subsequently examining the seat of operation was limited to a very few of the cases. Two subsequently returned for a second operation. Most writers, however, concur in the opinion that recurrence is due to want of thoroughness on the part of the operator to completely remove the growth.

In obtaining results, printed questions were mailed to the parents, and in most cases answers were received. Of those from whom no replies were received, the notes made at their last visit were depended on.

In cases of frequently relapsing ear trouble, it was expected of the operation to prevent recurrence. In the more acute cases, some improvement could be expected from treatment directed to the ears alone. In these cases, too, the operation was performed with a hope of preventing subsequent relapses of the ear trouble.

For the sake of easy comparison, we will classify the diagnosis of the ear into purulent and non-purulent otitis. The following tables show the kind and, as nearly as possible, the duration of the ear trouble:

PURULENT OTITIS.

One month or less	6 cases.
One year	3 "
Two years	5 "
Five years	1 case.
Total	15

NON-PURULENT OTITIS.

One month or less	19 cases.
Four months	1 case.
Eight months	1 "
One year	3 cases.
Two years	13 "
Three years	15 "
Four years	1 case.
Five years	2 cases.
Total	55

Considering the twenty-five cases of one month or less as acute cases, there have been but two cases of recurrence of otitis. Both of these were of the purulent variety. In one the ear remained healed eight months, when relapse followed an attack of influenza, the other was caused by whooping-cough. The results obtained in all of the cases is shown in the following table, which gives the time during which it is known no relapses have occurred:

PURULENT HEALED.

Two weeks	2 cases.
One month	4 "
Two months	1 case.
Four months	1 "
Eight months	1 "
Eleven months	1 "
Diminished otorrhoea	2 cases.
No improvement	2 "
Unrecorded	1 case.
Total	15

NON-PURULENT HEALED.

One to three months	23 cases.
Four months	1 case.
Eight months	2 cases.
Ten months	6 "
Eleven months	4 "
Twelve months	6 "
Twenty months	4 "
No improvement	7 "
Unrecorded	2 "
Total	55

The cases, I admit, are few to draw conclusions of great value from, still the long period of relief in many of the cases, whose previous history tells of frequent relapses, makes me think that much may be expected from the operation. It will be noticed that the results were somewhat better in the non-purulent than in the purulent, although the number of cases of the latter class is comparatively few. Decidedly favorable reports of the breathing were received in nearly all the cases. A few, however, had obstinate nasal catarrh, which made breathing still difficult. The results certainly show the benefit to be derived from the operation, and also gives us ground to believe that the patients will continue free from relapse.

APPENDICITIS: OPERATION, HERNIA, RECOVERY.¹

BY C. ELLERY STEDMAN, M.D., DORCHESTER.

J. P., aged nineteen, for many years was an undersized boy, but latterly had begun to grow, and was in good health. In June, 1882, he had an attack of appendicitis, for which I attended him. His symptoms were severe, and I had the benefit of Dr. Edes's opinion in consultation. I do not remember that at that time there was any question of operation. He made a good recovery in three weeks.

He was in a store in the city, when, on Saturday the 2d of February, 1889, he was seized with abdominal pain in the morning, and went to bed with it in the evening. Domestic remedies not availling, I was called in the afternoon of the 4th. He was sure he had had no chill. There was severe pain in the right iliac fossa, where slight dulness could be felt. There had been no dejection for two days, and to-day he vomited. Examination by rectum revealed a swelling, slight and soft, which could just be reached by the finger. His temperature was 102° and his pulse 104. Under treatment, the next three days the temperature retreated to 98 and 99°, and the pulse to 92 and 72, both generally less in the evening than in the morning; but the pain and vomiting increased. There was no movement of the bowels; the belly grew more swollen and tympanitic, and the countenance became pinched and anxious. These symptoms made me ask for a consultation. Accordingly, Drs. Fitz and Bolles saw him on Thursday, the fifth day of his illness. Then no sharply defined sensitive spot could be made out. Rectal examination gave pain, and a doughy sensation high up.

The next day there was no decided change; and the consultants agreeing with me on the necessity of operation, it was proceeded with on the seventh day (February 9th).

The treatment had been hot fomentations, and twenty drops of elixir of opium every three hours; when called for, as much milk and lime-water as he could take without nausea.

On the seventh day, after etherization, a sense of circumscribed resistance could be felt per rectum at the brim of the pelvis—none elsewhere. The account of the operation kindly furnished by Dr. Bolles is appended.

"The abdomen was moderately swollen and tender, especially tender in the lower part. There was no induration to be felt in the right iliac region, and not much more tenderness than in the hypogastrium, for instance. There was a little rather doubtful increase of dulness above Poupart's ligament on this side. Through the rectum a soft elastic tumor, that felt like a distended portion of intestine, was discovered, also a little to the right of the promontory of the sacrum.

"An oblique incision, four inches or more in length, was made an inch above the right Poupart's ligament and a little further towards the side. It was continued through the muscles, and down to, but not through the peritoneum. Then lifting the peritoneum from the psoas muscle, abscess or induration was sought for without success. After this it seemed best to explore the mass that was felt through the rectum; and without opening the peritoneum it was separated by the fingers from the muscles and great vessels until an opening over the brim of the pelvis finally reached it: an exploring needle and aspiration showed it was what it appeared to be—merely a coil of distended bowel—and that course was abandoned. Then I returned to the supposed site of the appendix, and scratching through the softest part of the peritoneum exposed, broke into a cavity containing a tablespoonful of stinking, shreddy liquid, and the swollen, ruptured appendix. The abscess wall was formed by the adhering surfaces of several coils of intestine, and as they were covered by only very recent lymph not much stronger than fresh curd, I did not dare to manipulate them much nor try to remove the sloughing appendix. So I washed the cavity and entire cut very thoroughly, put in two drainage-tubes, one into the abscess and one into the deep exploration, and sewed the skin and muscles together excepting where the tubes projected."

The patient seemed little relieved by the operation, and was very restless, but the temperature did not rise higher than 101°, and the pulse kept good. The pain and tympany continued; there was no movement of the bowels; milk, opium, and whiskey were given by enema.

The next (tenth) day, he was restless and delirious at times; there was no dejection; and the alimentation and medication by rectum was continued. The highest temperature was 101.6°.

It would be tedious to carry out the daily record. Emaciation became extreme; pain, delirium and enormous distention of the abdomen increased. The discharge was considerable at first, then decreased till the carbolized douches through the tubes returned clear. The stitches promised to hold well, but the wound grew sloughy, and one stitch after another gave way. Then there presented in the middle of the wound a knuckle of intestine as large as a hen's egg, which looked as if it would burst. Under these conditions it seemed as if life could not hold out, and the only encouraging symptoms were the pulse and tem-

¹ Read before the Boston Society for Medical Observation, April, 1890.

perature, the former particularly not rising above 108. Three-eighths of a grain of morphia hypodermically, were needed every two or three hours to control the pain.

As if these signs were not enough, a new threat appeared on the fourteenth day in the shape of a swelling of the right parotid gland. This, however, was offset by a pulse of 98, a temperature of 100°, and the retention by the stomach of five ounces of milk. The parotitis instead of going on to suppuration, subsided and gave no real trouble.

On the fifteenth day he got, for the first time, an injection of water per rectum, without result.

On the sixteenth day he retained sixteen ounces of milk with half an ounce of brandy given by mouth, and after an enema of three quarts of water there was a fecal discharge per rectum, but also through the wound; the temperature being 99.7°.

The seventeenth day his temperature was 100.4°, and his pulse 104; besides enemas, he retained in his stomach twenty-four ounces of milk and brandy. The abdomen which had been less swollen for several days, again required puncture, and it should have been said before, that this had been repeatedly done, with great relief, sometimes twice daily, whenever excessive tympanitis demanded the operation.

On the eighteenth day alimentation by rectum was continued on account of nausea, and two and a quarter grains of morphia in the day, hypodermically, were required on account of pain.

A glycerine enema was given on the nineteenth day, and followed by six dejections. Though very restless and uncomfortable, he had no pain, and passed much flatus. He vomited again twice in the afternoon.

The next day he had a good movement of the bowels preceded by sharp pain, and complained of very severe pain twice in the night. The motions continued daily, the faeces gradually disappeared from the dressings, and the stomach growing more tractable, the diet was largely increased. The exposed gut began to adhere to the edges of the cut. A note of Dr. Bolles's remarks: "At last, when the belly collapsed after the bowels had finally emptied themselves in the natural way, I was astonished to see this bowel recede, gradually forced in by the contracting cicatrix of the healing parieties."

It was noticed on the twenty-second day that he was still delirious when first awake. Two and five-eighths grains of morphia daily are demanded to relieve pain.

On the twenty-fifth day there was fecal discharge from the wound again followed by severe pain. The next day there was great prostration; the fecal dejections became very large; bromide of sodium began to be serviceable in the room of opium; the temperature normal; the pulse 96.

On the twenty-sixth day delirium was still occasionally present, though the dietary now comprised chicken broth, toast, custards and wine.

On the twenty-ninth day he first had a chop, and the appetite became prodigious.

On the twenty-eighth day a slight amount of fecal discharge was thought to have appeared on the dressings, the gut still peering through the wound. On the next day, codein was substituted for morphia, which was yet almost daily required—with good effect.

On the thirty-fifth day there were traces of fecal matter on the dressings, and delirium persisted at times till the forty-first day.

On the forty-fifth day he sat up for the first time twenty minutes, and from this time his progress was speedy and sure. The gut had receded to its proper quarters, at first covered by a thin membrane; but this soon gained toughness, and one would never guess in looking at the long, broad scar, that the bowel had ever protruded. The cicatrix is thick and strong, and no tendency to a hernia can be perceived. The patient passed the summer in the country, and his health was firmly re-established.

The points in this case, though not new, which made me think it perhaps worthy to be reported to this Society, are:

(1) The low run of the pulse and temperature, the former never having risen higher than, on two days to 118.

(2) The marked service rendered in relieving the painful and threatening distention, by pricking the abdominal wall with the long hollow needle. Though several times fecal matter followed through the punctures, and angry pustules formed round them, nothing but great benefit followed.

(3) The length of time, sixteen days, before the obstruction or paralysis of the bowel was relieved by a dejection.

(4) The hernia, and its cure by retraction and cicatrization of the wound.

The patient was shown to the Society in perfect health. Riding, driving and boating had not impaired the firmness of the cicatrix.

Hospital Practice.

BOSTON CITY HOSPITAL.

A CASE OF COCCYODYNIA: REMOVAL OF COCCYX, RECOVERY.

SERVICE OF ARNER POST, M.D., *Visiting Surgeon.*
REPORTED BY JOEL E. GOLDTHWAIT, M.D., *House Surgeon.*

Mrs. A., a boarding-house keeper, thirty-one years of age, has had, beginning a year ago, quite constant pain in the back, running down to the "tip of the spine." The pain has increased in severity and for the past five months she has been unable to sit squarely, being obliged to rest entirely upon one buttock. Of late the pain has extended down the legs. Defecation is quite painful, and for a few weeks micturition has been very frequent. The catamenia are regular.

The patient's previous health has been good, and she is ignorant of any cause for the present symptoms. She had a slight fall eight years ago striking upon the buttock, but suffered no inconvenience from it. She has had four children, the youngest being three years of age, and, as far as can be made out, the labors were normal.

Examination revealed great tenderness in the region of the coccyx, rendering a complete examination impossible.

After treatment by rest in bed, laxatives, etc., for ten days with no improvement, the patient was etherized and a thorough examination made for the first time. The lower half of the coccyx projected inwards, toward the rectum, at right angles to its nor-

mal position, and was freely movable. Aside from this nothing abnormal was found. The operation was immediately done. An incision, three inches long, was made just back of the anus, in the cleft between the buttocks and through this the lower portion of the coccyx was removed. A fracture was found which extended transversely across the bone at the point of mobility.

The wound was irrigated with a solution of corrosive sublimate (1-3,000), and tightly closed with silk sutures. A gauze dressing moist in the corrosive solution (1-3,000) was applied.

The recovery was rapid and uneventful. The wound healed by first intention.

On the fifth day after operation the bowels moved with much less pain than formerly.

Ninth Day. — Has had more or less pain for a few days, but upon removal of the stitches this was entirely relieved.

Sixteenth Day. — Is up to-day and is able to sit squarely, a thing she has not been able to do for a long time.

Nineteenth Day. — Has been up and about the ward for several days. Defecation is regular and not painful. Micturition is much less frequent. Says she feels twenty years younger. Patient was discharged on this day.

A short time after leaving the hospital she was again married, and, so far as her sensations about the coccyx are concerned, has been well.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

T. F. SHERMAN, M.D., SECRETARY.

ANNUAL Meeting of the Society, Monday, April 7, 1890, DR. W. INGALLS in the chair.

DR. F. L. JACK read a paper on

ADENOID GROWTHS IN THE NASO-PHARYNX; RESULTS OF THEIR REMOVAL IN SEVENTY CASES OF MIDDLE-EAR TROUBLE.¹

DR. FARLOW said: I have been very much interested in Dr. Jack's paper. It seems to me it is a very important subject. It is surprising, I think, how much can oftentimes be removed.

Dr. Farlow showed several specimens of growths which he had removed, and called attention to a pair of forceps in which the cutting part of the blade was much larger than in the forceps shown by Dr. Jack. When the soft palate is pulled forward by the palatine hook, there is plenty of room to use quite large blades.

Dr. Farlow showed a cast taken by a dentist, showing a very high palatine arch. The patient was perfectly deaf. There was no perforation of the drum, but a great deal of pain in the ear. The child was unable to go to school on account of the condition.

It is too early to predict what will be the final outcome in these cases. I have every reason to think, however, that there will be no recurrence. I don't quite agree with those who say that recurrence is always due to something left behind. After a man has done a good operation and has seen with the glass that there

is nothing of consequence left, he could not be sure that there might not be a recurrence; so that I think a man is not always to blame for a recurrence. Some children have a great tendency to the enlargement of the glands all up and down the back of the throat, as well as of the post-nasal space, and if the growth recurs one has simply to remove it again. Particularly is that the case after some of the exanthemata, and it seems to me that the exanthemata are sometimes the starting-point of these growths.

As regards removal with the finger I think that you can oftentimes get a good deal of benefit in small children where the growths are soft, but you can't always be sure that you get the growth all out.

I have two or three private patients seven or eight years of age, in whom, after the use of ordinary astringent and cleansing solutions, I have seen the growths diminish. I think it is always right to use an astringent and cleansing solution first, to see if that will not be sufficient to obviate the necessity of an operation.

DR. SPEAR said: Although I have no statistics to add to those of Dr. Jack, yet it has been my experience that in the larger number of the cases on which I have operated with the forceps and finger there has been no relapse and always an improvement, immediate and continued, except in the very rare instances in which the growths are combined with a chronic middle-ear disease of long standing. Such cases of deafness which have lasted some years are usually unimproved. I could add my experience to that of the reader that there is very little danger of relapse, and that the operation is advisable even where there is not very considerable obstruction to the breathing.

DR. LANGMUIR said: I do not think this subject has been exhausted, and I think Dr. Jack's paper is timely. One of the most important remarks in the paper is that, although there may not be nasal stenosis, still this operation may be imperative. In anterio-rhino logical times, Professor Holmes wrote a book upon "Deafness Caused by the Extension of the Faucial Tonsil behind the Soft Palate into the Region of the Eustachian Tube." He was certain that a great deal of ear-trouble which he called deafness was caused by the extension of the faucial tonsil into the region of the Eustachian orifice. When the subject of adenoid disease was studied more carefully, the investigation was not carried out with any view originally of benefiting cases of deafness or to account for cases of deafness, but it was for impeded breathing, and those of us who operated early paid no attention to the fact that the deafness was probably caused by the presence of the adenoid growth, except as we, in operating for impeded nasal respiration, found that deafness or disease of the ear which existed was frequently relieved.

It is only a few months since, at a meeting of the New York Laryngological Association, Dr. Tully called the aurists of the country to account for not paying more attention and operating more frequently in cases of adenoid disease, on account of the disease of the ear produced by the presence of these growths. Although the aurists claimed that they had not been unmindful of this cause of ear-disease, still not many facts were adduced to show that they had operated a great deal. Dr. Tully's paper was considered then a very timely paper, just as I consider Dr. Jack's to-night.

One remark of Dr. Jack struck me as eminently true, and that is, that sometimes a small amount of

¹ See page 297 of the Journal.

growth which may produce ear-trouble, and in fact may impede nasal respiration, will disappear under mild treatment. He instances the use of Dobell's solution by spray or otherwise, and I am sure that he is right about that. Sometimes, if these cases where a small amount of adenomatous growth is present are treated in a mild way very much relief is obtained, and by the next winter there is no return, so that, although I would say that the presence of deafness in a small child should always call attention to the possible presence of naso-pharyngeal adenoma, and that one ought never to be satisfied in treating disease of the ear until that adenoma is removed in some way; still, I would agree with Dr. Farlow that in a good many cases an operation, so called, may not be absolutely necessary.

With regard to permanent deafness my observation has been that in adults there is very frequently this conformation of the jaw, which would lead one to suppose that formerly there had been an adenomatous growth in the naso-pharynx; and I don't think it unlikely that the chronic disease of the ear was started at that time; the adenoma had disappeared, but the injury to the ear still remained, and the deduction from that is, that the greatest attention should be paid to children who have diseases of the ear with respect to the presence of adenoma. It is too late with the adult. The injury is done, but it may be prevented, it seems to me, if attended to early in life.

DR. FARLOW: Bearing on what Dr. Langmaid has said, I was attracted, last summer, to a young man, eighteen years of age, who had a typical mouth-breathing-mouth. I said he either has or has had trouble in his post-nasal space. His sister, who was three years older, had the same configuration. There was a child seven, and a child twelve years of age. At the request of the mother I looked at the child seven years of age. He was a typical mouth-breather, and had a large amount of adenoid disease. I looked at the other child, and while there was no real adenoid disease in the sense of a large mass, there was an irregular vault, which led me to think that there had been what appeared in the child of seven years. The jaw of the boy of whom I spoke was thoroughly deformed, so that it interfered with his looks. The sister had the same condition, though less marked. She was hard of hearing, and had a very pronounced upper jaw. I asked whether the father or mother had it, and the mother said: "I am afraid you will find it in me." Her sister had the same, and her sister who was married had a child the age of the youngest child, and that child I have operated on. I agree with Dr. Langmaid thoroughly that this configuration of the jaw was caused by the disease I saw in the younger children and removed; and I think it will not go on to the same extent in the younger children, and I also think if the older children had been operated on they would be better-looking to-day. I think it is not an uncommon disease in older people, and those who say children will outgrow it at the age of puberty make a great mistake. If we find patients seven or seventeen or older, I think we ought to investigate the jaws and the configuration of the throat, and see if there is not something left there. I have seen it in cases after the age of puberty. I operated three or four months ago on a young lady I had seen two years ago. She is now seventeen or eighteen, I think, and the growth was certainly larger

when I operated than it was two or three years before that.

DR. LANGMAID: A good deal has been said by every one who has written or spoken upon this subject about the conformation of the jaw, the high arch of the palate and the narrow jaw; but there is another deformity which, if it has been touched upon, I am not aware of it, and that is the lack of development of the nose. It will be seen that where this disease has existed a long time in an otherwise powerful boy, the nose is disproportionate in size to the rest of the bones of the face.

DR. FARLOW: The dentists sometimes say the deformities of these jaws are due to thumb-sucking. I have inquired of nearly every case since my attention was called to that fact, and in those cases there was no thumb-sucking; so that it seems that if thumb-sucking were not the only cause of the deformity.

DR. JACK: A number of the points mentioned I wanted to say something about, but I thought it would make my paper too long. I wanted to call attention to the ear. I did not feel that it was sufficient to free the nasal passages; I thought a little more should be done on the sides of the throat. I had seen a number of cases in which, after operation, there was trouble. The operation was done for the relief of the breathing.

DR. C. ELLERY STEDMAN read a paper on

A CASE OF APPENDICITIS: OPERATION, HERNIA THROUGH THE WOUND, RECOVERY.²

DR. BOLLES said: Dr. Stedman has not, in my opinion, overdrawn the after-history of the case in the least. The distension of the abdomen was enormous, almost hemispherical from the chest down to the pubes, and the tension of the skin was so great that no cicatrix of a week or two weeks old could possibly have held it. I don't think the stitches gave way so much by sloughing as by actual pulling. The part of the bowel which protruded through — I suppose it was a part of the colon or cæcum — was larger, it seems to me, than a hen's egg, and it was so far distended and thin that it was translucent, the light striking on it illuminated the interior, and little particles of fecal matter could be seen through it showing that it was almost to the point of bursting. Every day I saw it I expected that something like coughing or sneezing would happen to break it. The bowels remained torpid so long I was, in fact, almost tempted myself to puncture to relieve it. The healing I think is very remarkable. I don't think it is after all so very unusual in the history of these cases. I have seen several instances before in which there was hernia of the bowel and threat of rupture and finally, resolution and retraction of the bowel and a very good scar. I think the scar is apt to be stronger in these lateral cuts for appendicitis than in the median cuts for ovariotomy or other internal troubles.

I have two very interesting cases that have aroused a great deal of interest in my own mind in this subject, which I am not prepared to present to-night, as I wish to preserve them to report at some other time. I want to speak of one incident in the course of my first case which is brought to my mind by a remark of Dr. Stedman and that is the effect of large injections of water by the rectum. In the case to which I allude fecal matter had escaped from the wound perhaps

² See page 299 of the Journal.

five or six days, and then gradually grew less and shortly ceased entirely. For a week or ten days more there was absolutely no fecal matter from the wound, and the progress of healing seemed to be advancing in a perfectly satisfactory way. Every other day the bowels had been moved by a small enema of soap suds. On the day in question, the sixteenth day after the operation, an enema was given without effect. The nurse in attendance gave another—each time about a pint. The first had not come away, and the second producing no result, she gave a third, the amount of water used being rather indefinite. I estimated that at least two and a half quarts of water had been used at different times, all of which was retained. After the last injection there was a sudden escape of fecal matter through the opening and considerable water that had the same appearance as the soapy water of the injection. I mention this merely as an interesting incident or accident in the progress of the case. It had no effect. The fecal matter disappeared, and I think the case is well. I would simply say that while those escapes of fecal matter doubtless occur not infrequently in the convalescence of such cases, yet it would not be my order certainly, to give a large enema of two or three quarts of water. In my case it seems as if it were possible and rather probable indeed, that the water was the cause of the new opening which allowed fecal matter to escape. That being a possibility some caution should be used in moving the bowels. From that day my patient has succeeded very easily by suppositories of glycerine, or simply of cocoa butter in having a perfectly easy movement every other day.

AMERICAN ORTHOPEDIC ASSOCIATION. FOURTH ANNUAL MEETING.

THE several sessions of the Fourth Annual Meeting of the American Orthopedic Association were held at the College of Physicians, Thirteenth and Locust Streets, Philadelphia, Pa., September 16th, 17th, and 18th.

FIRST DAY.—MORNING SESSION.

THE PRESIDENT'S ADDRESS

was made by DR. DE FOREST WILLARD, of Philadelphia.

Having just returned from the International Medical Congress, held in Berlin, Dr. Willard confined his address chiefly to a narrative of his experience abroad. He told briefly of the establishing of a Section in Orthopedic Surgery in the International Congress, and its first meeting.

He thought that the appearances during the past year of "A Treatise on Orthopedic Surgery," by two members of this association, Drs. Bradford and Lovett, of Boston, marked a new era in the history of this branch of surgery. "The book will take," he said, "its place at once as the recognized index of progressive American Orthopedic Surgery."

Dr. Willard showed several new devices which he had happened upon while abroad, one a shoe for a club-foot detaining shoe, with ankle-joint made almost universal in movement by a thumb-screw and nut. Another ingenious device was an artificial knee and elbow-joint made of ivory. The ivory shafts of the respect-

ive artificial bones were intended to be driven into the medullary cavities of the proximal ends of the bones left after resection of the joints. In most of the cases experimented on with these joints a certain amount of sloughing of soft parts and bone has taken place, so that it could not be considered yet a great success.

Owing to the unavoidable absence of several members, some papers were read merely by title.

SPINAL DISTORTIONS AND THEIR TREATMENT BY THE STRAIGHTENED LEATHER JACKET.

by DR. BERNARD BARTOW, of Buffalo, N. Y., was thus read.

DR. E. H. BRADFORD, of Boston, read a paper on THE TREATMENT OF DEFORMITIES OF SPASTIC PARALYSIS.

Several interesting cases were reported in full, and from his experience he believed that the open incision and the complete division of the tendons of the shortened muscles was a therapeutic measure of great value. Hitherto surgeons had been contented with subcutaneous tenotomy; but an open incision, especially in the popliteal region and in the groin, offers the most thorough and satisfactory method for dealing with this class of cases.¹ The child is able to use the limbs far better. There are not the relapses seen after other less thorough measures. After the healing of the operation-wound, the child may be assisted by some form of light apparatus, and may be educated in the use of his muscles to greater advantage than when other methods of tenotomy are used.

A case was then reported of

TENOTOMY FOR THE RELIEF OF DEFORMITY IN A CASE OF SPASTIC HEMIPLEGIA,

by DR. ARTHUR J. GILETTE, of St. Paul, Minn., in which much relief had resulted from division of tendons.

DR. AP. MORGAN VANCE of Louisville, Ky., considered the subject of

AMPUTATION AS AN ORTHOPEDIC MEASURE.

He reported several cases in which amputation had been done for angular bony ankylosis at the knee-joint and also at the hip-joint in a case of extreme deformity. He believed that the proper application of a light, snugly-fitting artificial limb afforded more comfort and greater safety to life than the carrying about of a deformed limb which as a focus of tubercular disease, was always menacing the patient.

The medio-tarsal amputations ought to be obsolete and in place of them a clean amputation practised through the lower third of the leg. An amputation should not be done through the knee-joint, for mechanically it is contraindicated, but rather through the thigh just above the knee.

In the discussion which followed DR. JUDSON thought that the orthopedic surgeon should restrict his procedures to strictly mechanical ones—giving over to the general surgeon operative cases.

Some little difference of opinion was expressed as to the limit of the field of the orthopedist. The feeling of the majority present was that the orthopedic surgeon should combine the judgment and operative skill of the general surgeon with a knowledge of the

¹ The tendo-Achillis is divided, of course, subcutaneously, when it is found necessary.

clinical and theoretical value of truly orthopedic measures.

AFTERNOON SESSION.

DR. HENRY L. TAYLOR of New York, described his METHOD OF MAKING COUNTER-TRACTION AT THE KNEE-JOINT

in emergency and dispensary cases of acute synovitis and osteitis of the knee. He showed the apparatus which consists of two uprights on either side of the knee, extending to the middle of the thigh and leg respectively. The ordinary adhesive strips are applied from above the knee up and from below the knee down, each set ending in straps and webbing. The uprights have buckles attached at the upper and lower ends, and by buckling the webbing of the extension into these buckles over the end of the uprights, any desired amount of extension and counter-extension may be made. The side uprights may be so bent, if made of iron, or cut, if made of wood, that the pull is in the line of the deformity.

The important point that Dr. Taylor lays especial stress upon is that there shall be no twisting or rotating of the leg on the thigh, but that the pull shall be strictly to the line of the deformity, and the amount of the pull graduated to the comfort of the patient.

A bandage holds the thigh above steadily, and a bandage passed under the popliteal space steadies below. This can be applied to an ordinary plaster bandage from the middle of the thigh to the middle of the calf. Of course, the extension strips must be applied first, the webbing being pulled out over the end of the plaster case.

This addition to simple fixation in the treatment of synovitis and chronic osteitis of the knee is found in Dr. Taylor's experience to be of great value. A slight alteration in the amount of extension and counter-extension makes all the difference between perfect comfort and freedom from pain and the most intense suffering.

Exactly what happens by extension and counter-extension at the knee to the bony surfaces is not yet known. The fact that clinically it hastens recovery and relieves the patient is the one which Dr. Taylor wished especially to emphasize, together with the fact that it requires careful adjustment and readjustment to each individual case.

DR. BENJAMIN LEE, of Philadelphia, Pa., read a paper on

SACRO-ILIAC DISEASE,

reporting two cases, and advising some form of fixation of the pelvis and spine.

The papers by DRs. GIBNEY and TOWNSEND and RYAN were not read, on account of the unavoidable absence of the authors.

In the evening the members of the Association were given a reception by Dr. Willard, the President, at the Philadelphia Art Club, where many of the medical profession of Philadelphia were present.

(To be continued.)

— Dr. Jonathan Hutchinson recommends for the treatment of epistaxis the plunging of the feet and hands of the patient in water as hot as can be borne. He declares that the most rebellious cases have never resisted this mode of treatment.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, SEPTEMBER 25, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

DOCTOR AND DRUGGIST.

THERE are certain callings whose followers are brought into relations of peculiar intimacy with the followers of certain other callings, so that it becomes especially desirable for the successful operation of both, that the mutual attitude should be one of cordial understanding and support. Among such correlated crafts are those of the author and the publisher, the architect and the builder, the doctor and the druggist. Regarding this relation as far as it affects the last named pair of co-laborers, a few thoughts suggest themselves.

Friction has occasionally developed between the doctor and the druggist, because of what each has regarded (rightly or wrongly) as a usurpation on the part of the other of what belongs properly to himself.

The physician has valid ground of complaint when the druggist makes a business of counter-prescribing. Of course, within certain limits, the right to advise the customer who comes, not knowing just what he wants, must be conceded. Whether we think it altogether wise or not, people will go to a drug store for diarrhoea medicines, cathartics, for cough remedies, and we cannot find much fault if the druggist helps them to what they want. But when we find druggists cultivating the title of doctor, and treating patients for all sorts of ailments, we rightly protest.

Here is a typical and recent case of mischief so arising. A man came to a doctor with a glandular swelling of the neck which he said a druggist told him was mumps, and gave him medicine accordingly. An accompanying swelling of the lips had not attracted the druggist's attention, and the man, really suffering from a labial chancre, has in perfect ignorance, been in the danger, if not in the act, of distributing syphilis among his family and nearest friends for weeks.

Nor is it quite fair, we think, for the druggist to retort a *tu quoque* to a doctor who occasionally dispenses his own medicines. For the druggist in prescribing is assuming functions for which he has had no education, while the doctor in dispensing is doing

nothing but what he can do with perfect safety to his patient, and for the latter's convenience and therefore good. Few doctors in other than rural districts probably do this to any great extent, but there is an unquestionable advantage to the patient in the doctor's leaving him outright, for instance, a few doses of morphine in quantity unknown to the patient and without the possibility of the latter's going on with the medicine by constantly refilling the prescription to an undesirable extent. In emergencies and at night the doctor should have the commoner remedies with him. Further than this, the use of triturates and other palatable and portable preparations has a sufficient warrant in convenience to patients, in accuracy of dosage important in the case of active drugs, and to some extent on the ground of lessened expense. On this latter point there is something to be said on both sides.

Not long since, one of the metropolitan dailies, in its perennial quest for a sensation, sent a reporter with two prescriptions to several druggists, and succeeded in showing a great difference in price at different stores. The lesson sought to be derived from this experience was the enormous profits of the pharmacist. But the daily paper seems to have taken no account of the skill necessary to dispense prescriptions with safety. No class of men, we think, are more ready to insist on the propriety of liberal compensation to the druggists than are doctors, for no persons better realize the responsibilities involved in the safe handling and the accurate dispensing of powerful drugs.

But while holding these views most firmly, doctors are disposed to question some features of the druggist's charges. For instance, they are a little impatient in these days of perfected machinery, when a druggist insists upon manufacturing his own pills, at a highly increased expense of time and of money to the patient. The druggist's charge is not too much for the work he does, but the doctor feels that the work is unnecessary when a better made product might have been furnished at a far less cost.

Again the doctor fails to see the equity of the system of charging so commonly practiced in the dispensing of common remedies, for the *bulk* of the prescription, without regard to the actual value of the menstrua or diluents used. An ordinary prescription is charged so much, because it is a two or a four ounce mixture, quite independently of what it contains.

The great charge for a costless menstruum is one of the arguments occasionally put forth as a reason why all dispensaries for out-door patients should furnish their own medicines at something like cost-prize to the poor, who should be the only object of their charity. It is incongruous for the doctor to be the one to give his services absolutely, while the druggist is paid his fullest charges. There is indeed a tacit understanding with some druggists that the initials "P. P." appended to a prescription by a physician shall entitle the purchaser to minimum charges, but all prescriptions issu-

ing from a hospital dispensary ought to be considered as belonging to this category, which as a matter of fact they are not.

The druggist has certain rights which the physician sometimes fails to allow him. One such undoubtedly is to sell proprietary medicines, if he chooses. A certain portion of the public will have these, and the druggist is the tradesman to whom most naturally the retail part of this business falls. We do no good and rather hurt ourselves if we attempt to discipline the druggist for doing this business. Even the soda-fountain cannot be found fault with as an adjunct to the drug-store, if it is attended by some one who is not also responsible for the prescription desk, though physicians naturally prefer those pharmacies in which prescription business is given the place of prominence, to those, whether adjuncts of dry-goods shops or otherwise, where a general "notion" business is the chief aim of the proprietor.

Again, it is probably unwise if not unfair, to adopt the habit of exacting in prescriptions the product of certain manufacturers. The manufacturers are legion, and the druggist complains that his shelves are cumbered by what are practically duplicate preparations, from rival houses, one of which is favored by one physician, another by a second. Better far to leave the selection of the maker to the dispenser, simply holding the latter responsible for the quality of the product.

How far shall the doctor allow himself to be indebted to the druggist for his stationery? in other words, how far shall he let the druggist keep him supplied with prescription blanks? The custom is common enough. Druggists lay out considerable sums in getting up tasteful and often very convenient prescription books for the doctors' use, having of course the advertisement of the firm which issues them. That it is a paying investment, or at least that they think it will prove so, is evident from the readiness with which they make the outlay. Yet the acceptance of the favor seems to put the doctor under a sort of obligation which is not altogether comfortable. He certainly makes himself in a manner responsible for the reliability of any druggist whose blanks he may so use, and if he confines himself to the blanks of any one druggist he is likely to acquire the ill-will of those whom he does not similarly favor.

Finally, doctors and druggists need mutual consideration for their possible mistakes. Jupiter sometimes nodded, and all mortals may be caught doing the same thing. Prescriber and dispenser should be a check on each other's errors. Not all doctors are good penmen, as druggists (and shall we add privately, also editors and printers?) know to their cost. The mathematics as well as the chirography of a prescription occasionally goes astray. Many a mistake has been set right, and that quietly and courteously, by the druggist, to the lasting advantage of the doctor. Let the reciprocal service, if occasion offers, be done with equal consideration.

THE DÉCOLLETÉ IN MEDICAL PRACTICE.

MISS ELIZABETH STUART PHELPS's (Mrs. Ward's) article on "The Décolleté in Modern Life" in the August number of the *Forum*, will doubtless gain the wide reading which attends any production of her pen. But her plea for social purity, needed as she may think it, and strongly put as it is, will suffer a weakening of its cogency to many by the bringing into the discussion of what she calls "the fashion of resorting to physicians of the opposite sex in cases where any sensitive woman would seek a woman's care if it could be had for the praying or the paying." This remark surely applies, if it applies at all, to childbirth, at which time a sensitive woman does doubtless crave a woman's care — and should never, if possible, be without it. But whether there shall not also be a man's care, as a skilled *accoucheur*, may at least be left to the wish of the patient. Waiving any question of the relative professional skill of the two sexes, it may happen from the mental bias of a particular patient that she feels safer to entrust herself in her time of peril to a man rather than to a woman; and, if she does, it is certainly cruel and unjust for any one to speak of the "injury wrought upon her delicacy" by such a confidence.

Again, with a vagueness which is certainly wanting in the remainder of the article, the writer, after admitting the honor of upright "physicians who happen to be men," adds: "But for young women who prefer attendance which is abhorrent to nature, to that which the progress of science has rendered practicable from woman to woman — for girls who choose the one when they can command the other — there is no condemnation too severe."

Does the author mean that medical attendance, as such, from man to woman, is abhorrent to nature? Or does she limit her anathema to such kinds of attendance as she thinks are abhorrent to nature? The former interpretation will be repudiated by the medical profession, including, we believe, women as well as men. The latter one begs the whole question of whether any aid that a suffering mortal can claim from a fellow-man is "abhorrent to nature."

Nor is it true that the "progress of science" has as yet offered a sufficient number of *competent* female physicians to attend all the wants of all female patients, or, in other words, to do three-fourths of all the medical practice of the world.

On one point we are happy to express agreement with Miss Phelps, namely, in her admission that some of the blunting of delicacy in speech which she laments, is due to the increase of popular physiological discussions. The "Brahman lady of the earlier day" had not become used to ladies physiological institutes and clubs: and partly from that reason, as well as from her innate modesty, did not indulge in "swapping symptoms" with her casual acquaintances.

Medical practice does involve seeing patients, to some extent, unclothed, mentally and morally as well as bodily; but this may be, and we feel sure generally

is, quite a different thing from the other evidences which Miss Phelps presents of the *décolleté* in modern life.

The remark attributed to the publisher of the books of an authoress — of whom Miss Phelps says that "she has written one of the most exquisite and purest love stories in the English language," — to the effect that she was not to be blamed for another and "questionable" book because "she was born *décolleté*," is quoted in this article with evident relish.

To us the quotation and the manner of making it reflect Miss Phelps's mental attitude towards the whole subject which, as we think, she has unfortunately undertaken to discuss. Apparently, instead of being born naked, as is and has been the case, Miss Phelps would have female children, at least, born with a full outfit of dress-reform clothes on, buttoned well up the neck; and if such improvement upon "abhorrent" nature has been unprovided for, let them enter a second time into the mother's womb and be born again!

"There is an indescribable expression of the eye — every fine observer knows it — which distinguishes a modest girl from a matron. Look for it in the eyes of our girls to-day!" etc.

This quotation from Miss Phelps is best left without comment. We must, however, allow ourselves to protest against the false physiological conclusion to which her investigations, more curious than wholesome, have led the writer; and to express the hope that she may have few followers in a department of research which seems to border on the prurient. We really wonder it did not occur to Miss Phelps that an "indescribable" thing of this sort had better be left out of print.

MEDICAL NOTES.

— The British Local Government Board has issued an order prohibiting the importation of rags into that country, at least until the end of the year.

— It is intimated that Pope Leo is likely soon to issue a manifesto against the use of hypnotism, which as involving a loss, even temporarily, of will-power on the part of its subject, is in his opinion, likely to cause a lapse of moral control and self-restraint.

— One "Sequah, the Prairie Flower," has lately been carrying the benefits of Western medicine to the rural districts of Ireland, and his methods of cure were ventilated before a magistrate where certain poor cripples testified to drawing a stipend from "Sequah" for being daily cured of their maladies. One said that that distinguished medicine-man from the far West was in the habit of renting cripples, who appeared amongst the crowd, were duly "hoosched" up, rubbed and cured, and got two shillings for every day afterwards during the visit of the apostle of healing, on the strict condition that they carried no stick, and walked with carriage erect, so as to do credit to the "Prairie Flower." If they absented themselves for a day from the show, they received an immediate post-card requiring their attendance.

— Two doctors have organized, at Chicago, according to a western contemporary, an institution to be known as the "Railway Brotherhood Hospital," for the care of railway employees and their families during sickness or accident. Claim for patronage is based upon the statement that this enterprise is for the benefit of the railroad men. The reasons for the establishment of this charity are as follows:

"(1) The railroad surgeon is sent to the case to protect the interests of the company and to obtain the company's release for a nominal sum. Advantage is taken by the railroad surgeon of the helpless and shocked condition of the patient's nervous system to induce him to sign a paper releasing the company from all claims for damages by the payment of a nominal sum.

"(2) As a larger fee is obtained by amputating than saving a limb, the railroad surgeon embraces the slightest pretext for an operation, in a case that greater care and proper treatment might save the limb in whole or in part.

"(3) In the proposed 'Brotherhood Hospital' all this will be changed. The knife and the saw will only be used when all other measures fail."

Railroad men are invited to classify themselves into three classes, of which a man in No. 1 pays \$16 a year for the right (shareable by any of his family) to eight weeks' treatment; No. 2 pays \$12 for a possible six weeks' treatment; No. 3 pays \$10, equivalent not stated.

— Dr. Guido Baccelli, President of the Accademia Medica of Rome, and Professor of Clinical Medicine at the Sapienza, as we learn from a foreign exchange, took the chair at a recent meeting of the Società per il Bene Economico di Roma, to consider the means of ensuring the success of the International Medical Congress to be held three years hence in the Eternal City. Among the adjuncts to that Congress it was decided to form an International Exposition of Hygiene in connection with the Sanitary Department of the programme, and, with that object, to appeal to all the leading industrial and professional centres throughout the peninsula to contribute their best and latest additions to the "Armamentarium Hygienicum," so as to place Italy at as great an advantage as possible in the inevitable contrast between her own sanitary work and that of the other powers represented on the occasion. Florence, which has hitherto led the van in hygienic progress in Italy, has already promised her energetic coöperation; and other cities, like Turin and Milan, are expected to do likewise. Concurrently with the Medical Congress, an International Exposition of the Industries of All Nations is also being organized, so that Rome will be the busy scene of quite a gathering of the nations, on a scale she has not yet known since she ceased to be mistress of the world. The early summer months, May or the beginning of June, or the early autumn months, the latter half of September or the beginning of October, are likely to be those selected for the Medical Congress

— all danger of malaria at either time being improbable.

NEW ENGLAND.

— The medical staff of the Elliot Hospital in Manchester, N. H., have resigned on account of certain differences of opinion regarding the rules of the hospital.

— In a recent trial for manslaughter at Providence the jury brought in a verdict of "not guilty." During a fit of exasperation about the 25th of September, 1889, one Blanchard seized a stick of four-foot cord-wood, and struck one Andrews over the head. The latter died on the 5th of October. The defence claimed that the treatment extended the wounded man by his physician of Woonsocket, was incompetent, in that he did not perform as much cutting away of the parts of the skull that had lost their vitality as he should, and that he removed the antiseptic bandages too soon.

NEW YORK.

— The Tenement-house Summer Corps of Physicians, acting under the direction of the Board of Health, has made its report of the work accomplished during the season just past, through Dr. Moreau Morris, who had charge of this service. The report states that 40,364 tenement-houses have been visited during the eight weeks ending August 30th; which visits included calls upon 321,012 families. Among these 16,501 sick persons were treated. As there are only about 37,000 tenement-houses in the city limits, some of them were, of course, visited more than once, and the total number of visits was about 5,000 more than in the summer of 1889.

— President Wilson of the Board of Health has sent a letter to Mayor Grant in answer to one recently addressed to him by the Mayor in reference to the census figures of the city. In his letter Mr. Wilson encloses elaborate schedules on the death-rate of the city of New York, and the total number of deaths in all the years since 1879, as well as all estimates of the population that have been made by the Health Department between 1879 and 1890. From these tables he makes the following deductions, which go to show the justice of the demand which has been made for a revision of the figures arrived at in the recent Government census:

— Between the months of March and December in the year 1888, the Health Department, through its sanitary police, took a census of the population of New York living in tenement-houses. Under the law of 1887 a tenement-house is one occupied by three or more families living separately, and although this census did not include the better class of apartment-houses, it practically included all that are constantly under the supervision of the Board of Health. It furnished by street and number the population of each house, classifying the inmates as five years old and more, and under five years of age. The result of this census was as follows:

" Number of tenement-houses, 32,390; number of families, 237,972; population, 1,093,701, or, an average of 33.76 to each house.

" Between the months of January and July of the present year, a careful inspection of all the tenement-houses (the number at that time being 37,316) was made. Taking the estimate of 1888 of the average number of people in each house, there should have been on the first day of July, 1890, in tenement-houses, 1,259,788. The estimate of the population in lodging-houses is 12,000; under the control of the commissioners of charities, public institutions, etc., based upon Dr. Tracy's report, there are 23,556; showing in all 1,295,344. The report of the United States census taken in June, 1890, shows a population for the city of 1,513,501; from which should be taken, as above, 1,295,344, leaving only 218,157 persons living in hotels, private houses and first class apartments.

" The Bureau of Vital Statistics of the Health Department, estimated the population on the first day of July to be 1,622,018, or 108,514 more than that contained in the census enumeration just announced. If the census figures are correct, it increases the death-rate of the city for the year 1889 from 25.19 to 26.76, and will make it necessary for the Health Department to readjust the rate each year since the last census, in 1880. On the 15th and 16th of September, 1890, a careful enumeration by the sanitary officers of this department was made of the actual residents of the Second Ward — taking the street, number of houses, the names of residents — resulting in a total census of 1,196. The United States census shows in the Second Ward 922, the discrepancy being 274 persons, or an error of 29.71 per cent. In view of the facts presented in the enclosed reports, and the results of the enumeration just taken by the Health Department of the actual residents of the Second Ward, the Commissioners of Health, at a meeting held this Tuesday, September 16, adopted a resolution asking that means be taken for a recount of the population."

After receiving the letter the Mayor had a personal conference with President Wilson, and on the following day he sent to the Police Commissioners copies of the tabulated statements of the Board of Health, showing the inaccuracy of the recent census, accompanied by a letter in which he stated that the demand for a recount by the local authorities was of so general a nature, that he felt it to be his duty to have such a recount made. With the assistance of the police, he said, an accurate enumeration could be made, with only nominal expense to the public. He therefore requested the Police Board to detail a sufficient number of policemen to co-operate with him in preparing a complete enumeration, compiled so as to show the name, sex and residence of each inhabitant of the city, and whether adult or minor.

—George Kopp, a lineman of the United States Electric Light Company was killed on the night of September 15th, while handling an electric light wire that was supposed to be "dead" at the corner of 35th

Street and Broadway. It is felt that if the Board of Electrical Control were really efficient, such accidents could no longer be possible, and the Mayor has promptly called upon the Board for an immediate report in regard to the occurrence.

— The third annual meeting of the Association of Trustees and Superintendents of the New York State Hospital for the Insane was held at Middletown, September 17th. The sessions were held in the newly completed chapel of the Middletown Hospital, with Mr. Grenell Burt, President of the Board of Trustees of the Institution, in the chair. At the opening session an address was delivered by Medical Superintendent Talcott on "The Hospital Idea as Applied to the Treatment of the Insane," which advocated the making of insane asylums hospitals in the broadest sense, to which all appropriate cases could obtain early and easy admission, and where they could receive the advantages of the most scientific treatment, careful nursing, and perfect sanitary conditions. It was followed by a general discussion, and Trustee George H. Decker, of the Middletown Hospital, then read a paper on "Hospital Boards of Trustees; Their Functions and Responsibilities." The evening session was principally taken up with exercises dedicatory of the chapel in which the meeting was held.

Miscellany.

THE REIGN OF GOOD QUEEN BESS.

DR. B. W. RICHARDSON, in his recently published abridgement of "The Health of Nations," the great work of the late Sir Edwin Chadwick, in a chapter under the heading "Progressive Health," gives a comparison of mortality in the Elizabethan and Victorian eras:

" According to John Graunt's reports, from the parish registers, the condition of the whole city of London, in the time of Queen Elizabeth, was very much that of a 'slum.' The death-rate was in fact, that of a slum, it was more than 40 per thousand, but now, under some advance towards unity and centralization, it is about 20 per thousand, still including upwards of one-third of preventable deaths. The death-rate then largely exceeded the birth-rate, while now the reverse is the case. The death-rate of the children under five years was then one-third, or 33 per 100. It is now 27 per 100, and grievously too heavy. The deaths from old age, or the age then called old, of seventy, were 7 per cent, they are now sadly too low, but even in the city proper they are 18 per cent. As to personal security, John Graunt observes that not more than one in two thousand was then murdered annually, which he ascribes to good local government. At the same rate now murders in the whole of the metropolis should amount to no less than 2,500 annually, whereas they actually amount to an average of no more than 12 for the whole five millions of population — a population which approaches to that of the whole kingdom of England and Wales in the time of Elizabeth."

A NEW AND RAPID TEST FOR SUGAR.

The "Austrian Correspondent" of the *Medical Press*, July 26th, reports a simple and ingenious test for saccharine in urine, by Dr. Becker of Cairo, which was brought before the Surgical Society of Vienna at a recent sitting, by Professor Nothnagel. Ordinary visiting cards contain a considerable quantity of potash. Such a card is dipped with a solution of oxide of copper and dried. Sulphate of copper is then to be seen on the paper in minute crystals. Paper so prepared can be carried in the pocket. When urine has to be tested, point of wood — match end — is dipped into it, and two or three strokes are made with it on the prepared paper. The paper is then passed two or three times over a lamp, and immediately the marks scored will take on a more or less distinct brown color if sugar be present. Normal urine does not cause any change if marked on the paper in the way described, and it is a useful way of confirming the proof, to test a sample of urine known to be free from sugar at the same time as a counter-test.

A CASE OF HEMI-GLOSSITIS PHLEGMONOSA.

CASES of suppurative glossitis are not very uncommon, but the confinement of the affection to one-half of the organ is quite rare. A case of this kind is reported by Dr. Charles H. Knight, in the *Medical Record* for August 30.

It seems to have been a case of what has been called by Craigie 'lingual quinsy,' in other words, an acute inflammation involving the base of the tongue as well as the tonsil. The patient was a boy, fourteen years of age, evidently very poor, who came to the clinic at the Post-Graduate Medical School, June 14, 1890. He could hardly speak intelligibly, but it was learned that he had had "sore throat," gradually getting worse, for four days. He felt chilly, but had had no well-marked chill. Odynphagia prevented him from eating, even the attempt to swallow fluids being very painful. Salivation was extreme. The gums were red, swollen and sensitive, inclined to bleed, and along their dental margin there was a line of adherent secretion, almost like pseudo-membrane. The jaws could barely be closed without biting the tongue, the border of which was deeply indented and eroded. The tongue was absolutely fixed; it could not be protruded, nor could its tip be raised. Its dorsum was covered by a thick 'fur.' The odor of the breath was almost intolerable. Buccal temperature was 101° F. The left half of the tongue was not affected. The right side was much thickened, was very hard and resistant, and on passing the finger well back to the base, a point of extreme sensitiveness was found. Fluctuation could not be detected. It was difficult to explore the oropharynx, but both tonsils were seen to be large and inflamed, and the whole faucial region was very red; but there was no indication of abscess.

Another striking feature of the case was the extraordinary submental swelling. The tissues from the point of the chin to the hyoid were tense, brawny, very sensitive, and swollen. In the expectation that the tongue might need to be scarified, the boy was sent to the Manhattan Eye and Ear Hospital, ordered a calomel purge, the external application of ice-bags, and the use of a cold carbolized mouth-wash. The

next day the symptoms were somewhat worse, and for the cold treatment, hot flaxseed poultices and frequent irrigation of the mouth with hot water were substituted. On the visit the following afternoon, it was found that the abscess had ruptured during the morning. It was impossible to estimate the quantity of pus discharged, but it was sufficient to saturate the pillow on which the patient lay. All the symptoms were almost immediately relieved. The swelling beneath the jaw had disappeared; the tongue was still sensitive and stiff, but to a much less degree. The patient could speak more distinctly, and was anxious to try to eat something. From this time he steadily improved, and on the seventh day he left the hospital.

"The point of rupture of this abscess could not be exactly determined, in this respect differing from a similar case reported by the author five years ago. In the latter case the opening was found, and a bent probe could be made to enter the abscess cavity."

ECZEMA FROM THE USE OF CREOLIN.

QUITE a number of cases, according to the *Therapeutic Gazette*, have recently been reported in which more or less unfavorable results have followed the employment of creolin, in the majority of cases the effects being attributable to the phenic acid and its derivatives in this proprietary remedy. In the *Gazette Médicale de Paris*, No. 29, 1890, a report is published of a case observed by M. Borehmeyer of a child, two and one-half years of age, whose finger was crushed between cog-wheels, by which a severely-contused wound was produced, which was treated by applications of a one and a half per cent. solution of creolin. On the fourth day the finger was covered with vesicles, both small and large, which ruptured spontaneously, giving issue to a yellowish liquid. The eruption soon disappeared from the injured hand, and, on the removal of the application, a cure was rapidly produced, though the eruption again returned on renewed application of creolin. So also Dr. Wackez publishes an account of seventeen different surgical cases treated by creolin. In ten of these, union by first intention occurred; in seven the creolin produced eczema, erythema, and vesicular eruptions, and desquamation of the skin in large patches; at the same time the patients had more or less severe constitutional disturbance, and an examination of urine showed that these poisonous effects were attributable to the presence of phenol. It would seem, however, that children are especially susceptible to the deleterious effects of phenol and its derivatives, and hence are more readily influenced by creolin.

Correspondence.

[From a Special Correspondent.]

THE BERLIN INTERNATIONAL MEDICAL CONGRESS.

SECTION OF NEUROLOGY.

BERLIN, August, 1890.

MR. EDITOR:—The Tenth International Congress was really opened by the Neurological Section, which, with commendable but uncomfortable zeal, held most of its sessions at an early hour in the morning. Therefore, on

Monday, before the crowd had gathered in the Circus Renz, before Virchow had pronounced the Tenth Congress opened, and before Bacelli had shown that neither the Latin tongue nor the Latin eloquence was dead in Italy, the Neurological Section had met, organized, listened to papers, and adjourned. Jolly, of Strasburg, who comes to Berlin to fill the chair left vacant by Westphal's death, was elected chairman, and, among the many honorary chairmen, Meynert, Hitzig, Erb and Mierzejewski occupied the chair during subsequent sessions. But two papers were read, the most important being by Minor, of Moscow, on syringomyelia and hematomyelia. Many traumatic cases, of rapid onset, present symptoms similar to those of syringomyelia (thermanesthesia, analgesia, atrophic paralysis), but the paralysis rapidly disappears, leaving only the sensory disturbances. The cases are often confused with syringomyelia; but the rapid onset and history of trauma indicate hemorrhage rather than gliomatosis. A beautiful specimen of central hemorrhage was shown. Remak contended that such cases presented the symptoms of Brown-Séquard's paralysis rather than those of syringomyelia.

Horsley bore away the honors of the day on Tuesday, and, in fact, to him belong the chief honors of the session. He spoke briefly on the surgery of the central nervous system, supplementing his remarks with tables and photographs. He reported forty-three cases of trephining for various cerebral affections, with ten deaths. His counsel, although not new to those who have followed his work closely, was certainly startling to many of those present. He advised trephining in every case of fracture of the skull, in obstinate localized headache, in cases of inaccessible tumors, or tumors of uncertain location to relieve the pressure and headache; in septic meningitis he was still in doubt. In cerebral hemorrhage, if seen early, the carotid should be tied. Eighteen cases of trephining the vertebrae were reported, with only one death. The benefits from this operation, however, were less marked. In fracture the improvement had not been very great, but some cases had been benefited. In tumor the operation was indicated. In caries the benefit was still questionable, although he had had some tolerably successful cases, one of them, which I saw in London, being a girl completely paraplegic, who, after the operation, was able to walk a little. In the discussion that followed, Pescarolo, of Turin, reported the successful removal of a tumor of the spinal dura, Dunin, of Warsaw, reported the removal of a cerebral tumor, and Oppenheim reported the removal of a cyst in a case of cerebral infantile paralysis, and also the continued improvement of his patient (a case already reported) from whom a cerebral tumor had been removed. Three months after the operation, the woman was successfully delivered of a healthy child. Erb held a very conservative position with regard to the benefits to be obtained from surgery; our knowledge of localization was still defective, and in many cases of trephining the lesion had not been found at the point supposed; our diagnosis, too, was at fault in determining the difference between hemorrhage and thrombosis, in the latter case ligature of the carotid would do no good; in spinal affections, too, the outlook was not favorable. Burkhardt followed Horsley's paper with another in the same line, reporting improvement in four out of five cases where he had trephined for mental impairment. Von Monakow, of Zurich, reported a case of hemianopsia with a lesion in the cuneus, and a case of soul-blindness with incomplete hemianopsia, when the cuneus was intact but the angular gyrus was affected. The elaborate study of cases of periodic insanity by Magnan deserves a word, but the interesting and graphic charts were a most important addition, showing, at a glance, the periods of excitement and depression in cases of twenty years' duration.

The session of Wednesday proved, beyond a doubt, that the neurological brain is superior to every variety of Katzenjammer, even that which was offered at the Berlin Rathaus. Promptly at half-past eight, on Wednesday, the session opened, with uniminished vigor and attendance. On account of the general session the meeting was brief,

the paper of chief interest being the report by Horsley and Beever of their experiments on the cortex of the orang-outang, demonstrating the site for the representations of the various movements, which differ somewhat from those of the monkey, especially in that there is no march of movement from one segment of a limb to the other. They reported also the results of their experiments on stimulating the internal capsule in the monkey, showing that the various movements represented in the cortex have a similar representation in the fibres of the capsule.

In the afternoon, the Neurological Section joined with the Sections in Laryngology and Physiology, and before the three sections Horsley and Semon demonstrated their experiments on the innervation of the larynx. The trachea of a dog was divided, and the light thrown down his mouth and through the trachea on the wall, thus projecting the shadow of the glottis. On stimulating the cortex it was thus plainly seen that the movements of the vocal cords were diminished and the cords were seen to be approximated, unilateral stimulation producing bilateral movement.

On Thursday occurred one of the most interesting and warmest discussions of the session, on the so-called traumatic neuroses. Schulze, of Bonn, opened the discussion maintaining that there was no single affection which could be termed the traumatic neurosis. Trauma produced various neuroses and psychoses. Simulation was common, and objective symptoms were rare; the limitation of the visual field and the existence of anesthesia were regarded as of slight value. Oppenheim opposed many of Schulze's conclusions. The cardiac symptoms were of distinct importance, and anesthesia and a perimetric examination of the visual field were also important, and gave valuable information. If a patient recovers, it is not to be regarded as a proof of simulation. Seeligmüller held that twenty-five per cent. of the cases were simulators, and thought it would be a good plan to have an asylum for the observation of doubtful cases. Hitzig thought exaggeration and hypochondriasis were commoner than simulation. Mendel had observed many of Oppenheim's cases and thought that simulation was not uncommon. An asylum would be an admirable school for the simulator. Thyssen upheld Charcot's views, and proposed to substitute traumatic hysteria for traumatic neurosis. Hoffmann, finally, took a more advanced view on the subject of simulation than any one else, maintaining that a third of his cases were simulators. The general opinion seemed to be that there was no one traumatic neurosis, and that simulation was more or less common, and that we had, as yet, no means of excluding it absolutely.

The session on Friday began with a discussion on the pathology of general paralysis, opened by Mendel, of Berlin. He showed a dog in which the symptoms of general paralysis had been produced by rapid rotation, and maintained the view that the primary change was in the blood-vessels. This view was supported by the presentation of specimens from the early stages of general paralysis, among others a beautiful preparation of isolated capillaries, showing the earliest changes in the vessel walls. Here again there was much discussion, several holding the opposite view, that the primary process was an atrophy of nerve-cells and fibres, and others supporting Mendel's opinion. Later in the session, Berillon read an interesting paper on hypnotism, maintaining the familiar Nancy view that hypnotism is a harmless panacea, which can cure most earthly ills, — a view which few of the men I have met in Europe seem disposed to adopt.

The closing session, on Saturday, was short and crowded. Many papers were still left on the programme, and only a few could be read, and these only in abstract and without discussion. Among the papers of which abstracts were read may be mentioned two by Americans; one, a report of the successful removal of a tumor from the pituitary center by Bremer, of St. Louis; and the other, a paper on cerebral infantile paralysis by Sachs, of New York, who reported cases with autopsies, and maintained that there was no cerebral infantile paralysis as a distinct disease, that paralysis was due to a variety of lesions in children

the same as in adults, and that there was little or no evidence in favor of Strümpell's polioencephalitis or Gower's venous thrombosis. At an early hour the session adjourned in time for the last general meeting, when the tenth session of the International Congress was declared at an end.

In other sections, too, there was much to interest the neurologist, notably in the Anatomical Section, where Turner and Waldeyer discussed the convolutions, and His spoke on the histology of the nervous system; some of the papers in the Section for Internal Medicine were also on neurological subjects, but of these I am unable to speak.

The general features of the Congress and its social aspects were also full of interest. The administration was excellent, and the stranger found everything done for him, and the fullest directions for his guidance. The weather was unfortunately at times too warm for comfort, but no cloud or rain disturbed the meeting. The exhibition was admirable, pathological specimens, medical administration, and scientific instruments occupying the chief place, and drugs and preparations being very subordinate. The hos-

pitality of Berlin, too, was something that surpasses description; the opening reception on Monday, the city banquet at the Rathhaus with its inexhaustible abundance, the five crowded balls on Thursday, and the farewell reception on Saturday, at Kroll's, given by the Berlin physicians, gave the visitor such an impression of German hospitality as can never be effaced. To these must be added, as especially neurological, the dinner of the Section at the Philharmonic on Wednesday, where some two hundred neurologists dined together, and where after-dinner or rather intra-prandial speeches were made by Jolly, Lachr, Erb, Thysen, Tuke, Meynert and others, and the reception to the Section given by the Berlin Neurological Society on Friday. When Sunday came, both mind and body had been filled to repletion. It is too soon to pronounce upon the scientific value of the papers read, but from the few crumbs which I could gather, it seems safe to say that much of importance will be found in the transactions. In attendance, in interest, and in its social features, the Congress certainly was a most brilliant success.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 13, 1890.

Cities.	Estimated Population for 1890.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consump.	Diphtheria and Croup.	Diarrhoeal Diseases.	Typhoid Fever.

Woburn	13,089	—	—	—	—	—	—	—

Deaths reported 2,298; under five years of age 1,042; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 588, consumption 260, acute lung disease 165, diarrhoeal diseases 348, diphtheria and croup 63, typhoid fever 68, malarial fever 29, whooping-cough 28, cerebro-spinal meningitis 13, measles 10, scarlet fever 5, erysipelas 2.

From malaria fever, New Orleans 13, Brooklyn 8, Baltimore 5, New York 3. From whooping-cough, New York 14, Brooklyn, Baltimore, Boston and Charleston 2 each, Nashville, Lowell, Cambridge, Brockton, Salem and Newburyport 1 each. From cerebro-spinal meningitis, Washington 6, New York and Quincy 2 each, Brooklyn, Baltimore and Cincinnati 1 each. From measles New York 7, St. Louis, Springfield and Lawrence 1

each. From scarlet fever, New York 3, St. Louis and Boston 1 each. From erysipelas New York and Washington 1 each.

In the twenty-eight greater towns of England and Wales with an aggregate population of 9,715,559, for the week ending September 6th, the death-rate was 19.0. Deaths reported 3,649: acute diseases of the respiratory organs (London) 180, diarrhoea 425, measles 83, whooping-cough 82, scarlet fever 61, fever 46, diphtheria 29.

The death-rates ranged from 12.7 in Huddersfield to 30.4 in Manchester, Birmingham 17.6, Bradford 14.1, Hull 21.9, Leeds 18.5, Leicester 20.3, Liverpool 22.2, London 17.9, Nottingham 13.6, Plymouth 15.9, Sheffield 18.3.

In Edinburgh 16.2, Glasgow 21.6, Dublin 19.2.

The meteorological record for the week ending Sept. 13, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending	Barom-		Thermometer.		Relative Humidity.		Direction of Wind.		Velocity of Wind.		State of Weather.*		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 13, 1890, TO SEPTEMBER 19, 1890.

By direction of the Acting Secretary of War, the following changes in the stations and duties of officers of the Medical Department are ordered: Major CHARLES L. HEIZMANN, surgeon, is relieved from duty at San Antonio, Tex., and will report in person to the commanding officer at Fort Clark, Tex., for duty at that station, to relieve Captain EDWARD B. MOSELEY, assistant surgeon, who, upon being relieved by Major Heizmann, will report in person to the commanding officer at San Antonio, Tex., for duty at that station. S. O. 211, Par. 23, A. G. O., Washington, D. C., September 9, 1890.

By direction of the Acting Secretary of War, Major JOSEPH J. CONSON, surgeon, is relieved from duty at Fort Sherman, Idaho, and will report in person to the commanding officer, Vernon Barracks, D. C., for duty at that station. S. O. 212, Par. 4, A. G. O., September 10, 1890.

By direction of the Acting Secretary of War, a board of medical officers, to consist of Colonel EDWARD P. VOLLMER, surgeon, Major GEORGE M. STERNBERG, surgeon, Major ALBERT HARTSKIN, surgeon, Captain WILLIAM E. HOPKINS, assistant surgeon, is constituted to meet, in New York City, on October 15, 1890, or as soon thereafter as practicable, for the examination of candidates for admission into the medical corps of the army. S. O. 213, Par. 8, A. G. O., Washington, D. C., September 11, 1890.

By direction of the Acting Secretary of War, leave of absence for three months, commencing about October 1, 1890, is granted Captain FRANK J. IVES, assistant surgeon, provided one of the acting assistant surgeons serving in the Department of the Missouri is constituted to duty in his stead at Fort Hall, Idaho Territory, during that time. S. O. 213, Par. 26, A. G. O., Washington, D. C., September 11, 1890.

By direction of the Acting Secretary of War, Captain JOHN J. COCHRAN, assistant surgeon, now on duty at Fort Adams, R. I., will proceed to Mount Vernon Barracks, Ala., and report in person to the commanding officer of that post for temporary duty, and on completion of the duty contemplated, he will return to his proper station. S. O. 214, Par. 2, A. G. O., Washington, D. C., September 12, 1890.

By direction of the Acting Secretary of War, the leave of absence for seven days heretofore granted Major HENRY McELDERNEY, surgeon, by the Superintendent of the United States Military Academy, is extended to November 10, 1890, on account of sickness. S. O. 214, Par. 5, A. G. O., Washington, D. C., September 12, 1890.

By direction of the Acting Secretary of War, leave of absence granted First Lieutenant WILLIAM N. SUTHER, assistant surgeon, in Special Orders No. 149, June 26, 1890, from this office, is extended fourteen days. S. O. 214, Par. 6, A. G. O., Washington, D. C., September 12, 1890.

By direction of the Acting Secretary of War, the following changes in the stations of officers of the Medical Department are ordered: Captain WILLIAM G. SPENCER, assistant surgeon, will, upon abandonment of Fort Bridger, Wyoming (his present station), report in person to the commanding officer of Fort Omaha, Nebraska, for duty at that station, relieving First Lieutenant ALFRED E. BRADLEY, assistant surgeon. Lieutenant Bradley, on being relieved by Captain Spencer, will report in person to the commanding general, Department of the Platte, for duty as attending surgeon at the headquarters of that Department. S. O. 214, Par. 16, A. G. O., Washington, D. C., September 12, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 20, 1890.

F. W. OL'COTT, passed assistant surgeon, ordered to the U. S. S. "Alert."

SOCIETY NOTICE.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—A stated meeting will be held at twelve o'clock on Wednesday, October 1st, in the hall of the Boston Medical Library Association, 19 Boylston Place, Boston. Active and associate members are cordially invited to attend this meeting and participate in the discussion.

THOMAS M. DURELL, Recording Secretary.

BOOKS AND PAMPHLETS RECEIVED.

Hypodermic Medication in Diseases of the Eye. By Charles J. Landy, A.M., M.D., Professor of Diseases of the Eye, Ear and Throat, in the Detroit College of Medicine, etc.

Deformity from Prominent Ears Cured by a New Method of Operating. By W. W. Keen, M.D., Professor of Surgery in the Jefferson Medical College, Philadelphia, etc. Reprint. 1889.

The Cause and Treatment of Pneumonia. J. M. G. Carter, M.D., Sc.D., Ph.D., Chairman, Waukegan. Report of the Committee on Practice of Medicine, Read before the Chicago Meeting of the Illinois State Medical Society, May 6, 1890.

Longevity and Climate. Relations of Climatic Conditions to Longevity, History, and Religion; Relations of Climate to National and Personal Habits; The Climate of California and its Effects in Relation to Longevity. By P. C. Remondino, M.D., San Diego.

Dupuyer's Finger Contraction. Operation by Removal of the Contracting Band by Open Wound. Immediate Cure without Reaction or Pain. By W. W. Keen, M.D., Professor of Surgery in the Jefferson Medical College, Philadelphia, etc. Reprint. 1889.

Two Suggestions in Surgical Technique. I. A New Method of Compressing the Subclavian Artery. II. A New Method of Ascertaining whether the Bladder is or is not Ruptured. By W. W. Keen, M.D., Professor of Surgery in the Jefferson Medical College. Reprint. 1890.

A System of Oral Surgery, being a Treatise on the Diseases and Surgery of the Mouth, Jaws, Face, Teeth and Associate Parts. By James E. Garrison, A.M., M.D., D.D.S. Illustrated with numerous wood-cuts and steel plates. Fifth edition, thoroughly revised, with additions. Philadelphia: J. B. Lippincott Co.

A Text-book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, B.Sc., M.D., Clinical Professor of Diseases of Children and Demonstrator of Therapeutics in the University of Pennsylvania, etc. Octavo 632 pages. Cloth \$3.75, leather \$4.75. Philadelphia: Lea Brothers & Co., 706 & 708 Sansom Street.

Influenza or Epidemic Catarrhal Fever, An Historical Survey of past Epidemics in Great Britain, from 1510 to 1890. Being a new and revised edition of Annals of Influenza, by Theophilus Thompson, M.D., F.R.C.P., F.R.S. By E. Symes Thompson, M.D., F.R.C.P., Gresham, Professor of Medicine, and Consulting Physician to the Hospital for Consumption and Diseases of the Chest, Brompton. London: Percival & Co., King Street, Covent Garden. 1890.

Original Articles.

THE TRUE POSITION OF ELECTRICITY AS A THERAPEUTIC AGENT IN MEDICINE.¹

BY MORTON PRINCE, M.D.,
Physician for Nervous Diseases, Boston City Hospital, Out-patient
Department.

THERE IS no department of therapeutics in which romance has played so conspicuous a part—and this is saying a good deal—as in electro-therapeutics. There is a well-known professor in Vienna whose lectures, used to be described as "pleasing oriental tales." I think the same thing may be said of the tales told of the use of electricity in medicine in many of the text-books. One reads not only of wonderful cures of hitherto incurable diseases, but from the vast variety of afflictions which we are assured yield readily to the galvanic or faradic currents, or to the latest introduction, static electricity, we are impressed with the firm conviction that here at last is a panacea for every ailment of mankind, possibly rivalled only by the latest proprietary medicine advertised in the newspapers or heralded amongst the poetic gems of horse-car literature. One is instinctively reminded of the well-known advertisement of the famous Russian salve, "Warranted to cure all cuts, burns and bruises of every description; also good on bread." Not the least entertaining portions of the text in these treatises, especially those of our German *confrères* (freely borrowed by writers of other nationalities), are the diagrams which demonstrate satisfactorily the exact effect of the current, just as the pictures in mediæval theological works used to prove to the most sceptical sinner the existence of a future life by actually showing an impious heretic roasting on a gridiron. I remember as a student having been impressed by all this—that student could help it?—and to having thought that if any one failed to galvanize the spines of every case of locomotor ataxia, or multiple sclerosis, he was most negligent of his duty. A vague but strong impression was created in me by the text-books, that electricity had a sort of special affinity for nerve cells and fibres, and that under its mysterious influence the decayed ones were eliminated while brand-new ones grew in their places, like the bean stalks of Jack the Giant-killer, if not in a single night, at least with equal certainty. This was a long while ago. But the same sort of notions have been vaguely current in the profession; the reason for this being that certain authorities, like our Vienna professor, having asserted that it was all so, nobody liked to contradict them. Of late there has been a reaction against these extreme views; and, as is apt to be the case, the reactionists have tended to go too far the other way, and deny, if not all, at least the greater part of all virtue to electricity.

For these reasons it has seemed to me not inopportune to review the subject once more, and to endeavor, so far as I may be justified from my own experience, which may be fairly said to have been somewhat extensive, to show what in my opinion, is the true position which electricity should hold in medicine. An experience of ten years in hospital and private practice has convinced me that *electricity, properly used, is a valuable agent, but that it has been misused and abused, and its merits both extravagantly extolled and depre-*

ciated.

It has a place in the consulting room, or by the bedside, which can scarcely be filled by any other agent, and to one accustomed to its use, it is well-nigh indispensable. It is difficult to understand how the neurologist can do without it; but it is not a universal panacea, and like everything else its use must be governed by rational principles.

But first, before taking up electro-therapeutics, although not strictly coming under the subject matter of this paper, I shall speak of

ELECTRICITY AS A MEANS OF DIAGNOSIS.

It is well known that in certain diseases of the nervous system electricity is a most valuable aid to diagnosis. By the electrical reactions, we are able to form an idea of the nutritive condition of the nerves and muscles, and the central ganglia, and thus often be able to distinguish between peripheral and central lesions. It is of great service in recognizing the different forms of muscular atrophy and paralysis; in deciding whether an atrophy or paralysis be due to neuritis, to disease, to a myopathy, to disease of the spinal cord, or brain, or to functional disease; and not the least important is the possibility of determining if a given paralysis be fraudulent or due to actual disease. This last may often be done by testing the electrical reactions. And here it may be well to emphasize the fact that to properly test the electrical reactions there is required great care and no little technical skill. It is not to be done by merely applying the electrodes in a haphazard way, but only after using the greatest caution, making sure that they are applied at the proper points; that the current is maintained at a constant strength, and is not affected by varying resistances; that the proper sized electrodes are used; that a known strength of current is employed in every case, and so on.

This is mentioned here, because it is not rare to hear testimony accepted from the witness-stand regarding the reaction of nerves and muscles, when it is apparent from the manner in which the tests were made that nothing but valueless results could have been obtained. For such examinations proper electrical apparatus is indispensable. The apparatus ordinarily employed is entirely unsuited to give trustworthy results.

Passing now to the subject of therapeutics, I will first speak of

1. Neuralgia.

Electricity (in particular, galvanism) is justly regarded as one the most valuable remedies in the treatment of neuralgia; but we should distinguish between its effects as a *palliative* and as a *curative* agent.

As a palliative, nothing, as a rule, can be more useful, and its effects are often as astonishing to the physician as to the patient. It is no uncommon thing to see a patient who has entered the consulting-room limping with pain, or who has been unable to take off or put on his coat without difficulty, walk out as if provided with a new leg, or put on his coat as if his brachial plexus had never given him a twinge. It is often amusing to observe the look of pleasurable surprise on the faces of such patients, who sometimes regard your treatment as bordering on the miraculous. Even the severe pains from neuritis, or old-standing sciatica are greatly relieved and the patient given many hours of comfort in place of constant suffering. By chance, I am interrupted while writing this paragraph by a patient who applies for relief of pain in the upper part of his arm and in the shoulder, due to an

¹ Read at the annual meeting of the Massachusetts Medical Society June 10, 1890.

old strain. The movements of the shoulder-joints are constrained, and the extremes of movement painful. I apply electricity — this time static — and to the patient's surprise he swings his arm about, and puts on his coat for the first time without pain or difficulty, as he declares, for months. Whether the pain will return or not, I cannot say.²

Now it is this liability of neuralgia to return, that compels us to regard electricity, in many cases, as a palliative agent. It too often happens that after the pains have been relieved, completely or partially, they return again after an interval of some hours. It may be two, four or twenty-four hours. But they frequently do return; and it is because the sanguine physician too often shuts his eyes to this disappointing fact that electricity has been extravagantly over-estimated as a curative agent. But even with this limitation it is no small thing to be able to afford hours of relief, while other means are made use of to effect a cure.

In other cases, however, we are fairly entitled to attribute curative properties to this treatment. The cases are not few in which the neuralgic pain relieved each time, returns in a less and less degree after each sitting, till finally it disappears for good. It must further be borne in mind that a patient is not sent to the neurologists for electrical treatment till the family physician has exhausted his patience as well as the pharmacopia, before he relinquishes his own hand: so that, as a rule, only the most obstinate cases are entrusted to us.

In illustration of the curative influence I may cite a case just dismissed from my office. It was one following a neuritis of the brachial plexus, from which the patient suffered eight years ago. The muscles of the right upper arm and shoulder were softer and smaller than those of its fellow, and they were considerably weaker. There was no reaction of degeneration. The patient suffered from almost constant "nagging pain" in different parts of the arm, and a peculiar severe pain consequent on certain motions. It was a case of neuralgia occurring in nerves previously diseased. She was treated with galvanism, sometimes combined with faradism and static electricity. After eleven sittings, she was dismissed, free from the constant pain and certain violent paroxysms she had had following certain movements. The arm could be moved freely without pain, though it was of course comparatively weak and easily tired, and consequently ached somewhat after strong muscular action. Two months after her last visit she still remained free from the paroxysm and the arm only ached at times from over-use.

Another case, which I may cite because belonging to what, as a rule, are a more intractable class, is a case of "tic dououreux" treated within the last two months. Everybody knows how obstinate these cases are, and this one has been no exception. This patient had suffered at intervals since 1885. Each attack had lasted varying lengths of time; the first one, a month; the present attack, since September last. The pain is not constant, but comes in paroxysms, each paroxysm lasting but a few seconds; but in describing its severity, the patient says: "It is to a toothache what a red hot coal is to hot water." When he first appeared in my office he seemed to be pretty well wrecked, physically and morally. He had last

been treated by some sort of system of massage or percussion, which had greatly aggravated his condition. He was afraid to blow his nose, to open his mouth, to eat, to wash the right side of his face, or to expose himself to the slightest draught for fear of a paroxysm. He slept in a hot (80°) closed room at night, and was afraid to leave the house except in a closed carriage. He was living on liquid nourishment. His tongue was coated, breath foul, skin pale and anaemic, expression anxious, and his mental condition that of constant apprehension of suffering. "Gives the impression of being a much sicker man than the diagnosis would warrant," my notes say.

I applied twenty milliamperes of current, positive pole, to the right cheek. After the first sitting he had a return of the paroxysm on one or two occasions only. In a few days he was eating solid food, and gradually, as confidence returned, he resumed the habits of a normal individual, and could blow his nose and wash his face with impunity. After the first few sittings, wine, cod-liver oil, malt, etc., were given. He was dismissed at the end of thirteen sittings, his health in every way improved. The only thing then complained of, beside a certain apprehensiveness of future trouble, was what he called "ticks," a symptom I have not spoken of, but which he had had more or less continuously. These "ticks" were not pain, but, as far as I could make out, sort of instantaneous sensations of shocks in the trigeminal nerve (second division) as if tapped with the finger. They were not really suffering, but caused apprehension. They were felt a few times in the day. I have learned that they have since taken their departure.

This case should, perhaps, be classed as one of neuritis rather than of true neuralgia, as there was some anesthesia of the cheek. From this fact and his previous history, it is likely that he will have a recurrence³ of his difficulty. But whether so or not, he has been lifted out of a veritable slough of suffering by electricity, and I can only hope that his improved physical health may enable him to remain as he is.

This case is all the more striking because tic dououreus is not, as a rule, amenable to electrical treatment.

II. *Acute or Subacute Neuritis.*

Whether the inflammation be in a motor, sensory or mixed nerve, I am unable to endorse the opinions of those who regard electricity as having a curative power. Whatever effect is produced is, in the great majority of cases, palliative, and consists in temporary relief of pain — a relief that is often grateful. I am not, however, prepared to deny that the atrophy which often follows a neuritis may not be partially prevented by the use of electricity, and that when the nerve has recovered its functions, it will find the muscles in a better condition to respond than would have been the case if electrical stimulation had not been employed.

This brings us to

III. *The Atrophy and Paralysis following Infantile Paralysis, Joint Lesions and Disease.*

These are all benefited by electricity and the two last may be said to be cured. The results of this treatment in infantile paralysis, even when of long standing, have been in my experience so positive that I think it should be used in every case. It will be

²The patient returned, greatly improved, for one more sitting, after which he was apparently well.

³This patient still remained well when last heard from, about two months after the last sitting.

remembered that at the first onset of infantile paralysis a greater number of muscles are affected than remain permanently paralyzed or weakened; that is, that in the natural course of the disease, there is a tendency to recovery of many of the muscles originally paralyzed. This means that many spinal centres either recover from the inflammation or were only indirectly affected (oedema, pressure). But if the muscles connected with these centres are left to themselves, they recover their control power very slowly, or remain for a long time in a semi-paralyzed condition. Now the effect of electricity upon such muscles is to hasten their recovery, and perhaps produce a restoration of function which otherwise would not occur. I have repeatedly seen children who could walk or use their arms only with great difficulty, immediately begin to recover their power after electrical treatment. Those muscles (if any) which are to remain permanently paralyzed will not be affected, but the remainder will, and the gain may mean the restoration of a limb for ordinary purposes.

This is not to be understood as meaning that other adjuvant treatment should be neglected. To hope to directly influence the disease in the spinal cord is out of the question, but the distal effect of the disease is counteracted. The effect of electricity on atrophy following *joint lesions and disuse* is equally satisfactory. I believe that experience teaches that recovery is quicker and begins sooner under electricity than without it — a matter often of great consequence to a man anxious to resume his work.

IV. *Cerebral Hemiplegia (haemorrhage).*

In spite of the fact that the lesion is in the brain, the effects of electrical stimulation of the muscles is beneficial. Such patients, when improvement takes place, recover the use of their limbs (if they are to do so at all) much more rapidly than if not treated. I attribute the effect to artificial exercise of the muscles which otherwise would partially lose (from disuse) their capacity to contract, and would not respond so readily to the enfeebled nerve currents.

V. *Diphtheritic and Pressure Paralysis.*

These improve more rapidly under this treatment than without it, the latter especially. One can observe an increase in power almost day by day.

VI. *Hysteria.*

The different manifestations of hysteria such as anaesthesia, aphonia, paralysis, pain, etc., often yield readily to one or the other form of electricity. So-called *hysterical joints*, whether following an injury, or an attack of rheumatism or gout, are often rapidly cured by electricity in one form or the other. I know of nothing more satisfactory than the treatment of such affections by electricity, although I believe — a point I shall later revert to — that the effect is to be ascribed to suggestion rather than to the physical agent.

VII. *Muscular Rheumatism.*

This is usually regarded as particularly amenable to electricity, especially to the static variety. In fact this agent is considered almost a specific. But I cannot help regarding its influence as more palliative than curative. It is true that the patient is an exception who does not walk out of your office either free from pain, or greatly relieved; but it too often happens that the pain sooner or later returns. It is much, however,

to be able to make the patient more comfortable, and to enable him to attend to his business while nature cures his infirmity.

VIII. *Articular Rheumatism.*

It is claimed by some that this disease, in both the acute or chronic form, is benefited by electrical treatment. I have had no experience with the *acute* form but quite recently Lewandowski, of Vienna, has advocated very strongly the application of faradism by means of wire brushes to the acutely inflamed joints. He reports forty-two cases treated exclusively by this means. He claims that it not only relieves the pain and is a substitute for narcotics, but has a direct curative effect, lowering the fever, reducing the swelling, and hastening absorption. The current as employed by him was at first weak, and then gradually increased to a point beyond that which could be normally borne. The sittings may have to be repeated several times a day (Lewandowski has treated in all seventy-five cases). Others also claim satisfactory results. If the effect be as claimed, the action of the electricity must be as a counter-irritant, or by reflex action through the sensory nerves. It is hardly possible that the faradic current acts directly on the disease process. At any rate, if it will produce the anodyne effects claimed, it is worth using.

I have used galvanism in *chronic articular rheumatism*, and considering the obstinacy of such cases to all modes of treatment, I think it is worth trying. In many cases the patients claim that it relieves the pain, and even that the swelling and thickening of the tissues are reduced. While I can conceive this possible as the result of electrolytic action, I have never been able to satisfy myself that such is the case, in spite of the assertions of the patient. When a patient feels better he imagines a good deal. Still there are cases where the treatment is advisable. The cases which will most probably be benefited are those in which the pain and disability are out of proportion to the local changes.

IX. *Painful Neuroses.*

These, as a class, are amenable to electricity. Many of these localized pains, for which we are often puzzled to find an adequate cause, we can best reach by one or the other of the different forms of electricity. Reflex pains, unexplainable pains in the back, pains which are the result of old sprains and strains (the organic processes having long since recovered), often disappear like magic under electricity. These cases often drift into the neurologist's office as a *dernier resort*, and more frequently still into the nervous department of a hospital which is, I am afraid, looked upon by our colleagues as a reception room for all the unclassified aches and pains to which "flesh is heir to." Hither are sent from the other departments — from the surgeon, the dermatologist, the general physician, the otoriologist, the oculist, and all the other specialists — a heterogeneous collection of rebellious, atypical, unknown affections, which often defy diagnosis as well as every other mode of treatment. Some of these we can cure, some relieve, some return as they came. We have, at least, the satisfaction of knowing that others have tried their hands and cannot do any better.

X. *Neurasthenia and Allied Affections.*

In that protean disease, or rather group of diseases, neurasthenia, electricity is often a useful help, but

only a help, we can often combat many of the distressing symptoms which try our patience. It often acts as an excellent tonic, relieves nervousness and dispels insomnia. The effect in these cases is probably largely moral; nevertheless, it produces the desired effect, and enables us to so influence the bodily condition of the patient, that recovery is hastened. When a hypochondriacal element obtains, the result is particularly successful; but *it is in no sense a cure for true neurosenia*. Many of the neuroses following *la grippe* yield in a remarkable manner to electricity, and this brings us to

XI. *Psychoses and Neuroses.*

In psychoses and neuroses one of the various forms of electricity will often dispel the symptoms like magic.

Insomnia often yields at once. I have seen sleep at once ensue when persistent insomnia had been a most distressing, and sometimes the sole symptom. Before relying upon this treatment, however, we must carefully inquire into the cause of the insomnia, and satisfy ourselves that the case is likely to be benefited. When the insomnia is only a symptom of some deep rooted disease we must not expect to cure the disease itself. It is much, however, to have an agent that will replace morphine and the hypnotics.

Many of the pains and uncomfortable feelings which are ordinarily classified under this heading can be relieved, especially by the static variety of electricity.

XII. *Organic Destructive Diseases of the Spinal Cord and Brain, such as Locomotor Ataxia, Disseminated Sclerosis, Progressive Muscular Atrophy, Paralysis Agitans, etc.*

So far I have given a fairly favorable—I hope not too rose-colored—report of electricity. There remain its failures. If you take down your text-book on nervous diseases you will find no organic incurable disease of the spinal cord or brain for which electricity is not recommended, and you may think it your duty to follow the advice given therein. If you do, shirk it. Electricity is not of the slightest use in curing such diseases as locomotor ataxia, disseminated sclerosis, progressive muscular atrophy of the spinal type, myelitis or general paralysis. There is not the slightest evidence that electricity applied to the spine affects the cord favorably in such diseases, or indeed, that it affects it directly at all. It may, as a counter-irritant, relieve temporarily some of the discomforts; but the same results can be obtained in other ways, as, for example, by blisters and dry cups.

XIII. *Epilepsy, Megrin, etc.*

Electricity has been recommended for such so-called neuroses as epilepsy and megrim, applied to the brain or sympathetic system; but my experience warns me that any one who puts faith in it for such purposes, is doomed to disappointment. Nor is it of any more use to attempt to restore muscles irretrievably wasted and paralyzed as the result of old nerve injuries, and idiopathic neuritis of long-standing. When the wasting and paralysis are moderate, and where there is reason to believe that the nerve itself has become in a fair measure regenerated, we may be able to improve the condition of the muscles; but unless the function of the nerve and spinal centres have been in part restored, all attempts to reclaim the muscles will be hopeless.

The fact is, attempts have been made to do impossible things, and the consequent failure has reacted to the detriment of electro-therapeutics.

In the books, you will find cases of locomotor ataxia recorded as cured by electricity. While these cases may have been cured, there is little doubt in my mind that they were not true examples of the disease. It is now well-known that peripheral neuritis simulates locomotor ataxia in a remarkable manner, so that it is sometimes difficult to distinguish clinically between them; and before the fact was known, these cases of the nerve disease were mistaken for true locomotor ataxia. The cases of supposed cure were probably cases of neuritis, and not of disease of the cord; or it may be that a more prolonged observation would have shown a return of the symptoms.

MODE OF ACTION.

It would be beyond the limits of this paper, which is meant to be purely practical, to discuss the mode of action of electricity—a theoretical question. For practical purposes it is of no consequence *how* electricity produces the desired effect, so long as it does do so. I will content myself with merely saying that *faradism* probably works, first, by reflex action through the sensory nerves, inhibiting the pathological process in the nervous centres, upon which the local process probably depends; and secondly, by direct stimulation of nerves and muscles. It is by the reflex action that pain is probably inhibited.

Galvanism probably acts by the same modes, but very possibly produces local chemical and physical changes which aid in its therapeutic effects. It is claimed for galvanism that it has electrolytic effects. These chemical and physical changes are difficult to demonstrate, but their possibility is suggested when we bear in mind the well-known escharotic effects of strong currents on the skin, the actual dissolution of tissue when the current is condensed from a needle as an electrode, the fact that solids in solution can be made to pass through the uninjured skin by the action of the positive pole, and the fact that fluids and solids in solution are resolved into their component elements. These and other facts render it highly plausible that the therapeutic effects of galvanism may, in part, depend on the direct physical effect of the current.

But there is one other way in which the results of electrical treatment are brought about, the recognition of which is of highly practical importance. I refer to the influence of *suggestion*. There is no doubt in my mind that in a very considerable percentage of cases the relief obtained by electrical treatment, whether by faradism, galvanism or franklinism, is purely and wholly through *suggestion*. The class of cases which are more particularly influenced in this way are the psychoses and neuroses, and those afflictions where pain plays a predominant part. By taking advantage of this influence we can often cure, when every other moral influence, including drugs, has proved abortive. That such influence is suggestive, it is easy to demonstrate, and I will cite two widely differing cases as proofs.

The first was a young girl who suffered from insomnia and dislike for food. She was moderately anemic, and somewhat debilitated. She slept perfectly well so long as a current, faradic or galvanic, was passed through her head, but if this was omitted she failed to sleep. In order to test the nature of the

influence exerted, on several occasions I applied the electrodes without allowing any current to pass. The effect was the same; she slept perfectly. Her ability to eat could also be influenced in the same way, though not in the same degree. She was finally entirely cured. This patient had been sent to me for the purpose of being treated by hypnotism. I was not only not able to induce hypnosis, but suggestions made according to the hypnotic method were without effect.

The second case is equally instructive, though the evidence of the suggestive influence may not be so satisfactory to some. The patient, a man, was afflicted with mild *petit mal*, which sometimes took the form of ambulatory epilepsy. This had not, however, prevented him from carrying on his business, which he had done with great energy up to about six months previous to the time at which he came under my care. The symptoms, for the relief of which he had come to me, were great mental depression, amounting to melancholia; inability to concentrate his mind or fix his attention; insomnia; suicidal impulses; and general prostration. He had been unable to attend to any business for six months; he could not read, and took no interest in anything. He complained of a heavy weight or pressure on his head. The treatment was static electricity. The effect of the first sitting was immediate; his depression disappeared, his spirits rose, and he walked out of the office a different man. The next day the symptoms returned in a less degree, but at the end of eight sittings he was well. The epilepsy, of course, persisted.

While it is difficult to prove that the electricity had no direct physical effect in this case, to me the result seemed plainly due to suggestion. The effect produced at each sitting was just such as I predicted to him in positive terms would follow. If I told him the sense of pressure would disappear, it disappeared. If I told him his depression would be removed, his spirits returned, and so on. Hypnotic suggestion was without effect, as he proved not to be hypnotizable.

My experience has been that whenever the disability is of the nature of a psychosis, static electricity is particularly serviceable as a suggestive agent. In what proportion of cases the effect is due to suggestion, it is impossible to say. Medical electricians may not like to admit the fact of suggestive influence, but nevertheless it is, in my judgement, a fact, and it is of practical importance that it should be recognized. Because if we set clearly before our minds that in a given case we are going to effect the result in this way, we shall be more likely to succeed. I should not wish to be understood as overestimating the suggestive influence, but merely as pointing out *one of the ways* in which electricity acts in special cases, — an influence which we can often take advantage of with profit.

THE CHOICE OF KIND OF ELECTRICITY.

Thus far I have spoken of electricity in general, without particularizing the kind of electricity to be used in each affection, whether galvanism, faradism or the static variety (franklinism). In truth it is not easy to lay down hard and fast rules, and often the choice must depend upon trial in each individual case irrespective of the disease itself. When our intention is principally to stimulate the muscles, to give them tone and exercise, and prevent atrophy, the preference is to be given to faradism. In the different forms of hysteria

faradism usually works better than galvanism. If, however, as a result of degeneration of the nerves, the muscles fail to respond to faradism, as is often the case, galvanism must be used. When we wish to relieve pain and hasten absorption (?) of inflammatory products, when we hope to produce a direct effect on the nutrition of nerve and muscle, galvanism should be selected. When pain alone is the offending symptom, either galvanism or franklinism. Although faradism has its advocates in neuralgia and muscular rheumatism, static electricity is a most powerful factor. Sometimes it is well to combine two or more kinds, especially galvanism and faradism. Sometimes, especially when the diagnosis is uncertain, we can only determine by trial which will be the most beneficial. When, however, we wish to work by "suggestion," to obtain a purely moral effect, static electricity is to be preferred.

HOW TO USE ELECTRICITY.

One reason why electricity so often fails in the hands of the general practitioner is because of the inadequate apparatus made use of and the insufficient methods of application. A physician should have at his command a complete medical outfit. He should have a galvanic battery capable of giving him always 50 volts and better 100 volts, E. M. F.; a good faradic battery, and a first-class static machine. It will be well if the apparatus is so constructed that the faradic and galvanic batteries can be combined. He should be able to use these three different forms of electricity, because it is often advisable to change from one to the other, according to the effect produced. In circuit with the galvanic current should be a good rheostat, for regulating the current, and a good galvanometer.

I have frequently seen failure follow the use of electricity owing to insufficient apparatus. When a battery of low electro-motive force is used, if the resistance of the external circuit (the skin and electrodes) happens to be large, so feeble a current may pass as to be inoperative. Unless a good galvanometer is in the circuit, this fact will escape observation. The physician should have at his command a galvanic battery capable of giving twenty-five milliamperes of current and maintaining that current under the severest conditions of resistance.

The electrodes should be of varying sizes from six by three inches to one-third inch diameter, according to the effect to be produced. In connection with the subject of electro-diagnosis I spoke of this necessity of having proper apparatus. For this latter purpose a battery of high electro-motive force is particularly indispensable. It is very difficult to make a proper electrical examination of muscles and nerves without having a current which is unaffected by the variations in the resistance of skin and electrodes which ordinarily occur during the course of an electrical examination.

The next point is the proper application of the electricity. The electrodes must not be applied haphazard, but in definite predetermined ways, according to the effect desired. If the intention is to stimulate the muscles, the motor points should be carefully selected, and one electrode applied over them. If the nerves are to be stimulated, the electrode should be placed over their course and the current frequently made and broken. When pain is to be combatted it is generally best not to interrupt the constant current, but to let

it flow steadily through the painful parts. Sometimes pain can be best alleviated by strong faradism applied with a wire brush. This method is strongly recommended by some writers for facial neuralgia and acute rheumatism. It is also the best means of stimulating the sensory nerves, as in some forms of anesthesia.

When only a general tonic effect of galvanism or faradism is required, it is sufficient to paint, so to speak, all the muscles and nerves of the body with the electrodes, which should be large, making the muscles contract if possible. Passing the electrodes up and down the spine is very useful for this purpose. Sometimes as a result of nerve-degeneration, the nerves and muscles will not respond to faradism. Galvanism must then be used. As a general tonic, static electricity is often to be preferred to either.

In conclusion, I would say if you wish to obtain success in using electricity never put the battery into the hands of the patient to use himself; never entrust it to a nurse; never employ a student if you can help it. Always apply it yourself.

ELECTROLYSIS.

Before closing, I would say a few words regarding electrolysis. I cannot say anything regarding this treatment of uterine tumors, pelvic inflammations and other gynecological affections about which we have heard so much during the past few years, as I have had no experience with them.

I can, however, strongly recommend electrolysis for many affections.

Hair can be removed from the face without injuring the skin or leaving any blemish behind. As satisfactory as this operation is, I cannot believe that its possibilities are as well known as one would suppose would be the case, judging from the instances of this affection one observes in the streets.

Vascular tumors of the skin, such as cavernous angioma and naevi can be removed as well as warts and other facial blemishes.

Port wine stains can be greatly improved. I have for a long time been experimenting with the treatment of this deformity, and I hope soon to be able to report a greatly improved method of using electrolysis.

The dilated veins which often in advancing years deform the face, particularly that prominent feature, the nose, are easily and satisfactorily cured.

Goitre is one of those new growths which, it is claimed, can be cured by electrolysis. The best method is to insert the needles from both the poles into the gland, and to pass through them a powerful current of from forty to eighty milliamperes. The needles should be insulated where they pass through the skin, and moved about in different directions. The whole process should include several sittings of twenty to thirty minutes each. Dr. John Duncan reports having treated fourteen cases by this method. Three were under treatment at the time of the report. Four had been lost sight of. Of the remaining seven, six were absolutely cured. The seventh case was not changed by one operation. The treatment is one well worth trying.

For vascular tumors just referred to, such as naevi and cavernous angioma, it is by far the best method of cure that we have, particularly where it is desirable to avoid disfiguring scars. The scar left by electrolysis is white and does not contract. The operation is

bloodless, safe, and free from after-pain. The only drawback is that it may require several sittings to obtain the best results.

A CASE OF GUN-SHOT WOUND OF IMPORTANT ABDOMINAL VISCERA WITH RECOVERY.

BY J. F. URICK, Assistant-Surgeon U. S. N.

On the morning of the 24th of May, a shooting-accident occurred at the rifle-butt of one of our government stations in New England, in which a marine, acting as marker for the target-practice taking place at the time, was seriously wounded.

The unfortunate man, seeing a defect in his target after it had been run out ready for firing, had come out from behind the "bullet-proof" to remedy the defect, neglecting, however, to raise the danger-signal, and had placed himself in the line of fire just as one of his comrades fired the shot wounding him.

The severity of the wound, seen even at first sight; the gravity of the conditions in the days immediately following; and, on the other hand, the magnificent physical state of the wounded man prior to his injury, give the conditions of a fight in which Nature came out the victor, instructive, at least, in that it shows how well she can take care of serious injuries with circumstances fairly favorable.

According to the statement of the wounded man, which was verified by the character of the wounds of entrance and exit, he was facing the target and the bullet, a 45-calibre conical rifle-ball entered from behind, pierced the body about two inches to the right of the spine of the twelfth dorsal vertebra, and made its exit in the right hypochondrium, four and three-quarters inches from the median line, and passing in an oblique course between the ninth and tenth ribs.

The wounded man was immediately removed to the hospital of the station, suffering acutely, but showing little or no evidences of shock. There was very little hemorrhage.

The patient was a man of less than twenty-one years, of fine physique, and in magnificent condition. His bowels had been freely evacuated a few hours before the accident, and four hours had elapsed since food had entered his stomach.

Immediately after his entrance into the hospital an attempt was made to explore the wounds, and in the anterior wound it was possible to pass a probe a distance of three and a half inches in an oblique direction, the course following the direction of the ribs, probably due to a deflection of the bullet by them. Posteriorly there was no entrance to the probe beyond the superficial structures, the bullet having apparently split the strong, deep fascia of the lumbar region, which then had closed tightly and permanently. Without doubt the liver was wounded, and almost as surely the kidney of that side; whether the intestines, either in the superior portion of the ascending colon, or in some of the loops of the first part of the small intestine had been touched, was a matter of conjecture. The position of the wound did not exclude the stomach from a possible injury. Pulse 120, strong and full. It was not deemed expedient or advisable to make an exploratory incision, and an expectant plan of treatment was adopted. The superficial wounds were thoroughly cleansed and disinfected, and in the anterior small

pieces of gut were introduced for drainage; dressed antiseptically. The extreme pain was controlled by morphia, and digitalis and brandy were administered frequently.

At 7 p.m., pulse was 144; respiration 27; temperature 100.6° F. At this time, inability to micturate was complained of, and the patient was catheterized, the urine drawn off, showing the presence of blood in moderate amount.

On the following day the patient's condition was deemed very critical. His stomach had become irritable, and retained even stimulants poorly, but no evidence of a wound of that organ was given. There was some abdominal tenderness, though localized to the site of the wound, and he suffered severely, locating the pain over the course of the wound. Afternoon, temperature, 101.4° F.; pulse 156, weak; respiration 36, thoracic. Urine was bloody and clotted, diminished in amount. Treatment, morphia and stimulants.

There was no appreciable change on the third day, pulse 140 to 150, and very feeble, stomach still irritable, urine bloody and some abdominal tenderness. Suffering was less intense, and much less morphia was necessary.

A decided improvement was apparent on the morning of the fourth day. Pulse was of good volume and strength, 108, diminishing in frequency to 88 in the evening; temperature 102° F. The patient rested well till midnight, when an attack of severe pain in the region of the wound made it necessary to administer morphia again. Conjunctive and skin beginning to show a tinge of jaundice. Urine clearing.

He continued to do well on the fifth day, stomach of better tone, and retaining nourishment, milk and lime-water well. The wounds discharged slightly, the dressing being stained with a few drops of pus. The urine still showed the presence of some blood. Afternoon, temperature, 101° F., pulse 95 to 74. On the sixth day a rubber drainage-tube, two inches long, was introduced in the anterior wound. Patient was quiet, and rested well through the day without a spasm; was slightly jaundiced.

On the seventh day the patient rested quietly till near midnight, when he was awakened by a severe attack of pain in the epigastrium, which required morphia and counter-irritation for its relief.

On the following day there was an improvement in all the symptoms, jaundice nearly disappeared, urine only microscopically showing a trace of blood. Afternoon, temperature 100.2° F. Bowels were evacuated for the first time since the accident, by means of an enema.

Ninth day. There was another attack of epigastric pain. Diet was limited to milk.

The next day brought two attacks of paroxysmal pain, always referred to the epigastric region, and now followed by vomiting; relieved by a glass of hot water. General condition of patient good.

From this day until the twenty-third of his illness, the wounded man continued to improve, wounds healing rapidly, falling temperature, normal urine, and a disappearance of jaundice. He had an occasional attack of pain in the epigastrium, but none of any severity.

On the twenty-third day of his illness the patient had an especially severe attack of pain, referred at first to the epigastrium, and later to the dorsal region

of back; nausea and vomiting followed, and about 500 grms. of partially-clotted blood was ejected from the stomach. The hemorrhage was controlled by ice, and there was no return of the bleeding at any time after. His temperature was slightly elevated for a day or two, and he was nourished per rectum. The rectal feeding causing irritation, after two days iced milk was administered by stomach without any disturbance following, and gradually full diet was restored.

His recovery from this time was uninterrupted, and on the forty-ninth day from the date of the shooting, he was up and about the wards, the wounds closed and healed, and the patient rapidly convalescing.

REPORT ON THE RECENT PROGRESS OF SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

THE TREATMENT OF ERYSIPELAS.

LAUENSTEIN¹ and Meyer² report in favor of the "Kraske-Riedel" method. The object of this method is to limit the spread of the disease, and this is accomplished by making a barrier by multiple short superficial incisions or punctures at the border of the affected area, and subsequently using a wet (carbolic or sublimate) dressing. The dressing is changed two or three times daily. If the disease crosses the barrier at any point, fresh incisions are made. Both have modified the original method in that the scarification is made in healthy skin just beyond the disease, and not partly in infected and partly in the uninfected surface, as was done in the original method. Meyer claims that this is the most efficient and best means of controlling this affection.

Of interest in this connection is the new recommendation by Wolfer³ of treatment by compression by adhesive plaster. Four new cases are added to his previous list. His plaster ring is placed over healthy skin, and since this boundary is not always accurately determined, a second ring outside the first is employed. Wolfer claims that this method is free from the objection to the "Kraske-Riedel" method, namely, the pain from the scarification and its resulting scars, especially on the face. His (Wolfer's) method is stated to be efficient, easily adopted and without especial discomfort. H. Kröll⁴ claims to have accomplished the same result by an accurately fitted rubber bandage.

TREPHINING FOR EXTRA-DURAL HÆMORRHAGE.

In an interesting paper on the above subject, Deaver⁵ divides intra-cranial hemorrhage into four varieties:

(1) Where the blood escapes or finds its way between the inner wall of the cranium and the dura mater.

(2) Where it finds its way into the sub-dural space.

(3) Where it finds its way into the sub-arachnoid space and into the meshes of the pia mater.

(4) Where it escapes into the substance of the brain or into the ventricles.

He states that in the diagnosis of extra-dural hæmorrhage, the following points are to be observed:

The mental condition may be normal, or there may

¹ Deutsch. Med. Wochschr., 1880, xv, 11.

³ Wien. Med. Wochschr., 1889, xxxix, 23-25.

⁴ Therap. Mon. Hefte, 1889, III, 8.

⁵ Medical News, February 15, 1890, pp. 176.

be cerebral irritation. Unconsciousness, complete or incomplete, or coma.

Condition of Pupils.—Both may respond to light normally. Both may be dilated, and show no response; or one may be widely dilated and the other normal. When the dilated pupil corresponds to the injured side, it is caused, as pointed out by Hutchinson, by the pressure of a large clot, extending deeply down into the base of the skull, on the cavernous sinus, leading to fulness of the vessels, with protrusion of the eyeball and dilatation of the pupil. It is also accounted for by compression of the oculo-motor nerve, through the medium of the clot.

Respiration may be stertorous, or Cheyne-Stokes in character.

Pulse.—Little changed or rapid and feeble, depending largely on the severity of the concussion, or slow and full, depending upon the severity of the compression.

Limbs.—May present any of the following conditions: Hemiplegia, well or but little marked; monoplegia, paralysis, twitching, convulsions or spastic rigidity.

Scalp.—Presence of contusion, or bagginess due to the injury; the latter also due to leakage from within the cranium through a fissured fracture.

The stages presented by a typical case of extra-dural hemorrhage are three:

(1) Complete or partial unconsciousness, the result of the concussion or shock, caused by the fall or blow, as the case may be.

(2) Consciousness or lucidity. This stage may vary in length from a few minutes to several hours. "Is present in about one-half of the cases," says Jacobson.

Deaver has observed that a very large haemorrhage may produce compression at once; his observations being verified by post-mortem examination. Compression may also come on immediately, caused by co-existing depression of bone, injury to the brain and alcoholism.

THORACIC EMPYEMA.

Sabbotin⁶ has proposed the following operation for permanent relief in long-standing cases of empyema. His purpose is to cause the collapse of the chest wall, thus obliterating the pleural cavity. He claims a successful result. A portion of the seventh rib (six to eight centimetres) is resected as usual, the pleural cavity opened and then thoroughly irrigated. The opening is then packed to prevent infection. The fourth, fifth and sixth ribs are now exposed through a longitudinal incision along the border of the pectoralis major muscle. Without removing the periosteum, a wedge-shaped piece is removed from each of the ribs, so that it becomes movable at this point. A similar longitudinal incision is now made in the post axillary line, and at this point the same ribs are again resected as before. The incisions, which have no connection with the pleural cavity, are at once closed by sutures. The portion of the chest-wall lying between the longitudinal incisions now sinks in as healing occurs, and is fixed in this depressed position. The chest cavity is protected and the tendency to scoliosis is diminished.

LAPAROTOMY IN TUBERCULAR PERITONITIS.

Loehlein⁷ reports the results of six cases where laparotomy was performed for relief from this affec-

tion, which seems rather to corroborate the view already advanced that laparotomy accomplishes its best results in cases of primary not secondary tubercular peritonitis.

AN IMPROVED METHOD OF GASTROSTOMY.

Hahn⁸ has devised a new method of gastrostomy which differs principally from former operations in that the site selected for the formation of the gastric fistula is in the eighth intercostal space. He has during the past three years followed this method in eight cases. He claims the following advantages: A small contracted stomach is more easily reached and secured with less tension. The wound heals more surely since it is better protected from the contents of the stomach. Since the cartilages of the ribs act as compressors of the tube used in feeding, there is no trouble from leaking around the feeding-tube while *in situ*. They also prevent subsequent dilatation of the gastric fistula and no obturator is required. The technique of the procedure is as follows: The primary incision (five to six centimetres long), is parallel to the left costal arch, and distant from it one centimetre. The peritoneal cavity is incised through it to the same extent, and the eighth intercostal space sought which is easily found, since the seventh costal cartilage, by its attachment to the base of the xiphoid process, is easily recognized. A second incision is now made in the eighth intercostal space, commencing close to the junction of the eighth with the ninth costal cartilage, and extending outward and downward. The parietal peritoneum when exposed, is punctured with a pair of compression forceps, and the wound dilated to the extent of the incision by opening the blades. Then through the first incision the left thumb and forefinger directs the blades of the forceps to that portion of the stomach nearest the fundus. This portion is grasped by the forceps and dragged out through the intercostal wound till the stomach wall protrudes one centimetre beyond the skin, when it is fastened by a "serous" suture (Serosaumhüte), the other (abdominal) wound being previously covered with antiseptic gauze. The opening of the stomach can be delayed a few days till the peritoneal surfaces are united, or can be immediate. In the latter instance the suture includes serous muscular and mucus layers. The abdominal wound is then sutured. Investigations in the dissecting-room show that the diaphragm is not injured by the oblique incision outwards and downwards in the eighth intercostal space, as described, which is generally two centimetres distant from this point.

THE RESULTS OF RADICAL CURE FOR HERNIA.

Bull⁹ read before the American Surgical Association a valuable paper on the results following attempts at radical cure for hernia.

In all, he had operated upon 134 cases, 16 of them being children under fourteen years of age. In this whole series there were but three deaths. In one of the fatal cases strangulation existed at the time of operation.

In four cases the gut was wounded in separating adhesions; no bad results followed this complication. Once the vas deferens was injured and suppurative orchitis followed; the patient, however, ultimately recovered. In about half the cases primary union

⁶ V'rach., 1888, No. 45.

⁷ Deutsche Med. Wochschr., 1889, No. 32.

⁸ Centrbl. f. Chir., 1890, xvii, 11.

⁹ Medical News, May 24, 1890, p. 571.

took place. Where silk was used in the deep sutures, stitch abscesses developed without exception.

He operated on one series of cases by applying a ligature to the neck of the sac, dissecting the latter free and excising it, or if it were very large and adherent, draining it. In another series of cases he ligatured and excised the sac, and sutured the columns of the rings in close apposition. In still another series, he ligatured and excised the sac, and by a double set of sutures closed the entire inguinal canal. The results show that relapse is as prone to follow the more difficult and tedious methods, as is the case in simple ligation and excision of the sac; hence the latter operation should always be preferred. The essayist stated that no operation had yet been devised which satisfactorily stood the test of time. In the large majority of cases relapse was assured. Whether or not the wearing of a truss following operation exerted a favorable influence could not be determined. In the cases where this point had been observed, no such influence was noticed. Although there was no prospect of obtaining a radical cure by operation, the surgeon should not hesitate to use the knife under certain circumstances; since the risk to life is very slight, and there is nearly always an improvement in local conditions. The circumstances under which operation should be advised are:

- (1) In children who cannot wear a truss, or in whom no improvement follows after prolonged trial of a truss.
- (2) In adults who cannot wear a truss, or in whom the hernia is either irreducible or strangulated.

NEW OPERATIONS FOR THE RADICAL CURE OF HERNIA.

Halstead¹⁰ has recently reported in the Johns Hopkins Hospital Bulletin, five cases of hernia treated by the following method:

(1) The incision begins at the external abdominal ring, and ends one inch (less than one inch in children) to the inner side of the anterior spine of the ilium on an imaginary line drawn through the anterior superior spines of the ilia. Throughout the entire length of the incision everything superficial to the peritoneum is cut through.

(2) The vas deferens, with its vessels, is carefully isolated up to the outer termination of the incision, and held aside.

(3) The sac is opened and dissected from the tissues which envelop it.

(4) The abdominal cavity is closed by quilted sutures passed through the peritoneum one and one-half to two inches above the so-called neck of the sac.

(5) The vas deferens and its vessels are transplanted to the upper angle of the wound.

(6) Interrupted, strong silk sutures, passed so as to include everything between the skin and the peritoneum, are used to close the deeper portion of the wound, which is sewed from the crest of the pubes to the upper outer angle of the incision. The cord now lies superficial to these sutures, and emerges through the abdominal muscles about one inch to the inner side of the anterior superior spine of the ilium.

(7) The skin is united over the cord by interrupted stitches of very fine silk. These stitches do not penetrate the skin, and when tied they become buried.

They are inserted in the under side of the skin, and made to include only the deeper layers — the layers which are not occupied by sebaceous follicles. Thus infection of the sutures from organisms which may be present in the follicles is avoided.

(8) One or two small, short, gauze plugs are used as wound drains.

The immediate result in all the cases reported was good. Three of the patients were children, two adults. Sufficient time has not yet elapsed to test the ultimate results.

THE SURGICAL TREATMENT OF HEPATIC ABSCESSSES.

At the end of Mr. R. J. Godlee's¹¹ lectures on this subject he submitted the following rules for the treatment of the several varieties:

(1) Pyæmic abscesses do not call for surgical interference, or, if in rare cases one should point, it is only opened to relieve symptoms, but without hopes of doing permanent good.

(2) The same observations apply to abscesses resulting from suppurative phlebitis of the portal vein.

(3) Multiple abscesses associated with dysentery or ulceration of the bowels are very unfavorable for surgical treatment. They must, however, be opened and treated on the same lines as the single or trophical abscess, because they cannot be certainly diagnosed.

(4) Single abscess of the liver, whether trophical or not, must, if it approach the surface, be opened, the following precautions being adopted:

(a) If it present at the epigastrium, the presence of adhesions must be ascertained before incising the liver.

(b) If through the chest wall, a spot must be chosen below the normal limit of the pleura; but, if by chance either pleura or peritoneum be opened, the opening must be closed with a double row of stitches before incising the liver.

(c) Strict antiseptic precautions must be adopted throughout, either carbolic acid or some slightly soluble salt of mercury being employed for the dressings.

(d) The tube must be of large size at first, and a tube of some sort must be kept in until the discharge is reduced to a very minute quantity.

If the abscess have burst into the lung, pleura, pericardium, peritoneum, or kidney, and the position of the abscess can be clearly determined, it must be opened without delay. If the position of an abscess be only suspected, and the patient be losing ground, it is right to puncture the liver in the most likely situations, bearing in mind that, though usually quite harmless, a slight amount of risk accompanies this very trivial operation. This rule applies to cases in which the abscess has ruptured into any of the cavities enumerated above. If, on the other hand, whether the abscess has ruptured or not, there are no means of diagnosing the whereabouts of the matter, and the patient be not losing or even gaining ground, the surgeon should hold his hand for a time.

(5) Hydatids of the upper and back parts of the liver are to be treated upon the same lines; but in cases of this sort, and in those of sub-diaphragmatic abscess, it must be remembered that the diaphragm may be pushed up a very great height, thus closely simulating intra-pleural suppuration.

(6) Empyema, pericarditis, and peritonitis caused

¹⁰ Annals of Surgery, March, 1890.

¹¹ British Medical Journal, January 25, 1890.

by rupture of an hepatic abscess or hydatid must be promptly dealt with on general principles.

ARTERIAL SUTURE.

Jassinowsky (Dorpat), by means of numerous experiments on animals, has furnished some valuable data relating to the suturing of injured arteries.¹² According to his experience, primary union is possible. Hemorrhage is prevented, and does not recur. The procedure does result in thrombus formation within the vessel or aneurism of the vessel walls, as has been feared. The suture is available for recent clean-cut longitudinal wounds, for wound causing a flap, the long axis of which corresponds to the axis of the artery, and for transverse wounds which do not exceed one-half the circumference of the larger arteries. The operation can only be successful under the strictest aseptic conditions. It is easily accomplished by occluding the artery on either side of the wound. Then the artery wall is exposed at the point of suture by pushing aside the sheath. The suture penetrates only the adventitia and median coats horizontally. The suture is secured by the ordinary knot, and the ends cut short. Then, while the vessel wall is compressed and supported, the clamps are removed. The vessel, sheath, the fascia and skin are then successively united by separate sutures. Photoxylin.

THE VALUE OF THE OPERATIVE TREATMENT FOR GLANDULAR TUBERCULOSIS.

N. v. Noorden has published the results¹³ of an interesting investigation of 506 cases of glandular tuberculosis treated at the Tübingen clinic: 217 were hospital cases, 289 were treated as out-patients. All were cases where the diagnosis is reported as fixed beyond doubt. In 286 cases operative treatment was employed. In the remaining 220, a conservative method was pursued. V. Noorden succeeded in obtaining a collection of 149 cases where three years had elapsed since the operation, and found that in 93 (62.4%) no local recurrence had occurred. In the remaining 56, recurrence took place. Glands situated in localities other than those primarily affected became diseased in 7% of the cases; 28 (18%) of the 149 patients died of tuberculosis during the ensuing sixteen years, and 14 of the survivors are already phthisical.

IODOFORM IN THE TREATMENT OF TUBERCULOUS ARTHRITIS AND OSTSTITIS.

Attention is again called to the alleged power of iodoform in checking tuberculous processes in bones and joints when injected parenchymatously into the neighborhood of the diseased areas.¹⁴ The ether solution was discarded, on account of pain and occasional gangrene. A mixture of iodoform and oil (5:25) is recommended as more efficient. The mixture must be freshly prepared. Two to three cubic centimetres are injected once weekly. In case of fistula into the surrounding tissue, sublimate gauze dressings were afterwards used. Results: 109 cases, 28 operations. (Perfectly healed, 36; improved, 37; unrelieved, 12; 24 still under observation.) These statistics are Heusner's.¹⁵ It is not stated if this amount of iodoform is used in abscess cavities freshly curetted.

¹² P. Wagner Schmidt's *Jahrbücher der gesammt. Med.*, 1890, Bd. 225, p. 123.

¹³ Beitr. z. Klin. Chir., 1890, vi, 607.

¹⁴ Schmidt's *Jahrbücher der gesammt. Med.*, 1890, Bd. 225, p. 55.

¹⁵ Centbl. f. Chir., 1890, xvi, 38.

To the above, Krause¹⁶ has contributed his results with iodoform mixtures in the treatment of tubercular arthritis. After some experience he chose the following mixture as most satisfactory:

B	Pulv. iodoform. subtiliss.	50.00
Muel.	gummi Arab.	25.00
Glycerin	83.00
Aq. dest.	q. s. ad 500.00	

That is a 10% iodoform mixture which shows no trace of decomposition even after many weeks. He has used this only as yet in severe cases of tubercular articular disease, where recovery without operative interference was improbable. More than one-half the cases were complicated with cold abscesses. The mixture was injected into the joint in 43 cases, under strict aseptic precautions. The amount varied from 5 to 80 grammes. Passive motion and massage of the joint followed the injection, to insure a thorough distribution of the mixture throughout the joint. The injection was repeated every four weeks.

The rapid cessation of pain was quite striking. The swelling of the capsule and surrounding soft parts diminished more slowly. Suppuration in the joints and periarticular abscesses recurred several times, and only disappeared permanently after repeated injections. Krause still holds the method *sub judice*, and has not yet expressed his final opinion of the method.

OPERATION FOR THE DEFORMITY OF THE EARS.

Professor Keen,¹⁷ in the *Annals of Surgery*, January, 1890, describes a new operation which he has recently performed for the common deformity of prominent ears. The operation consisted in removing from the long axis of the posterior aspect of the auricle a long oval piece of skin, the cartilage being laid bare by the dissection. A strip of cartilage of the same length, but narrower and V-shaped on cross section, was then removed, taking great care not to cut through the skin on the opposite side. In the left ear three catgut sutures were introduced through the cartilage in addition to those in the skin. On the right side reliance was placed entirely on the sutures through the skin. The result was equally satisfactory on either side. The two operations, performed at the same time, were attended with very free bleeding, which, however, was easily controlled. The stitches were not removed until the tenth day. The result was perfectly satisfactory.

RESULTS OF THE TREATMENT OF FRACTURED PATELLA WITHOUT OPERATION.

Bull¹⁸ has made a study of this subject and has contributed a paper of considerable interest.

His paper was based upon the histories of twenty-two cases of fractured patella which had been treated without operation, and had been followed for periods varying from one year and nine months to thirteen years after the injury. There were sixteen cases of primary fracture and six of refracture; but as the latter class cannot be expected to yield such good functional results as the former, they were not considered. The results of treatment were classified under three heads, namely: (1) Functionally perfect—ten cases, in which flexion and extension of the limb have been complete and strong, the ligament firm, and little or no atrophy of thigh; (2) good—four cases, in which

¹⁶ Berlin Klin. Woch., 1889, xxvi, 49.

¹⁷ Medical News, February 15, 1890, p. 181.

¹⁸ Medical News, March 22, 1890.

flexion and extension were imperfect, but the joint was sufficiently useful to satisfy the demands of the patient's occupation, and only showing weakness after unusual exertion; and (3) bad — two cases, in which there was no power of extension, and the patients were compelled to wear supports, or to walk with a cane. Three-fourths of these patients were between the ages of twenty and forty years, and their occupations were sufficiently laborious to test the efficacy of the treatment. Bony union was obtained in one instance, and it is noted in two others that there was no appreciable separation of the fragments; while in the remaining cases the average length of the ligament was nine-tenths of an inch. This corresponds very well with the statement usually made that the length of a useful ligament varies between one-half inch and one inch. In one case the ligament was observed to shorten during a period of some years, owing to the formation of bone in the ligament.

Out of six cases of refracture, three occurred within two months after being discharged from the hospital, and in one case the lower fragment was fractured while the ligamentous union remained intact. The results in two cases out of this series were surprisingly good, and in the remaining four there was deficient extension, three having long ligaments.

Neither the age of the patient nor the character of the injury seemed to influence the result. From the first series good results were obtained in eight out of ten cases by the use of simple retentive apparatus, provided no accident endangered the newly-formed ligament. As refractures were considered accidents, they should be included with those giving a less favorable although still a very good percentage — seventy-three per cent.

If the cases were seen soon after the injury, the knee was slightly elevated, equable pressure was made by means of cotton compresses and snug bandaging, and, after an average period of five days, the limb was elevated and a gypsum bandage applied, the fragments being approximated by loops of plaster. It is possible, by proper application of a figure-of-eight bandage, not only to tilt the fragments but to separate their margins. After the effusion has subsided, there is no tendency to drawing up of the fragments. After the gypsum bandage has "set," the patient is allowed to sit up. Six or eight weeks later this bandage is removed, and a posterior splint, or the posterior half of the gypsum dressing, is bandaged to the limb during the day. At this period vigorous shampooing and the use of electricity should be begun. About the third month extension is usually good, although flexion is only possible to about forty-five degrees. The patient may now be allowed a cane, but the use of knee-caps should be discouraged, and passive motion is rarely advised. The patient is to make daily efforts to bend the knee slightly, the foot being upon the floor. There is no liability to accident by this method.

Many surgeons are still opposed to the use of plaster-of-Paris, thinking that it causes atrophy and interferes seriously with the circulation; but the use of plaster is not recommended by Dr. Bull until the swelling has subsided, and cotton is always applied underneath.

It will be seen that the total time of treatment is about six months; but the patient is confined during six weeks and allowed only moderate movement for six weeks more. The time of treatment cannot be advan-

tageously shortened. If the ligament and joint functions begin to weaken, it is advisable to resort to wiring the bone, and the operation is easier at this time than subsequently, when the fragments are more widely separated. Cases of refracture should be treated upon the expectant plan until it is apparent what the results will be.

Malgaigne's hooks have been employed both with and without antiseptic methods, and Treves speaks favorably of them; but it does not seem that there is anything gained by their use. All such measures aim to secure bony union, but they are both risky and meddlesome.

DISINFECTION OF CATGUT.

Döderlein¹⁹ (Leipzig), after some experimentation with infected catgut, asserts that it can be sterilized with certainty by soaking for twenty-four hours in an aqueous solution of sublimate (one-tenth per cent.).

Brunner²⁰ has also endeavored to find a practical method of making this material, so useful in surgery, aseptic. He has decided that the following will give the most satisfactory results: The raw gut is scrubbed with potash soap. Then directly, or after soaking one-half hour in ether, it is kept for twelve hours in a sublimate solution (aqueous, 1 to 1,000). After this bath it is kept till used in a solution consisting of sublimate (1.00), absolute alcohol (900.00), and glycerine (100.00). Immediately before using it is placed in the aqueous sublimate solution. Clinical experience has shown Brunner that gut so prepared is aseptic.

THE ACTION OF IODOFORM.

A recent investigator²¹ of this drug concludes after considerable experimental work, that iodoform, when added to a wound is usually largely in excess of any microbes, a condition under which, during experimentation, iodoform seemed to show an aseptic power. Experiments with pure cultures are conditions which do not exist in actual practice, since no fresh operation wound would ever be in a position to contain on its surface anything like a pure culture. So that practically when used clinically, iodoform is in excess of microbes present, a condition as above stated, favorable for the advantageous use of its antiseptic properties. Hence the proper use of the drug is in large quantities. Its especial value lies in its prolonged action. When used with pure cultures little or no antiseptic action was observed.

"SILK PROTECTIVE" DRAINAGE.

Fessler²² reports that strips of silk protective rendered aseptic by a 1 to 1,000 solution of sublimate, have been used at the Nussbaum Klinik during the past two years, for the drainage of all kinds of wounds, with the best results.

Clinical Department.

A CASE OF CONSIDERABLE CEREBRAL HÆMORRHAGE WITHOUT SYMPTOMS.¹

BY GEORGE R. SHATTUCK, M.D.,
Visiting Physician Boston City Hospital.

J. B., fourteen years old, a pupil of the Blind Asylum, South Boston, entered the City Hospital, April 30th. He came to the hospital on a horse-car, and walked in from the street.

According to the history given later, he had convulsions when a young child; at the age of four years, after "a sunstroke," became blind. At the age of seven, he had scarlet fever and diphtheria; but since then had been well, up to January of this year. During the time he was a pupil at the Blind Asylum, about four and a half years, he was reported to have made fair progress in his studies. Since January he had complained of its hurting him to walk, "the trouble seeming to be a lameness (rather than pain) in his legs, and he seemed comfortable when sitting; he had also complained of headaches, of the severity of which it was difficult to judge because he was so easily moved to tears. He was in bed several times, for a day or two, since January 1st, from these ailments, and twice during the time seemed so ill that he was sent home, and remained nearly two weeks each time, the last being in March. He finally went home for the spring vacation, March 28th, and was taken sick almost immediately." This was the account obtained from the Asylum.

He and his parents stated, when questioned on admission, that he began to have frontal headache towards the end of January, and had had more or less headache every day since; he had had considerable cough for a month, and night-sweats occasionally; he had lost flesh and strength during the two months previous to entrance; had no pain except the headache; he got out of breath easily when walking.

Physical examination showed that he was poorly developed, with the extremities somewhat cyanotic. The forehead was flattened, and the eyeballs were protruding; he had an idiotic expression, and the palatal arch was very high. The pupils were equal and dilated; there was no strabismus. The tongue was protruded in the median line. There was no impairment of motion or sensation. The reflexes were normal.

The area of cardiac dulness was enlarged; there was a double murmur at the base, and a presystolic and systolic murmur at the apex. There was moderate dulness over both lower backs, with fine, moist râles extending well upwards with diminishing dulness.

The urine was pale, acid, specific gravity 1.010, with large trace of albumen, and numerous hyaline, fine granular and epithelial casts. Temperature normal, pulse 120, respirations 32. No diagnosis was made, except such as was plainly indicated by the physical examination.

The next day, May 1st, the temperature rose to 103.8°; he became stupid and drowsy, though he could be easily roused, and answered questions intelligently; he passed his water in bed.

May 2d. The drowsiness had increased, though he still responded when roused, and complained of headache. There was well-marked retraction of the head, and he complained of pain on pressure over the cervical vertebrae. There were no motor or sensory disturbances; the tendon reflexes in the lower extremities were normal. He became unconscious at 8 P. M., and died an hour later.

The *autopsy*, made by Dr. W. W. Gannett, showed hemorrhage into the pia of the medulla and pons. Hemorrhage, the size of a large English walnut, into the white matter of the right hemisphere behind the fissure of Rolando, which was continued into the right lateral ventricle, and also into the third and fourth ventricles, as shown by small clots of blood. There was a softened area around the seat of the original hemorrhage, indicating an age of ten days or longer. The blood-vessels showed nothing abnormal.

The heart was enlarged in both diameters; there was acute and chronic valvular endocarditis, stenosis and insufficiency of the aortic, and stenosis of the mitral orifices. There was edema of the lungs, and cloudy swelling of the kidneys. There were also large adenoid vegetations in the naso-pharynx, as was suspected ante-mortem.

I have called this "A Case of Considerable Cerebral Haemorrhage without Symptoms," which certainly is not absolutely correct. There were the premonitory symptoms of headache and weakness in the limbs, as manifested by easy fatigue. But how far these could be regarded as prodromata of hemorrhage, with the crippled condition of the heart, and consequent changes in the lungs and kidneys, as shown both clinically and post-mortem, and without appreciable changes in the cerebral vessels, is, at least, doubtful. The seat of the hemorrhage was posterior to the motor tract. But it is still surprising that there were no symptoms from pressure. No loss of consciousness was mentioned; no motor or sensory changes were detected.

The age of the patient, fourteen years, is also of some interest. In Gintrac's table of 653 cases of cerebral hemorrhage, quoted by Gowers, 15 were between one and ten years of age, and 20 between eleven and twenty years of age.

— The President has nominated Colonel Edward P. Vollum to be Chief Medical Purveyor of the United States Army, with the rank of Colonel, vice-Colonel Baxter, promoted.

¹ Read at the Boston Society for Medical Improvement, May 26, 1890.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, May 26, 1890, the President, Dr. W. L. RICHARDSON, in the chair.

DR. C. E. STEDMAN showed a

CANCEROUS LIVER.

The patient was about seventy years old; had been ill some six or eight weeks. I was called to him a fortnight ago. His symptoms were obscure. Temperature was 102°. He had sweats. He had been an invalid some time, but no diagnosis had been made, and I declined to make any on taking charge of the case. There were no physical signs. The abdomen was flat. The free edge of the liver could not be felt below the ribs, and was not touched by the disease. The diseased limit, nearly the size of the fetal head, was in the upper and back part of the liver; and its existence was not suspected by any one who attended him, including myself. He died of exhaustion. There was in the lung some evidence of old phthisical inflammation having healed, and of recent inflammation at base of right lung. There was no dropsey of any kind, no distension of the abdomen. So far as I can make out the disease was primary. We could find no evidences of cancerous disease elsewhere.

DR. M. H. RICHARDSON showed a

SMALL TUMOR OF THE UPPER JAW,

removed to-day from a young lady twenty-four years of age. It had begun three years before at the base of the second molar tooth of the upper jaw on the left side, and had followed an abrasion of the mucous membrane. Various methods had been tried for its extirpation, but none had proved lasting. There was a vascular growth between the first and second molars about as large as a walnut, filling the space between the teeth and the cheek, and also extending inwardly and involving a small portion of the mucous membrane of the roof of the mouth. It had been found necessary to remove a portion of the alveolar process, after sacrificing the three molars. The growth proved to be a round-celled sarcoma, Dr. Whitney not being able to discover any giant cells. It seemed a pity to sacrifice three teeth in the removal of a growth possessing so little malignancy as the ordinary epulis. But in these less malignant types of new-growths, as in cancer itself, the tendency of the profession is to do too little at the outset, when there is a strong probability that a thorough excision with a wide margin will be a permanent cure. We keep just ahead of the tumor at the beginning, as well as at the subsequent operations, and leave so narrow a margin that we are about certain to have a recurrence. At the next operation, for some reason—to have enough skin to cover, to avoid some vessel, or for some similar reason,—the experience is repeated, and finally we find that it is impossible to make a thorough dissection, from extensive infiltration. In no class of tumor is the advantage of a thorough dissection more apparent. I recall at least four cases of epulis, operated upon by myself during the past year, in all of which an attempt had been made to remove the growth without sacrificing the teeth, and in all there

was prompt recurrence. Thus far the thorough removal after drawing the teeth from whose base the tumor had sprung, had been effectual, and was likely to continue so. In all the cases of tumor of this kind removed at the hospital from 1878 to 1888, that I was able to follow, there had been neither recurrence nor death.

It does not follow that it will be necessary to remove the teeth in all cases. Where the growth appears on both sides of the alveolar process, at least one of the teeth, and often both, must be drawn to give free access to the periosteum. In this disease, however, the dangers of palliative delay are not great, on account of the fact that it has, in the beginning at least, only a local malignancy.

In the specimen exhibited, the growth could be seen clinging to the base of the teeth, and to the portions of bone removed. The third molar was remarkable from its having but one fang, and from its diminutive size.

DR. STEDMAN: Has Dr. Richardson ever had occasion to observe in pregnant women appearances almost identical with epulis and with malignant tumors of the jaw, which threaten badly, bleed at the touch and disappear on delivery of the child?

DR. RICHARDSON: No sir.

DR. STEDMAN: Has Dr. W. L. Richardson observed that?

DR. W. L. RICHARDSON: I have observed that in four instances. These cases caused me some anxiety at the time, but they all did well.

DR. STEDMAN: I have a patient who has a tumor resembling the description given every time she is pregnant. The first time I thought it would have to be operated on, but I put the matter off until after delivery, and it disappeared.

DR. M. H. RICHARDSON: This tumor had been growing three years in an unmarried woman.

DR. MIXTER: Dr. Richardson spoke of the necessity of giving a wide margin to these growths. I think in many cases a wider margin is given than is necessary. I have seen a great many of these cases in which not only a number of teeth were removed at the operation, but a considerable piece of the jaw, the alveolar process, was also taken out with the cutting forceps. As I understand it, these growths spring from and are confined to the periosteum entirely at first, and it is absolutely unnecessary if you can peal off the periosteum to take off any of the bone. That applies to the early stage of the disease.

Another point about clinical diagnosis of epulis is that you often find a tumor of the gum which looks exactly like the ordinary form of giant-celled sarcoma which may be nothing but fibroid tumor, and which can be peeled off very easily. The other day I took off, under cocaine, which I supposed of course was the ordinary epulis. In that case there was a considerable interval between the teeth so that it could be easily removed in the space between. That proved on microscopic examination to be nothing but a fibrous tumor having nothing of the sarcomatous character about it, and none of the giant cells.

DR. RICHARDSON: In reply I would say that I agree with Dr. Mixter that this is the one form of malignant disease that admits of palliative treatment. I do not think, however, it is a safe plan to assume that all tumors of the gums are of a form to admit of mild operative measures, such as curetting or cauteri-

zation, until the diagnosis has been made by microscopic examination. The other day a most lamentable case came under my observation. The growth began, as nearly as I could ascertain, in the gums between the teeth. It was treated locally by various insufficient methods. When the case came to the hospital the whole upper jaw was infiltrated, and nothing could be done. I do not think it is necessary to take out a lot of sound teeth in all cases, but where the growth has recurred after various forms of operation it is better to be thorough even if you have to sacrifice the teeth, periosteum, and bone itself.

DR. S. J. MIXTER read a paper on

STRICTURE OF THE OESOPHAGUS—ITS TREATMENT BY INTUBATION.¹

DR. HOMANS: Can't this tube be swallowed without the probang?

DR. MIXTER: No sir; the funnel is a little too large.

DR. HOMANS: I have had a number of these cases. I recall one case in which a man was unable to eat anything, and had been treated for dyspepsia. I dilated the stricture, and he was comparatively comfortable. That case I followed to the autopsy. The cancer had eaten into the left bronchus. A portion of his food went into the lungs causing excessive cough. Dr. Whitney has placed the specimen in the Warren Museum. I think this man could have been made much more comfortable with one of these tubes which Dr. Mixter has shown.

I should like to ask the doctor if there has been any trial made to stretch the oesophagus further by passing one tube inside of another.

DR. MIXTER: I think there have been various methods of dilating the oesophagus. That would do for cases of non-malignant stricture, but in these cases, however much you stretch these malignant granulations, they spring right back into place, and the passage of any instrument is accompanied by hemorrhage. The object of this form of treatment is that it keeps these granulations back in place, and keeps a perfectly smooth passage so that you can, on removing one tube, pass another.

DR. HOMANS: Is there any explanation of the tolerance of the oesophagus in these cases? These people with intubation-tubes seem to get along perfectly well while most of us want to vomit if we have a foreign body in the oesophagus.

DR. MIXTER: They always complain at first of a tickling sensation which is produced by the string in the pharynx. In one case I first sprayed the pharynx with cocaine, and there was not the slightest trouble.

DR. HOMANS: Is the oesophagus supplied with nerves just like all other organs?

DR. MIXTER: Yes, sir.

DR. HOMANS: The oesophagus certainly must be very unsensitive. We swallow hot things and cold things, and have very little sensation, except in the back of the mouth.

DR. RICHARDSON: I was especially interested in the second case mentioned, which entered the hospital in my service some time in the summer. There was no doubt that the stricture had been caused by caustic potash. I should think that in ordinary cicatrical contraction the tube would become compressed.

¹ Publication deferred.

DR. MIXTER: It was very difficult to get any instrument through. After a time, however, you could pass this instrument with perfect ease. I saw her in the Out-patient Department day before yesterday, and she was looking well. An oesophageal bougie is now being passed. That is a case in which the tube should be worn a long time.

DR. RICHARDSON: It seems to me that this method is very valuable in certain cases, and I think we are indebted to Dr. Mixter for having demonstrated so well its merits. In my experience there are very few cases of oesophageal stricture where this method cannot be used to advantage.

DR. MIXTER: These tubes always stain above and below the stricture. I don't know the reason of this. I presume food may be swallowed around the tube. It is astonishing how well they can swallow with the tube in place.

DR. B. CUSHING reported a

CASE OF OBSTRUCTION OF THE BOWELS.

Mrs. ——, age about fifty-six. Was constipated, with, at times, diarrhea (in my experience a common combination). Was supposed to have cancer of the intestine, and had been under treatment — just how long I do not know — taking a good deal of opium. She came from the eastward to be under the care of Dr. Blanchard, who had attended her and her family when she lived in Dorchester.

Dr. Blanchard diagnosed the case at once as one of impacted feces. By means of injections and otherwise, he removed a good deal from the rectum, but did not quite reach the sigmoid flexure. As this time I saw the patient with him. She was etherized, and an examination made by the rectum. I could just reach a hard mass with the tip of my finger. It was like scratching a rough stone. Then, as before, attempts were made to dislodge the mass by injections, but without success. A solution of epsom salts (one ounce to a pint of water) was then given, a tablespoonful every hour, with the result that the intestine was emptied. I have found this means succeed before in like cases when other means have failed me.

I did not see the patient again, but Dr. Blanchard told me that she returned to her home in Maine relieved of the stoppage. She did not, however, regain her strength entirely, and seemed enfeebled in mind.

She died eleven months later.

Wishing to know whether there had been any autopsy, and the history of the last illness, I asked Dr. Blanchard to write to the attending physician; and in his reply will be found the principal interest of this case. He says:

"There was no autopsy.

"Cause of death appeared to be chronic intestinal disease, and resulting defective performance of the digestive functions. There was paralysis of the lower extremities, and some loss of power of the arms.

"There was no subsequent mechanical obstruction, but some tenderness at point of old obstruction at times.

"Mrs. —— used, for a great many years, a hair-coloring lotion, presumably containing lead. Could this have gradually poisoned the system, and produced the paralysis and peculiar cachexia existing so long before death?"

DR. STEDMAN: Was the patient subject to colics?

DR. CUSHING: I think so. At all events she was at the time mentioned.

DR. G. B. SHATTUCK reported a

CASE OF EXTENSIVE CEREBRAL LESION WITHOUT SYMPTOMS.²

AMERICAN ORTHOPEDIC ASSOCIATION.¹

FOURTH ANNUAL MEETING.

SECOND DAY.—MORNING SESSION.

The second day of the meeting was devoted to papers upon Lateral Spinal Curvature.

DR. BENJAMIN LEE, of Philadelphia, read a paper on

THE NERVOUS AND MUSCULAR ELEMENTS IN THE CAUSATION OF IDIOPATHIC CURVATURE.

Dr. Lee suggested the possibility of a primary lumbar curve being due to the unequal contraction of the psoas muscle, kept up by reflex nervous phenomena in the region of the ovaries.

DR. C. L. SCUDDER, of Boston, reported the results of an investigation into

THE STRENGTH OF THE BACK MUSCLES OF ONE THOUSAND ONE HUNDRED AND FORTY-ONE OF THE SCHOOL-GIRLS OF BOSTON.

An index of strength of the back muscles for each growing age was established. The relation of this standard of muscular strength to the etiology and treatment of lateral spinal curvature was shown.

DR. R. W. LOVETT, of Boston, read a paper upon

THE ETIOLOGY OF LATERAL CURVATURE,

giving briefly the most important and probable theories held at the present day. Lateral curvature appears earlier in life than formerly was supposed. The general condition of the child holds an important place in the etiology.

There are three theories of causation that are of value: (1) The theory of unequal muscular contraction; (2) that of unequal bony growth; and (3) that attributing the cause to the superercent weight of the body falling upon a spinal column held in a faulty position. Dr. Lovett believes that the latter view is the most probable.

DR. JUDSON, of New York, stated his view of the cause of rotation of the vertebrae in lateral curvature of the spine to be an unequal lateral displacement of the body and spinous process, the former being free from lateral attachments, and, therefore, departing from the median plane; while the latter is held in the median plane by its muscular and fibrous attachments.

Dr. Judson then explained his interpretation of the apparently unusual course of the bullet through one of the vertebrae of the body of President Garfield. The normal rotation of the vertebra in question, as the President inclined his body, he thought sufficient explanation.

Between the morning and afternoon sessions an interesting lecture was given by **DR. T. G. MORTON**, of Philadelphia, at the Orthopedic Hospital, upon his

METHOD OF DEALING WITH CLUB-FOOT.

Many patients were exhibited, demonstrating the results of treatment. In cases not easily reduced, Dr. Morton removes the astragalus, keeping the foot afterward in a tin shoe, and discarding apparatus as early as possible.

After the lecture, lunch was served, and an opportunity afforded for an inspection of the hospital building.

AFTERNOON SESSION.

DR. E. H. BRADFORD, of Boston, read a valuable paper on

THE TREATMENT OF LATERAL CURVATURE.

He divided, for clinical purposes, lateral curvature cases into four classes:

- (1) The non-resistant.
- (2) Those with some resistance.
- (3) The still more resistant.
- (4) The permanent curvatures.

Class 1 he advised treating by postural methods; cultivation of correct habits of carriage, and by partial recumbency in case of overgrowth; by massage and electricity; and by muscular exercises.

Class 2 is to be treated by the same methods as those used with Class 1, but more thoroughly and carefully carried out.

In Class 3 the methods to be used are those suggested in both Classes 1 and 2, and, in addition, suspension, and some form of support during rapid growth, together with forcible correction of the deformity at regular intervals. Various methods of forcibly correcting these cases were described.

Class 4, Dr. Bradford thought, could be treated by preventing any further increase in the deformity by retentive apparatus, and by using suitable support to the spine to prevent pain.

DR. HENRY L. TAYLOR, of New York, read a paper on

THE TREATMENT OF LATERAL CURVATURE,

in which he advised particularly the use of massage and forcible passive movements adapted to correct the deformity. Apparatus is, he thinks, of little use other than as a means of holding the deformity from increasing. Breathing exercises are of importance whether voluntary or assisted by suitable instruments.

THIRD DAY.

Several of the papers announced for the last day of the session were not read, on account of the absence of the writers.

DR. JOHN RIDLON, of New York, made

A REPORT OF SIXTY-TWO CASES OF HIP DISEASE OBSERVED IN THE PRACTICE OF HUGH OWEN THOMAS, OF LIVERPOOL.

DR. JAMES K. YOUNG, of Philadelphia, read, by invitation, a paper on

DISEASES OF THE EYE ASSOCIATED WITH SPINAL CARIES.

He described briefly those diseases of a strictly strumous or tubercular origin which are associated with any of the tubercular inflammatory processes in bone.

¹ Concluded from page 304.

² See page 324 of the Journal.

DR. SAMUEL KETCH, of New York, read a paper upon

POSTERIOR RACHITIC CURVATURE OF THE SPINE.

He thought the posterior curve due to superincumbent weight upon a soft bony column.

Dr. Ketch dwelt on the differential diagnosis between spinal curves due to caries and rachitic curves. The best treatment is recumbency. Apparatus in very young children, in whom the curvature is most apt to appear, should be avoided.

DR. R. W. LOVETT, of Boston, read a paper upon

LATERAL DEVIATION OF THE SPINAL COLUMN IN POTT'S DISEASE.

He emphasized the occurrence of this deformity of lateral deviation with a certain degree of rotation in the beginning of almost all cases of caries of the spine. Accurate measurements of this lateral deviation had been made. Its importance as an early diagnostic sign was dwelt upon, and it was thought to be easily controlled in most cases by the customary methods of treatment, recumbency and fixation of the spine.

THE PROGNOSIS OF PRESSURE PARALYSIS

was considered by DR. T. H. MYERS, of New York.

His remarks were based upon a study of the cases of pressure paralysis occurring in the cases of Pott's disease treated at the New York Orthopedic Hospital and Dispensary.

The Association was pleasantly entertained by Dr. James K. Young and Dr. Benjamin Lee.

DR. A. B. Judson was chosen President, and DR. John Ridlon Recording Secretary and Treasurer of the Association for the following year.

The Association adjourned, to meet with the American Association of Physicians and Surgeons at its meeting next year in Washington, D. C.

Recent Literature.

Transactions of the Association of American Physicians. Volume IV: Fourth Session, held at Washington, D. C., September 18-20, 1889. Volume V: Fifth Session, held at Washington May 13-15, 1890. Philadelphia: Printed for the Association. 1890.

These two volumes of valuable papers appear somewhat nearer together than usual, the interval between the last two sessions having been only eight months, and the last volume of transactions appearing with commendable promptness.

Volume IV contains the President's Address, by Dr. Francis Minot, on "The Progress of Medicine during the Last Fifty Years," and nineteen other papers, embracing as wide a range of subjects as General Paralysis (early symptoms), Tetany, Thrombosis of Cerebral Sinuses and Veins, The Effusion of Chyle and Chyle-like Fluids into Serous Cavities, Substitutes for Opium, Cases of Slow Pulse, Chlorosis and Its Relation to Various Anæmias and to Hodgkin's Disease, Subjective False Sensations of Cold, Gastric Neuralgia, The Contagium of Diphtheria, The Frequency of Lead in the Urine, Tuberculosis in Cows as a Source of Danger from the Milk, Hot Air Inhalations in Pulmonary Tuberculosis, Malignant Disease

of the Duodenum, of the Gall-Bladder and Ducts, and the Anatomical Relations of the Lesions of the Heart and Kidneys in Bright's Disease.

Volume V, while somewhat smaller than its predecessor, contains almost exactly the same number of articles, and includes papers on Enteric Fever, Inflammation of the Appendix, Varicose Aneurisms of the Aorta and Superior Cava, Antiseptic in Midwifery, Seizures Characterized by Shock and Sudden Coma, Some Disorders of Sleep and Insomnia, The Anesthesia of Hysteria, The Etiology and Treatment of Migraine, Pathological Demonstrations, Culture of Tubercle Bacillus, Purpura Haemorrhagica, Rheumatica, Acute Pancreatitis, The Limitation of Tuberculosis in Man, Methods of Examination and Diagnosis in Diseases of the Stomach, Cases of Acromegaly, Diathetic Causes of Renal Inadequacy, and the Etiology of Pleuritis.

Several of these papers are to be found in former numbers of the JOURNAL.

— The *British Medical Journal* fails to be impressed by the medical law of the State of Washington, U. S. A. It says that the Americans carry their love of protection into matters medical as well as other things, and accordingly, a man who has obtained his diploma in one State cannot practice in another without passing a fresh examination; the number and diversity of the diploma-granting bodies are no doubt a sufficient justification for protective measures. A letter from a successful candidate shows how this system works in the State of Washington, and does not add much to the reputation for common-sense which the Americans are supposed or suppose themselves to be so largely possessed of. The examining board is composed of four regular practitioners, three homœopaths, a "physio-medic" and an "eclectic"; what the peculiar tenets of the two latter practitioners are, or in what way they differ from each other, we have no idea; but their professional attainments are abundantly evidenced by the questions they asked. The writer of the letter referred to gives several of the questions, of which we may select the following as sufficient for our purpose. The "physio-medic" asked: "What does delayed dentition prognosticate?" The candidate could not tell, nor could the two or three members of the board to whom he afterwards submitted the question. Amongst the problems—for we can call them nothing else—propounded by the "eclectic," one was, "What's the *peremptory* condition of pepsin in the stomach?" It was ascertained that the proper answer to this abstruse question was "hydrochloric acid." Another of his problems was, "What's the effect of too much red corpuscles in the blood?" Altogether, our contemporary does not think that the board, as at present constituted, is likely to do much credit to the governing body which has called it into existence.

— An Omaha aurist and oculist has been discovered, it is said, to have an arrangement with jewellers and opticians, whereby the latter send him patients, of whose fees he remits fifty per cent. to the sender.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, OCTOBER 2, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

THE SIGNIFICANCE OF FEVER. — I.

PROBABLY on no pathological subject has so much been written the past twenty years as that of fever. Into the various experimental investigations and speculations to which this study has given rise we do not propose to enter. The two theories of fever which have now found almost universal acceptance are (1) the combustion theory, according to which the rise of temperature results from increased activity of the process by which heat is naturally formed in the tissues; (2) the neurotic theory, according to which the rise of temperature is due to impairment of that inhibitory force by which the heat-producing process is kept within normal bounds.¹ These two theories, as Macalagan shows, are not antagonistic to each other; each is complete in itself, and has its own special sphere of application. The agencies which they represent are doubtless co-operant in most cases.

While pyrexia is often of neurotic origin (for example, that which accompanies cerebral tumor or hemorrhage, injuries of the cervical cord), in other cases, and notably in the infectious fevers, the nervous symptoms are not constant, and when they do occur, they are secondary to the nutritive disorders; and the evidence all points to a pyretogenous cause at work in the blood, by its irritating effects on the anatomical elements of the tissues, exaggerating all the calorifacient chemico-vital processes. The principal seat of this thermogenic metabolism is undoubtedly the muscles whose oxidation is the chief source of animal heat in the state of health. According to MacAlister, the muscles contribute four-fifths of the normal body heat;² in fever, the proportion must be higher.

As to the pyretogenous agent itself, the pathologist of to-day has no hesitation; it is the deadly microbe, or some poisonous ptomaine elaborated by the microbe. Every infectious disease has its micro-organism; the fever is but a symptom of the destructive influence of the microbe on the tissues, either by direct action on

the anatomical elements, or by paralysis of the heat-regulating centres.

A few years ago, it was the prevalent notion that a high febrile temperature was itself a source of danger, and lurid pictures were drawn of the granulo-fatty degenerations which attended prolonged hyperthermia. The free use of antipyretics and especially of cold baths was regarded as indicated to save the patient from these effects. It was afterwards shown that these degenerative alterations of the viscera, and especially the heart, were not so much the effect of the fever as of the fever poison, and experiments proved that textural changes which were attributed to heat were capable of being produced by infective causes. Moreover, instances were noted of grave and fatal cases running their course, producing softening of the viscera, etc., with a phenomenally low febrile temperature. Consequently, there has been a reaction from the extreme doctrine originally propounded by Liebermeister and others, and it has been seriously maintained by some authorities that the febrile process is in the main salutary. This view is well expressed by Cantani of Naples, in an address recently delivered at the Berlin Congress:

Antipyretics diminish the production of heat; but are these remedies really useful? What is fever? Does the fever constitute the principal danger? How happens it that certain remedies combat effectually certain kinds of fever, while they do not act in others, or very slightly; they may indeed diminish the fever, but they do not shorten the duration of the disease by one day.

. . . Fever is the general reaction of the organism against the alterations which the morbid agent provokes in the molecular exchanges. The reaction is the condition of recovery. . . . When the organism fails to react, the morbid agent produces alterations so general and so intense that life is no longer possible. Recovery, then, depends on the reaction of the entire economy against the micro-organism; it is the struggle for life; when the microbe gets the best, the patient dies. . . .

It is not, then, the fever which constitutes the gravity of the disease, when the general condition remains good. The elevation of the fever has not a very grave prognostic significance; it indicates only that the body reacts in an energetic manner. . . .

The fever may act favorably in diminishing, by the elevation of the temperature, the virulence of the microbes. At the same time, many pathogenic bacteria, such, for example, as the bacillus tuberculosus, support degrees of temperature which fever cannot reach; others, on the contrary, as the bacillus of anthrax, the spirillum of malaria, the streptococcus, are destroyed by high febrile heat.

The fever may augment the action of the elements of the tissues, increase their power of resistance. It is unlikely that the whole struggle against the microbes belongs to the white globules alone; the other cells equally take part. Lastly, in modifying the molecular exchanges, the fever may sterilize the soil (*terrain*) and prevent the multiplication of the microbes.

We are not, then, called upon to fight the fever in itself. Our end will be to find means which shall annihilate the very agents of the disease. Thus it is that quinine acts in malarial fever, mercury in syphilis; their rôle does not consist in combating the fever, but in rendering the fever unnecessary, by destroying the very cause of the disease.

It is not, then, an antifebrile treatment that we are called upon to institute, but a pathogenic treatment. We are not warranted in blindly prescribing such antipyretics as kainin, phenacetin, acetanilid; they have no specificity; they have an effect solely on the production of heat; and they thus diminish the reaction of the body against the microbes and injure the organism. It is folly to think of endeavoring to stay the march of a febrile disease by arresting the production of heat. You

¹ See Macalagan, Lancet, March 12, 1887.

² Lectures in Lancet, 1887.

can only do this by diminishing the activity of the organic cells, and the employment of large doses of the antithermic medicaments may give rise to collapse. The end of our search should be to find remedies which may have a specific action on the pathogenic microbes.

Cantani qualifies these statements by the admission that in some cases a prolonged elevation of temperature may be more harmful than beneficial; then, it is desirable to resort to refrigerants, such as cold baths, cold douches, cold ablutions, which diminish the heat of the body without diminishing heat production.

The doctrine that "fever is no disease, but simply a symptom, an indication of the battle fought by the organism to get rid of a morbid condition" was taught before its enunciation by Cantani at the recent Berlin Congress, by Winternitz, of Vienna, by Samuel of Stuttgart, and by Professor Cohnheim. The latter, taking a teleological standpoint, and looking at fever as a manifestation of the *vis medicatrix*, anticipates the time "when physicians will more and more regard fever, not indeed as a condition free from danger, but as, on the whole, a wise provision of nature."

It is doubtless true that this view was a reaction from the exaggerated ideas which had been prevalent as to the dangers of high fever heat, and as to the necessity of vigorous antipyretic treatment. Clinical observations were not lacking to show that the prolonged existence of high temperatures was not necessarily followed by granulo-fatty degenerations of the viscera and myosites, and that these lesions were rather dependent on the irritant character and intensity of the infection. In fact, some of the most dangerous and fatal cases of septic and typhoid fevers run their course without presenting any continuous high elevation of temperature. Hayem in his "Studies on the Symptomatic Myosites" relates such observations, and Vallin reports the case of a typhus patient whose temperature never exceeded 100° F., and where the autopsy revealed not only fatty myocardium, but fatty degeneration with rupture and hemorrhage of the muscles of the abdomen and thigh.

The natural inference from observations of this kind was that expectancy rather than a vigorous antipyretic treatment was indicated. The pyrexia might be regarded as an evidence of a healthful reaction—an attempt on the part of the organism to burn out the micro-organisms or render the fluids and tissues unsuitable for their development; and therefore should be respected rather than combated.

The objections to this view have been well-stated by MacAlister in his Croonian lecture on "Antipyretics." It is true that some of the least known microphytes are checked in their growth or multiplication by high temperatures. Gaffky showed that typhoid bacilli formed spores with difficulty at 107.5° F.; Koch that tubercle bacilli ceased to grow after being kept for some weeks at a like temperature. The bacillus anthracis continues to grow but loses in virulence if kept for some weeks at 108.5° or for some days at 109.5° F. Surely it cannot be held that such facts are really

relevant. A body temperature of 107° to 109° kept up for days or weeks is too powerful a remedy. The body would be consumed before its parasite.

A less direct explanation was suggested in a recent lecture by Von Ziemssen; namely, that the pyrexia so alters the constitution of the tissues that the microphytes no longer find in them a suitable soil, and so perish. But against this is the fact that the exanthemata tend strongly to run a definite course, whether the fever be high or low.

Hilton Fagge and others cite cases in which the febrile paroxysm seemed to have a destructive effect on the living virus of relapsing and of intermittent fevers. The true explanation seems to be of a different kind, and is applicable to all the specific diseases attributed to specific micro-parasites. These parasites seem like other living creatures to have a definite life period, in which they grow, multiply, exert their special action, and decay. This period is independent of pyrexia, independent of antipyretic treatment, and independent of external conditions.

The definite duration of virulence in typhus, measles, small-pox, etc., and the sudden extinction of its vitality at the crises in croupous pneumonia, bespeak a normal biological property in the virus, a law of its life, which forbids it to live beyond a certain time. It has been shrewdly asked: If pyrexial temperatures are not in themselves dangerous, but merely serve to purify the body without injuring it, why are they in ordinary cases confined within such narrow limits? If fever be a process with a purpose, would it not be better to nip the growth of the microphyte in the bud by a prompt and intense rise of temperature at the beginning of the illness?⁸

These considerations seem to dispose of the teleological theory of fevers, and the evolution-hypothesis, strongly advocated by MacAlister, assumes that from the remotest time the microbes of septic processes and of fevers, have existed in common with the organisms on which they prey; that when the conditions are favorable, they invade these higher organisms, and take possession of the fluids and tissues, grow, luxuriate and multiply: a struggle for supremacy takes place between the cells of the organism invaded and the microbes, of which struggle fever is one symptomatic expression. Fever is the result of irritation by microbes and microbe-poisons of the anatomical elements which, in the recesses of the tissues—chiefly of the muscles—are the seat of normal thermogenesis; an inordinate combustion takes place, and the products of this combustion are seen in the increased elimination of carbonic acid, urea, and other waste substances. The thermotaxic or heat-regulating nervous mechanism is deranged—inhibited, paralyzed—by the microbe-poisons, and the thermolytic vasomotor centres are also deranged, so that there is failure in heat elimination. This process goes on until one or the other of the combatants is triumphant. The higher organism is favored in the struggle by the resistance of its cells,

⁸ Croonian Lectures on Antipyretics.

leucocytes, and fluids, and by the fact that the life history—the active period—of its microbic foe is brief; if the vital forces can be sustained until the microbe has had its day, *restitutio ad integrum* takes place. The microbe also is hindered, perhaps ultimately stayed in its progress by the poisonous ptomaines which are generated during the functional activity.

According to this view, then, fever can hardly be regarded as a teleological process.

How far can antipyretics avail, and what is the logical treatment of pyrexia; does it, in fact, need any treatment at all? These are questions which deserve separate consideration.

MEDICAL NOTES.

—The Society of Trained Male Nurses of New York City has been incorporated to unite together such male nurses as apply for admission and come within its requirements, which provide that the applicant shall be either a member of the training-school for male nurses at Charity Hospital, or a graduate, with diploma, of any other reputable training-school for male nurses; also, to provide a suitable meeting-place, where its members, when unemployed, can meet for social intercourse, and to discuss subjects of mutual interest in their line of work.

—Mr. Lawson Tait, in a paper before the recent Congress at Berlin, advocated an application or a re-application of the apprenticeship system to the study of young surgeons. The period of apprenticeship should be, according to Mr. Tait, two years. Hospital practice does not, he thinks, take the place of study of the management of patients in their own homes.

—The Chinese, as we learn from a contemporary, who reject scornfully nearly every application of Western medical science, are, according to the governor of Hong Kong, firm believers in the advantage gained from vaccination, and submit to the ordeal with a cheerfulness and philosophy which are characteristic of this wily Oriental. Protection by vaccination is especially required in Hong Kong, owing, as Sir William des Voeux points out, to the frequency with which small-pox is introduced by steamers coming from all parts of the world, and to its fatal prevalence when it has once obtained a footing.

BOSTON.

—The entering class at the Harvard Medical School is the largest since the establishment of the three years graded course. It numbers between forty and fifty more than previous classes.

NEW YORK.

—Expert Wheeler of the Board of Electrical Control in his report on the death of Lineman Kopp, who was killed at Broadway and 35th Street, on the night of September 22d, holds that the deceased was respon-

sible for his own death, because he failed to wear rubber gloves in making the repairs on which he was engaged when he received the fatal charge of electricity. The United States Company, on whose wires he was at work, provides such gloves for its operatives, and he therefore considered it blameless in the matter.

—Some three hundred applicants who desire to pursue the study of the professions of law and medicine, presented themselves in New York and Brooklyn on September 23d, for the preliminary examinations held under the direction of the Board of Regents of the University of the State of New York, in accordance with the provisions of the new law passed by the Legislature at its last session. The examinations were held at the College of Physicians and Surgeons, where Francis J. Cheney, Ph.D., State Inspector of Schools and Colleges, was in charge; at the University Medical College, under Ralph W. Thomas, and at the Long Island College Hospital, under Professor Massee. Similar examinations were also held at the same time at Albany, Syracuse and Buffalo. All the students were examined successively in arithmetic, geography, grammar, spelling and English composition, and United States history. In addition, those proposing to study law were required to pass in English history, while the medical candidates had to elect between physics and physiology. The examinations were all in writing, three hours being allowed for each branch of study, and a percentage of seventy-five was required in order to pass. Similar examinations will be held in November, January, March and June, and those failing to pass can present themselves again at any of these times. Under the new law, which is designed to lessen charlatanism and quackery, medical or law graduates, physicians or lawyers in practice, and graduates of colleges or high grade schools are exempt wholly or in part from such preliminary examinations. Up to the present time any accredited physician might practice in the State of New York by the simple act of registering with the clerk of the county in which he desired to practice.

—The attorneys for a Japanese murderer now in Sing Sing prison awaiting execution by electricity, have applied for a writ of habeas corpus for him, on the ground that the electrical apparatus now in possession of the State is incapable of producing instant death, as required by the statute. A portion of the petition is as follows: "Your humble petitioner further alleges that said machines can generate a normal force (expressed in volts) of only 1,050 volts; that such force is inadequate to immediately overcome the resistance of a body (expressed in ohms) of only 23,100 ohms, and only upon a human body of that resistance, can said machines inflict instant death; that while the application of the force from said machine to petitioner's body would kill him, that result would only follow the reduction of his resistance gradually, while he would meanwhile be slowly tortured and consumed by heat, and put in exquisite anguish by incessantly repeated shocks of the entire nervous organiza-

tion; that whether he would be unconscious during the torture, would depend on his ability to endure pain; but that if he should be unconscious it would be because he would be unable to endure the torture, not because the centres of nerve sensation would be destroyed or because of instant death. The machines and processes held out, and the only ones which the State has authority to use, are entirely incapable of producing any other or different effect. Your petitioner's electrical resistance exceeds 500,000 ohms. Your petitioner further alleges that no other means of artificially generating electricity now known, can produce any other result; that the State and its agents cannot procure or purchase a license to use any other dynamo-electric machines, and cannot manufacture such machines, which are protected by letters patent; that no adequate machines are made or can be made for the generation of an adequate current such as is by said sentence prescribed. It is, therefore, not possible to apply a current of electricity to the vital parts of petitioner's body under such circumstances or in the manner contemplated by the electrical execution statute of the State of New York."

—Mr. Stockton, the son of the Attorney-General of New Jersey, a short time since received such severe bites from a cat that fearing serious results might ensue, he has become a patient of Dr. Gibier at the New York Pasteur Institute. The cat, which had been acting strangely for some little time, terrified one of his children, and when he attempted to pick it up to remove it from the room, it made a sudden snap at him and lacerated his hand in a very bad way. The cat was brought with him to New York, so that it might be kept under Dr. Gibier's observation.

—By the will of Mrs. Harriet M. Remington, who died on August 23d, the Brooklyn Home for Consumptives receives \$4,000, and the Brooklyn Eye and Ear Hospital \$20,000.

Miscellany.

THE DIAPHANOUS TEST OF DEATH.

DR. BENJAMIN WARD RICHARDSON in the last *Asclepiad* speaks of a paragraph making the round of the scientific and general press which must be accepted *cum grano*. In this paragraph it is stated that the French Academy of Sciences ten or fifteen years ago offered a prize of £1,600 for the discovery of some means by which even the inexperienced might at once determine whether in a given case death had or had not ensued. A physician obtained the prize. He had discovered the following well-known phenomenon. If the hand of the suspected dead person be held towards a candle or other artificial light with the fingers extended and one touching the other, and one looks through the spaces between the fingers towards the light, there appears a scarlet red color where the fingers touch each other, due to the blood still circulating, and showing itself through the tissues, if life have not yet ceased. When life is entirely extinct the

phenomenon of scarlet space between the fingers at once ceases. The most thorough trials, it was said, had established the truth of this observation.

Dr. Richardson says that in his essay on absolute proofs of death he has described this test with the others, and has attached to it its true value. The statement that the test is sufficient of itself is, however, too solemn to be allowed to go without correction; and he therefore affirms, with all possible earnestness, that the test, trusted to alone, is capable of producing the most serious error. In the case of a person in a state of syncope, where the test was most carefully applied, there was not the faintest trace of red coloration between the fingers; yet recovery from the syncope was quite satisfactory without any artificial aid. The test is one which admits of being readily tried, and, *prima facie*, it is a good test to bring into operation. But as an absolute proof of death Dr. Richardson would put before it: (1) the pulsation of the heart; (2) the respiratory murmur; (3) pressure on veins; (4) the electric test for muscular irritability; (5) the ammonia hypodermic test; (6) coagulation of blood in the veins; (7) rigor mortis; and (8) decomposition.

CHILD-WIFE MURDER.

A SPECIES of injury for which the marriage customs of oriental countries probably give an especial opportunity, is illustrated by the following case which we find reported in the *Indian Medical Gazette*, August, 1890:

The case was recently tried before the Sessions Court in Calcutta. The accused was found guilty by a jury composed of six Hindus, one Mohammedan, and two Europeans, of inflicting grievious hurt through committing a rash and negligent act and sentenced to one year's rigorous imprisonment.

A well-developed and well-nourished native girl, aged at time of death, eleven years, three months and fourteen days, was married to a healthy Hindu (Ooriya Kastu caste) aged thirty-five, on the 11th of May, 1890 (age eleven years two months and nine days). She went to his house the day after the marriage and stayed eight days with him, and again after two days for part of a day. Her husband came to see her at her mother's house at the Snan Jattra (June 3d) and stayed three days, and again on Sunday, June 15th. The girl went to sleep with the sisters in a corridor, and about 1.30 of the 16th her cries were heard coming from the adjoining room where her husband slept. She was found lying on a charpoy weltering in blood the man standing beside. A doctor saw her about 6.30 next morning and found her labia a little swollen on both sides and a clot in the vagina. She was almost dying, pulseless. She died about 3 p. m. the same day (thirteen and a half hours). On *post-mortem* examination next morning the following facts were found: Body well-nourished. Mucous membranes pale, no hair on pubes, breasts beginning to be prominent, not developed. No external mark of injury. No abrasions or marks about the genital organs. Internal organs healthy with exception of edema at base of left lung; they were bloodless. A clot measuring three inches by one and one-half inches in vagina. Vagina smooth and dilated. No hymen or fourchette; no rugae. A longitudinal tear one and three-quarters long by one inch broad at upper end of vagina to right of os uteri. A haematoma

three inches in diameter in the cellular tissue of the pelvis. Vagina, uterus and ovaries small and undeveloped. No sign of ovulation. The police surgeon deposed the death was caused by exhaustion from bleeding caused by injury sustained during sexual intercourse.

BLISTERING BY HYPNOTIC SUGGESTION.

In the *British Medical Journal*, September 13th, we find notice of some remarkable experiments made by Dr. Iakov V. Rybalkin, of St. Petersburg, and published in the *Bolnitschnaia Gazeta Botkina*, Nos. 26, 27 and 28, 1890, p. 650, which confirm the statements made by Presalminis (1840). Focachon, Beaunis, Delbeuf, Forel, Jendrassik and Kraft-Ebing, that cutaneous blisters can be easily raised by hypnotic suggestion. The author's experiments were performed in the presence of a number of the medical officers of the Mariinskain Infirmary, the subject being a strongly made and well-nourished house-painter aged sixteen, suffering from typical hysteria magna and extremely sensitive to hypnotizing procedures and post-hypnotic suggestions. On February 21st, at 8.45 p. m., the patient was thrown into a deep hypnotic sleep, and then told that, after awakening, he was to shiver from cold and to approach a stove in the room in order to warm himself; when doing so he was to touch the stove with his right forearm and to contract a severe burn ("pain, redness, heat, bladder") about the middle of the inner surface of the part. The suggestions were repeated thrice, after which the lad was ordered to awake. He obeyed all the suggestions in the strictest possible manner, and even loudly screamed from pain as soon as the suggested area came in contact with the stove, (which was quite cold). On immediately inspecting the part, a slight, palish swelling, surrounded by a reddish zone, which proved to be painful on touch or pressure, was found exactly at the suggested point. The limb was at once bandaged, and the lad sent to bed (in the room). He could not fall asleep, however, being tormented by an acute "rending" pain caused by the "accident." On removing the bandages at 11 p. m., a considerable swelling with papular erythema was found, the adjacent zone four or five centimetres wide, being exceedingly tender. The limb was again securely bandaged, and re-examined at 10 A. M. on the next morning, when there were found two slightly yellowish semitranslucent blisters as large as a nut and a pea respectively, and around them a group of smaller vesicles (each of the size of a pin's head). On another examination at 3 p. m. (eighteen hours after the "accident"), all the individual blisters proved to have coalesced into one large bladder. Two hours later the blister burst. The after-course presented nothing different from an ordinary case of burn.

THE FIFTH DISTRIBUTION OF ARMS AND LEGS TO VETERANS.

ACCORDING to Washington correspondents of the daily press the office of the surgeon general of the army is now being besieged for artificial arms and legs. These artificial members, with which Government provides all the maimed veterans at stated periods, were appropriated for in the sundry civil bill, which was

delayed for so long in its passage by Congress. In consequence of this delay the cripples have been obliged to wait over-time for the limbs due them, and they have not done it very cheerfully.

The law, passed in 1870, declared that every soldier or sailor who had lost a limb or the use of it in the service of this country should be supplied with an artificial one to replace it once every five years at the Government's expense. Or, it was provided that, if the beneficiary did not wish to take the limb, he should be paid its cash value instead. Now, an artificial limb is a pretty costly thing, and many an old soldier prefers to stump around on a wooden peg and put his \$75 in his pocket. That is the sum given as "commutation" for a leg, \$50 being the amount paid for an arm.

The law covers not merely limbs lost but limbs rendered useless. Of course, there are many more old soldiers who have disabled limbs than have lost them, and they necessarily draw the money. Thus, out of eighteen thousand veterans who receive this bounty from the Government every five years, only about eight hundred call for actual arms and legs, the rest accepting cash instead. Perhaps as many as eight hundred more prefer to go without the artificial legs they need as a measure of economy, using stumps or crutches instead. The one-armed men take their checks nearly every time. When the law was first passed nearly as many arms were called for as legs; but the cripples soon discovered by experiment that, while an artificial leg is a most useful piece of mechanism and a very fair substitute for the article, the best false arm is hardly more than a thing for ornamental purposes. So it came about that there have been few applications for arms since, ninety-nine legs being made at Government expense for every arm.

The Government, continues the correspondent from whom we quote, has a list of about forty artificial limb factories in all parts of the United States, from which the veterans may make their own selections, so that any one may have his leg or arm turned out by any of these establishments that he prefers. All of the manufacturers on the list are under bonds of \$10,000 each to supply the old soldiers with satisfactory goods. It is provided incidently by the law that the person needing the limb being provided with a certificate for it, shall be given free transportation from his home to any city he desires, where a factory is situated, with sleeping-car accommodations, and return. Thus a veteran in New York may be desired to be measured for a leg in San Francisco, and, if so, is entitled to a trip across the continent and back once in five years in a Pullman palace car, free of expense. He must pay for his meals en route, however, which he is likely to consider an outrage. To the recent Grand Army Convention at Boston old soldiers went as dead-heads from all parts of the United States, for the purpose of being measured for arms and legs. This may be referred to, perhaps, as an illustrative definition of the slang term that puzzles so many people — "pulling one's leg."

A CASE OF TETANY.

DR. SCHENCK, of Illinois, read before the Section for Diseases of Children at the late meeting of the American Medical Association, the following case of this rather rare affection:

October 23, 1889, Clara L. Brine, of Grayville, Ill., was brought to my office; she being a well-developed, bright and healthy-looking girl of ten years. The mother and father, who accompanied her, were both above the average in size, of intelligent bearing, and barring a few slight attacks of unimportant sickness, had always been healthy. Their five other children were all well developed. Clara had been healthy until three years since, when she suffered from some ailment of the bladder, but which was of temporary duration. Near two years ago, while in her usual health, she was suddenly seized with a swimming sensation, and fell backwards on the floor; not, however, losing consciousness. Attacks of this character occurred at frequent intervals for nearly one year. She usually avoided falling by holding to some object until the sensation passed off. The physician who treated her told the parents the attacks were caused by some heart disease. Gradually these paroxysms were ushered in, or preceded, by more or less tonic cramps of the lower limbs, felt most severely at the knees; when the feet were involved, the toes would be drawn together and towards the sole of the foot. Later the upper extremities, and finally the jaws, became involved in the tonic contractions; but as they did so, the dizziness became less, and the cramps of the lower limbs grew lighter, and for the last six months had ceased entirely; while those of the upper extremities, neck and jaws had grown correspondingly more severe and more frequent, averaging about ten a day; being most frequent during the forenoon, but never occurring during sleep. In some of the most severe attacks there was decided opisthotonus. In all those attacks consciousness was never lost. During the past year she had been treated by a physician for epilepsy. During the time of her visit to my office, while I was familiarizing myself with a history of her case, she was seized with a severe paroxysm, while in the midst of sentence, and when not in the least excited. It came without any premonition and involved both upper extremities, and the muscles of the neck and jaws, in the order named. The muscles were so rigid that she was unable to speak, swallow, or move the head; the elbow-joints were flexed, and the arms held rigidly from the side; the right hand was closed into a hard fist; the fingers of the left were first irregularly over-extended, then drawn together, the two outer coming under the two inner ones, while the thumb was drawn down to the palm, forming the obstetric hand. The face became full and flushed. This condition lasted near two minutes.

The paroxysm was accompanied by radiating pains in the parts involved: "a sharp pain, with other pains shooting out from it," was her expression. She complained, after the attack, of numbness and formication in the muscles affected, also of ringing in the ears. Examination revealed slight edema of the hands and face; tendon reflex of knees and wrist entirely absent; Argyll-Robertson pupil well marked; pulse 120 per minute, small and hard. Had always suffered slightly from constipation; appetite good; sleeps well and quietly; temperature normal. There was no tenderness along the spine or over the ovaries, or any other part of the body; not subject to excessive perspiration; nervo-muscular irritability could not be produced by raking finger-nail in front of ear; there were no nausea nor vomiting after attacks; she had not been a

bottle-fed infant; had never suffered from rickets or laryngismus; did not pass large quantities of urine after paroxysms; pressure on the large blood-vessels or nerves did not bring on an attack; applying cold water to hands failed to cut short a paroxysm.

The treatment and progress of the case were as follows:

October 23, 1889.

R.	Liquor potass. arsenitis	3 j.
Soda brom.	3 ss.
Aqua	ad. 3 iv. M.
Sig.	One teaspoonful after meals.	
R.	Antifebrin	gr. xxx.
	Divide into fifteen capsules.	
Sig.	One capsule before meals.	

October 31st, symptoms very slightly improved; averaged five paroxysms per day since the former visit; pulse 120; tendon-reflex of the extremities imperceptible; Argyll-Robertson pupil still marked.

Thinking she might be afflicted with worms, the writer gave

R.	Hydrag. chlor. mitis	gr. ij.
Soda bicarb. santoninæ	as gr. vi.
Mix flat Chart No. vi.		
Sig.	One powder at 4, 6, and 8 p. m. on consecutive nights.	

Then to begin the following:

R.	Fl. ext. conium	3 j.
Sig.	Eight drops after each meal.	
R.	Glonoin	3 iv.
Sig.	Two drops two hours after meals.	

November 12th. Had passed no worms from santoninæ. During the first six days she had nineteen paroxysms, and none during the last five. Continues the two last prescriptions.

December 4th. Had no paroxysm since last visit; tendon reflex of both upper and lower extremities nearly normal; pupil responds properly to light. Continued the nitro-glycerine and stopped the conium.

February 3d. She had had no attack since last report; and May 10th, reported herself as quite well.

Correspondence.

THE STUDY OF MUSHROOMS.

22 MONUMENT SQUARE, CHARLESTOWN DISTRICT,
BOSTON, September 27, 1890.

MR. EDITOR:—Since the publication of my article on "Mushrooms and Mushroom Poisoning" (JOURNAL, September 18, 1890), I have had inquiries as to works relating to the study of mushrooms.

The following list of a few rather inexpensive English works will be of service to the student. It is not intended to be a bibliography. No mention is made of references to periodical literature, or of the larger and more expensive books, or the strictly scientific works of the earlier writers.

There is not as yet any work which answers for the cryptogams as "Gray's Botany" does for the phenograms. The nearest approach is Stevenson's work, to be used in connection with Smith's "Clavis." The American student must search periodical literature if he wants descriptions of strictly American species, particularly the very valuable reports of State Botanist C. H. Peck, of the New York State Museum.

The life-size figures on the charts which accompany "Mushrooms and Toadstools," by Worthington Smith, are

of great value. A new edition is soon to be, if not already, issued. Palmer's "Mushrooms of America," while not in every instance correct as to the botanical nomenclature, has most excellent plates, which are invaluable to the beginner. The "Boleti of the United States," by C. H. Peck, is exhaustive, and only lacks illustrations to make it perfect.

Outlines of British Fungology. By Rev. M. J. Berkeley. Illustrated by colored plates. London: L. Reeve & Co. 1860. **Handbook of British Fungi.** By M. C. Cooke. (Superseded by Stevenson's work.) London: MacMillan & Co. 1871.

A Plain and Easy Account of British Fungi. By M. C. Cooke. London: Robert Hardwicke. 1871.

Mushrooms and Toadstools. Illustrated with two large charts. By Worthington L. Smith. London: Robert Hardwicke. 1867. (Out of print, new edition about to appear.)

The Esculent Funguses of England. By C. D. Badham. London: L. Reeve & Co. 1870. (Most entertaining reading.)

Fungi: Their Nature and Uses. By M. C. Cooke. Edited by Rev. M. J. Berkeley. New York: D. Appleton & Co. 1875.

Toadstool Eating. By Julius A. Putnam, Jr. *Popular Science Monthly*, May, 1877. (A popular article, and worth reading.)

Mushrooms of America, Edible and Poisonous. Edited by Julius A. Palmer, Jr. Boston: L. Prang & Co. 1885. (A dozen good plates, with descriptions and rules for cooking and eating, only \$1.60.)

British Fungi (Hymenomycetes). By Rev. John Stevenson. Edinburgh and London: William Blackwood & Sons. 1886.

Clavis Agaricinorum: An Analytical Key to the British Genera. By Worthington L. Smith. London: L. Reeve & Co. 1870. (Essential to the analyst of species.)

An Elementary Text-Book of British Fungi. Illustrated by William Delisle Hay (using cuts from Cooke's Handbook). London: Swan, Sonnenschein, Lowrey & Co. 1887.

The Fungi Hunters' Guide and Field Memorandum Book. By W. Delisle Hay. London: Swan, Sonnenschein, Lowrey & Co. 1887. (Aids nothing of value to Smith's "Clavis" but the cuts taken from Cooke.)

Reports of the Botanist (Yearly). By Charles H. Peck, State Botanist, Albany, N. Y. (Public Documents.)

Boleti of the United States. By Charles H. Peck, State Botanist. Bulletin of the New York State Museum, No. 8, September, 1889. Albany: University of the State of New York.

Very truly yours,
EDWARD JACOB FORSTER, M.D.

Deaths reported 2,808; under five years of age 1,244: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 642, consumption 344, acute lung diseases 176, diarrhoeal diseases 340, diphtheria and croup 115, typhoid fever 99, whooping-cough 32, scarlet fever 18, malarial fever 18, measles 9, cerebro-spinal meningitis 8.

From whooping-cough, New York 17, Chicago and Brooklyn 4 each, Baltimore 3, Philadelphia, Washington, Lowell and Salem 1 each. From scarlet fever, New York 8, Chicago 3, Philadelphia, Brooklyn and St. Louis 2 each, Boston 1. From malarial fever, Philadelphia and Brooklyn 4 each, New York 3, Baltimore and Charleston 2 each, Boston, Nashville and Newton

1 each. From measles, New York 6, Brooklyn 3. From cerebro-spinal meningitis, Brooklyn 3, Chicago 2, New York, Boston and Washington 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,559, the death-rate was 18.6. Deaths reported 3,462: acute diseases of the respiratory organs (London) 210, diarrhoea 316, measles 70, scarlet fever 68, whooping-cough 68, fever 47, diphtheria 30.

The death-rates ranged from 13.2 in Bradford to 27.8 in Plymouth, Birmingham 21.2, Hull 19.0, Leeds 17.5, Leicester 20.9, Liverpool 22.8, London 16.6, Manchester, 23.4, Nottingham 13.4, Sheffield 23.5, Sunderland 21.8.

In Edinburgh 17.5, Glasgow 21.3, Dublin 17.3.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 20, 1890, TO SEPTEMBER 26, 1890.

Under the provisions of General Orders No. 43, c. s., Headquarters of the Army, Adjutant General's Office, the post of Little Rock Barracks, Arkansas, will be abandoned, to take effect not later than October 1, 1890. Captain PAUL R. BROWN, assistant surgeon, will accompany Company E to Fort Supply, Indian Territory, and there take station until further orders. G. O. 15, Headquarters Department of the Missouri, St. Louis, Mo., August 11, 1890.

The leave of absence for seven days granted Captain AARON H. APPEL, assistant surgeon United States army, by the commanding officer, Fort D. A. Russell, Wyoming, is extended twenty-three days. S. O. 70, Par. 3, Department of the Platte, September 17, 1890.

Major JOHNSON V. D. MIDDLETON, surgeon, is relieved from duty at Davids Island, N. Y., and will report in person to the commanding officer, Fort Columbus, New York City, for station, report to Major John R. Gibson, surgeon, and report by letter to the commanding general, Division of the Atlantic. Major Gibson, on being relieved by Major Middleton, will report in person to the commanding officer, Davids Island, N. Y., for duty at that station, and by letter to the superintendent of the recruiting service. S. O. 219, Par. 1, A. G. O., Washington, September 18, 1890.

Leave of absence for one month, to take effect the 1st proximo, is granted Captain C. B. EWING, assistant surgeon. S. O. 131, Par. 5, Department of the Missouri, September 22, 1890.

In view of the early abandonment of Fort Elliott, Texas, to which post he is at present assigned for station, Major J. P. KIMBALL, surgeon, is relieved from duty at that post, and will, upon the expiration of his present sick leave of absence, proceed to Fort Supply, I. T., and report to the commanding officer for duty. S. O. 132, Par. 2, Department of the Missouri, September 24, 1890.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting of the Society will be held, at 19 Boylston Place, on Monday evening, October 8th, at eight o'clock.

Readers: Dr. Henry R. Stedman, "The Selection of Cases of Insanity for Different Methods of Private Care"; Dr. A. N. Blodgett, "Continuous Inhalation of Oxygen in Cases of Pneumonia otherwise Fatal."

T. F. SHERMAN, M.D., *Secretary.*

RESOLUTIONS ON THE DEATH OF DR. WINTHROP FLINT STEVENS.

At a regular meeting of the Middlesex East District Medical Society, held September 24, 1890, the following resolutions were unanimously adopted:

Resolved, That the members of this Society express their deep sense of the sad details of the late associate, Dr. Winthrop Flint Stevens, a gentleman whose genial disposition, high sense of honor, skill, and unfailing courtesy endeared him alike to his patients and to his professional brethren.

Resolved, That we tender to his immediate family, his relatives, and the families he so faithfully attended, our sincere sympathy and condolence.

Resolved, That a copy of these resolutions be sent by the Secretary to Mrs. W. F. Stevens, and also to the *Boston Medical and Surgical Journal* for insertion there.

[Signed] WM. SYMINGTON BROWN,

CHAS. C. ODLIN.

OBITUARY. GEORGE LYLE KINGSLY.

Dr. George Lyle Kingsley, interne at the Massachusetts General Hospital, died, September 23rd, of diphtheria. Dr. Kingsley was born in 1864, at Rome, N. Y. He was graduated at Yale, in 1886, but was a member of the class only during the junior and senior years, having accomplished the work of the

first two years at home with a private tutor. He took high rank in scholarship, but was best known in the college as a collector of Yale memorabilia.

While a student at the Harvard Medical School, he distinguished himself by unusual fertility in the invention and manufacture of mechanical appliances. Readers of the JOURNAL will remember his article on "Calculation of the heart," which appeared in its columns, in 1888, in reference to the estimation of contraction and abduction of the leg in hip-disease. He was specially interested in the application of photography to medicine, and had recently presented to the hospital a small building for photography, with its dark closet and corresponding apparatus.

His diphtheria was of unknown origin, there being no disease of the sort in the hospital, nor other contagious disease, except two cases of erysipelas in another service.

As a house-officer, he had shown himself faithful, industrious and conscientious; by his fellows he was not only honored for his ability, but beloved for his unusual sweetness of disposition. He was a young man of great promise, and his early death is regretted alike by his associates and the general staff of the hospital.

OBITUARY. CORNELIUS D. MOSHER, M.D.

Dr. Cornelius D. Mosher, of Albany, N. Y., school commissioner, physician and public benefactor, is dead. Coming to Albany thirty-five years ago, he entered, as a student, the Albany Medical College, graduating in the spring of 1858. In the fall of that year Mayor G. Thacher appointed Dr. Mosher the corporation district physician, and subsequently he was made police surgeon. In 1857, he was elected a member of the Board of Public Instruction. To him is due the establishment of night schools.

Dr. Mosher was sixty-one years of age, being born in the town of Bethlehem, Albany County, in 1829. He leaves his widow and one daughter surviving him.

Lecture.**THE SCOPE AND THE TEACHING OF HUMAN ANATOMY.¹**

BY THOMAS DWIGHT, M.D., LL.D.,
Parkman Professor of Anatomy.

GENTLEMEN: In the old days, when the school term was divided into two parts, the winter term beginning about the first of November, lasting some five months, and comprising the essential part of the year's work, it was customary to begin this more serious part with a solemn introductory lecture delivered by one of the professors, attended by the whole school, by the president, by the faculty, and in general by friends of medical education, and those interested in the school. When we changed our system that was given up, and the change was rather characteristic of the spirit of the school. As one of our professors once said, we do not lecture, we teach; and the more formal proceedings have, therefore, gone by the board. Now I am not prepared to say that this was a mistake; but in some respects we feel the want, now and then, of that introductory lecture. It was an occasion on which any change of policy on the part of the faculty could be made public; or if the professor whose duty it was to speak had broad and important views on some matter of education, it gave him an opportunity to declare them before an intelligent and sympathetic audience. I may mention, unless I am mistaken, that the very last of these lectures conveyed an important message: it was that by Prof. J. C. White, which led to the beginning of the graded course, the new method of instruction, which this school may claim to have introduced.

Of course, it occasionally happened in those days that if some gentleman spoke because he had something to say, others spoke because they had to say something, and we have lost the one in escaping the other. It happens to-day that I, at least, think I have something to say, and I am going, therefore, for once to depart from my usual method, which is to begin the course without any shadow of introduction, to say a few words on the scope of human anatomy, to show that, far from being exhausted, it offers many opportunities for original work, that it is closely connected with many questions of general scientific interest, and that it has claims to be considered a part of a liberal education for those who do not study it as the beginning of their profession. I wish also to speak of the means at our command for anatomical study.

In the first place, although it does not form necessarily a part of the subject, let us say a word or two about the subject-matter of our course, that is, man, and how and where we are to place him in the system of Nature. You remember Huxley's celebrated little book on "Man's Place in Nature," a very excellent one — although there are points of importance from which I dissent — in which he said, that to study and to place man, we should consider ourselves in the position of scientific inhabitants of Saturn, to whom this new featherless biped had been sent, preserved it might be in a cask of rum. It seems to me that if we are to study the whole question of man as we see him and meet him as a living being, this is a very one-sided and insufficient view. Let us suppose, by way of

illustration, that there had dropped into this cask of rum an ant and a bee. The learned Saturnians may have had enough zoological knowledge to classify these animals correctly, but they never could have guessed from their structure the wonderful instincts to which they owe the prominent places they hold among animals. In the same way, by studying merely the structure of man, we fail entirely to find his great intellectual capabilities.

To my mind the best definition of man is that of a rational animal consisting of body and soul. In body he is simply animal. Every difference in bone, in muscle, tendon, organs, even the brain, between him and lower animals is entirely one of degree, and not in the slightest one of kind. When, however, we come to him as a whole, we find an immense difference, consisting in the soul, and one that brings him entirely out of the animal category. It may be asked how I should prove my words, whether I have any right to assume the existence of a spiritual part of man, and as I am not here to teach metaphysics, nor philosophy, I shall limit myself to giving you in about two minutes what it seems to me is at once the simplest and the most conclusive evidence, and this is simply the fact, which we know by looking inwards, of the freedom of our own wills. It is a fundamental law of physical science, that, given a certain condition of affairs, a certain cause will infallibly produce a certain result. It will do it once; and, all the conditions being the same, it will keep on doing it indefinitely. It, therefore, has to be accepted as a primary fact, that, given a certain cause, you must have a certain result. Now looking inwards, we see that a given cause does not always have the same result, that we are able to pursue one course or the other, as we see fit. We can see that in a thousand ways, from the most trivial to the most important. We know well enough whether we will listen to a speaker who bores us or to a friend who tells us a story. It is for us to choose. And we may by an act of the will give our attention to one or the other. In the same way, when we study the arguments which are given for and against a certain proposition, it is by a definite act of the will that we decide which one we will accept. I do not forget that there are those who tell us that all this is a delusion, that it is simply that we follow the stronger impulse, and that these impulses are so subtle that we fail to realize it, that when we think we are making a choice, in fact we are not doing so. The only answer to that is to observe for ourselves, and our consciousness tells us that it is not true. And, next, you can find no man who announces this theory who does not at almost every moment of his waking life practically contradict it, because there is no one that in his thoughts and reasonings does not recognize the word "ought," that a man ought to do or to have done such a thing; and unless we give up all idea of right and wrong, we must admit that we have free will. Enough on that point; but it seems to me, gentlemen, that as you are beginning your medical career, in which your patients are to be human beings, it was not amiss to say a word in support of the dignity of man.

Now let us come to the teaching of anatomy proper. It has been said — it was said as long ago as I was a student; for aught I know, it may have been said in the time of Aristotle — that there was nothing more to learn in coarse anatomy; possibly the microscope

¹ An Introductory Lecture to the First Class at the Harvard Medical School, delivered September 29, 1890.

would show us new things, but that in the anatomy studied with the naked eye we had got as far as we could. I want to call your attention first to a few points which have come out even during my time. One is of great practical importance in abdominal surgery. Here is a piece of the intestine. It is called the cæcum, the blind gut; and this, it was formerly said in all works published in France, in England and in America, had the lining membrane of the abdomen, the peritoneum, spread over it so as to cover its upper surface, but it left the posterior surface against the hind abdominal wall uncovered. In point of fact, one had only to look, to see that this was absolutely untrue, that the whole of it is covered, that it is surrounded, as can be proved by the way it can be swung about. It is but very recently that this fact has met with general acceptance.

Again, to show a point at which we still are working: there are given in the text-books certain plans of the distribution of the nerves of sensation on the hands; and you know, of course, that when a nerve that gives sensation is divided, there is no feeling in the parts of the hand to which that nerve was distributed. Well, the experience of the hospitals has been strangely at variance with that of anatomical teaching. It has been found, given a cut that divided a certain nerve, that the place where there was no feeling was in the majority of cases, in the first place, a good deal smaller than the distribution of the nerve; next, that around that place of abolition of feeling there was a neutral territory in which, although sensation was not abolished, it was weakened; and then, again, it was found that in many cases this loss of sensation appeared in very queer localities, not at all corresponding, as I say, to the facts taught in the text-books of anatomy. Now what is the explanation? Recent observations have gone far to show that the trouble is simply a want of accurate knowledge of the distribution of the nerves. The neutral zone, in which there is a little sensation left, is to be accounted for by the fact that the territories of two nerves overlap, and that when one is divided the other one carries on the work fairly well; and the queer displacement of the region without sensation is to be accounted for by the great individual variation of the distribution of nerves. There, gentlemen, is a practical point which has been cleared up to a certain extent by recent studies in Germany, but concerning which there is still a great deal to do; and there are many others. Allow me to allude to one or two in which our work here has not been without results. You see these lines. They are called sutures, by which these bones of the skull are bounded. In the infant the bones are distinct, then they gradually touch one another, points from one bone run in between the points of its fellow, and later bony growth goes across, so that they form really one piece of bone; and ultimately those lines are, or may be, entirely obliterated so as to leave no trace. This has been given as a guide to the age of the skull, and you can conceive that in medico-legal cases this is a matter of great importance. Let me read for you a few lines from the circular sent out by a very important bureau a while ago for the purpose of estimating the age of subjects on which certain anatomical observations were to be made when that age could not be otherwise ascertained, and the method given was that of the skull: "This (the condition of the sutures), it is claimed by anthropologists, affords the most reliable

guide to the determination of the age in such cases. If the sagittal or coronal suture shows bony union, the individual is said to be at or beyond middle life, or somewhere in the vicinity of forty-five years. If sagittal and coronal are joined, it indicates forty-five to fifty years. If sagittal, coronal and lambdoidal are synostosed, the age indicated is said to be from fifty-five to sixty-five; and if all the sutures are obliterated, the age is from sixty-five to eighty years." Well, during the past year or so, gentlemen, we have examined in the dissecting-room one hundred skulls, and all I can say is that there is not the shadow of foundation for these assertions.

Another instance is the breast-bone. It has been given by as great an authority as the celebrated Professor Hyrtl, of Vienna, that the relative length of the first and second pieces is a guide to the sex; that in man the second is more than twice as long as the first; in women it is not. I have examined over two hundred bodies, and, queerly enough, it appears that, although on the average, if you add up all the figures and take the average, the rule holds good, yet in forty per cent., or in two cases out of five, the rule is not true; and, therefore, in the case of deciding the sex of any individual, practically worthless.

Again, you will find in so valuable a work as Gray's Anatomy the statement of the time of union of the different pieces of the middle portion of the bone which originally were distinct. It is said to be completed at thirty-five to forty by the junction of its first piece with the next; and the one below that joined, if I remember rightly, at from twenty to twenty-five; and so on. That again we have investigated; and again we have found that these statements made long ago, I believe in France by Béclard, and copied without investigation from one book to another, are absolutely wrong. These are mentioned as instances of the important truth that even coarse anatomy has by no means been exhausted.

And now I would go on to point out some other aspects of anatomy which we are investigating here, and which not only are not exhausted, but have barely been touched.

I allude, in the first place, to the range of individual variation, from which very important consequences follow. One of the things now studied, and a question most worthy of study, is the effect of certain occupations, certain positions, especially in the young, on bodily growth, and what deformities they are likely to occasion; but before we can do justice to such a study, it is right that we should know what differences naturally occur between individuals on whom there is no reason to look for the action of any particular position. Now look, if you please, gentlemen, at this series of human shoulder-blades. See the difference in shape. If you will take a series from the large animals of the cat tribe (by which I mean lions, tigers, leopards, etc.), you will find decidedly less variation among the different shoulder-blades than you will see here in man. I cannot help thinking that the scientific Saturnian would have been tempted to allot to different species shoulder-blades as different as some of these.

Then, again, and closely connected with this question, is the other of the relation of parts of the skeleton to the figure. For instance, does a broad-shouldered man have a long shoulder-blade, or does he have a short and a broad one? What is the difference in make of shoulder-blade between square and drooping

shoulders? Those are points on which we as yet know absolutely nothing, points which we are beginning to study in a plodding way, for it takes a long time to get observations enough to settle such questions.

Then, as an example of that which has been pretty well made out, let me show you these thigh-bones and these shin-bones. This tibia is a very narrow one, of the kind which has been compared by French anatomists to a sabre blade, thin and sharp, found much oftener in prehistoric skeletons than nowadays, when it is found more generally in savage races. It has been shown that this narrow shin-bone is usually accompanied by what is known as the pilastered thigh-bone, one in which there is a good deal of curve and a strong, prominent ridge coming down the back. We have still to learn, however, what relation, if any, there is between the degree of hollowness in the back and the forward inclination of the neck of the femur.

Then, again, besides these questions of individual variation within normal bounds, there comes that of anomalies where there is some structure which, normal in animals, is not normal in man. Here, for instance, is the lower end of a humerus with the projection called the supracondyloid process, which in the fresh state was connected with this inner condyle by a ligament, so as to make an opening through which undoubtedly passed an artery and a nerve. That is the normal condition in many animals. Again, here on this thigh-bone is a well-marked, little rounded knob in a place where usually there is but a slight roughness. That is what is known as the third trochanter, and that corresponds to the prominence of that name which is found in the odd-toed ungulates, such as the horse, the rhinoceros.

It is too much the custom to try to account for anomalies by calling them reversions. Some are very hard to explain according to any system of descent. The whole question is one of great scientific interest. But the study of certain anomalies is of great practical importance. It is worth while for a surgeon to know that the irregular origin of a certain artery will bring it in the line of his knife, concealed till he cuts it in an important operation. It is well for him to know that the tendon of a certain muscle, but rarely developed, may go across a large artery at the place where he would be looking to tie it. Those are points which we are working up in the dissecting-room, and in which I hope to have your friendly assistance. It is a field in which the work of the student, as an adjunct to that of the teacher, is of the greatest importance.

Then, again, there are very interesting points in mechanics to be studied in the human body, more interesting still when we compare them with the arrangements in animals. It was our lamented Harvard anatomist, the late Prof. Jeffries Wyman, who called attention to the arrangement of the internal structure of bone to an architectural plan. This fact had indeed been partly seen before. It, however, has been since rediscovered, and his claims have been entirely ignored. He, however, pointed out the systems of "studs and braces," more recently called "struts and ties," in the internal structure of bone, a point on which I shall have more to say very soon, which today I only allude to. Here you have the human femur, the one to which he attached particular weight. Here we have the humerus and the femur, here is the anterior and the posterior extremity in chimpanzee, in gorilla, in lion. Here are heads of the humerus in

which you can see changed, but still there, the same general type of internal structure, with its peculiar mechanical advantages, in man, in the whale, in the dog and in the seal.

Now, gentlemen, I would not have you infer from this that it is at all my intention to lead you through the pleasing by-ways of abstract science. I entirely agree with Professor Huxley, who said in one of his addresses, that he considered that man guilty of a great offence who added one title to medical education that was unnecessary, that it was of less importance to know where quinine comes from, than where it is retailed cheapest. You may be sure that I am not going to lead you from more practical studies into the investigation of disputed points. These are questions which must not be allowed to turn us aside, in the regular course, from more elementary and technical work. Nevertheless, they may, perhaps I should say they must, be glanced at in passing; and they offer profitable and attractive lines of research for those to whom they are congenial, especially for those, if there be any such, as are following this course with a view to general culture rather than to practice.

And now, gentlemen, let me go on to the means of studying anatomy. Let me tell you what we have to offer, and give such advice as I may. In the first place, of course, there are the lectures. I have heard it asked what lectures are good for when the student can read it all in the book. With deference I would say, that good lectures are those which the student cannot read in the book, that it is particularly the duty of the teacher to point out those things which are of fundamental importance, to allude to and to pass more lightly over those of secondary. Moreover, by his experience he should be able to make clear points, which, however well described in the book, remain obscure; and finally, as much as possible, there should be absolute demonstrations of the points involved on the bones or on the subject, and in cases where these points are too minute to be seen at a distance, they should be made clear by means of models and diagrams. Our collection of models is one which we are very proud of, and as they are comparatively new—indeed, I have some to show you this year that never have yet been used—I venture to say just a word or two about them. Here we have the two top vertebrae of the spine. They are enlarged six times, if I remember rightly, and made with the greatest accuracy, from particular models, under my own eye. And we have others of all the great bones of the extremities and of the spine.

Then, besides the lectures, there are the recitations; and it is my object to divide the classes as much as I can on different occasions, up into small sections so that they may have the advantage in the recitations, which are always meant to be informal, of seeing things close to, of handling the specimens as much as possible, and of asking questions; and I should like to impress upon you very seriously the great value of recitations as making clear what any lecture may at times leave somewhat misty.

The system introduced by Dr. Holmes, but which now has attained to much greater development than in his time, is that of giving out bones. We have parts of the skeleton placed in boxes, which you are able to take out, to carry home to keep for a certain number of days, and then to return; and more than that you have an opportunity to take the same bones when you have time for an hour or so to study them in the build-

ing; in short, you may draw a bone very much as you would draw a book at the office of the circulating library. I need say nothing more of the importance of always studying bones and, as far as may be, everything else on the specimen itself.

Then, again, we have the dissecting-room in which, however, you will not begin your work quite as yet; and I say little of that lest I should take up your time in saying too much, because it is a matter of such vital importance for the learning of anatomy. There is only one thing I will say, and that is that the work should be done seriously and thoughtfully. It is not enough to uncover a part; if a man is too lazy afterwards to study what he has uncovered he may as well leave it undone. As one of our former demonstrators, Dr. R. M. Hodges, in his little book on "Practical Anatomy" says, "You should know what the books say, and cross-examine them in the presence of the subject."

There is, then, besides the course that I am giving to this class, the course which I give on Advanced Anatomy to the second-year students. That does not concern you, excepting that I have always thought it wise that a student should imbibe as much anatomy as he can; and though I would never have you neglect anything else for it, when you have a spare hour at the time of that lecture, I believe it may be very profitably employed there.

Then, again, there are the very excellent demonstrations of more or less Applied Anatomy given by Professor Richardson up-stairs. Those are open to the whole school. They are subject to examination to the second class, not to the first, but open to all; and for the same reason those should be very fully attended.

As for Histology I say little, but it is an important branch of anatomy. Prof. C. S. Minot will speak to you of that. I will only remind you that the lectures on histology form part of the subject-matter for the examination in anatomy at the end of the first year.

Another important method of study is the use of the museum. We have here collections of which we are very proud. In all respects they are by no means perfect, but in some they are very good. Our collection of bones in the museum is a very complete one, and we are beginning to place into series the bones illustrating the points that I have spoken of. This spine for instance, is a unique specimen, showing certain peculiarities which I will not now describe; it stands at the end of a line of some dozen others, all of which show less striking variations from the usual arrangement. We have a series of beautiful dissections of joints. There are many frozen sections, some mounted, some unmounted. We have a collection of corrosion preparations unrivaled by that of any school in this country, and which, I imagine, has few rivals in Europe, I certainly have seen none in England or France.

I regret that the museum has never been utilized as it should be as a place for study. It is a place where much may be learned.

—The *Medical Press*, July 30, 1890, complains that in England the announcement of a marriage or a birth is followed by confidential letters, offering, in exchange for the sum of one guinea, information bearing on the means of preventing any addition to the family circle.

CONSUMPTION IN MASSACHUSETTS.

BY J. M. FRENCH, M.D., MILFORD, MASS.

CONSUMPTION — like the poor, we have it always with us. From infancy to old age it claims its victims. From the tropics to the poles it carries off nearly one-sixth of the human race. No physician but has it to meet, and none but dreads it; no one but feels well-nigh helpless before it.

In the belief that any progress we may make towards conquering this dread scourge must come more from the study of the means of prevention than those of cure, I have been deeply interested in studying some of the antecedents of consumption, and especially the influence of environment upon its prevalence. In the studies, the results of which I present here, I have confined myself chiefly to Massachusetts, both because here it is that we have to deal with it, and because the necessary statistics were conveniently at hand.

These statistics have been obtained mainly, but not entirely, from the United States census returns and the Massachusetts Registration Reports. I am aware that they include various sources of inaccuracy, and, perhaps, even of fallacy. For example, we know that the record of the causes of death, as kept in many towns, is both incomplete and inaccurate; and that the term "consumption," as there used, undoubtedly includes, not only the different varieties of pulmonary phthisis proper, but also many cases of chronic bronchitis, chronic pneumonia, and other allied diseases. But making all allowances for these and other defects, I can only say of the statistics I have presented, that they are the best that I could obtain, and that I believe there is much to be learned from them.

First, then, as to the *mortality* from consumption in Massachusetts: For the period of forty-six years and eight months, ending December 31, 1887, consumption has been the cause of 209,056 deaths in our little Commonwealth, while only 75,189 deaths have resulted from pneumonia, 60,384 from old age, 55,394 from cholera infantum, 46,793 from typhoid fever, 46,699 from violence, and 46,201 from heart disease — nearly three times as many deaths from consumption as from any other single cause, and about one-sixth of the deaths from all causes.

During the five years, from 1883 to 1887 inclusive, 15.45% of the whole number of persons dying, or 3.03 out of every 1,000 persons living, have been carried off by this dread disease.

According to the census of 1880, the mortality from consumption throughout the whole United States was 12.05% of the entire mortality, or less than four-fifths as great as it was in Massachusetts alone during the years mentioned. In the other New England States, also, the proportion is less than in Massachusetts, though greater than in the United States as a whole. Thus, in New Hampshire, it was 13.57% of the entire mortality; in Vermont, 13.63%; in Rhode Island, 13.82%; and in Connecticut, 12.21%.

The questions arise, Why this excess in Massachusetts? What are the conditions specially favorable to the prevalence of phthisis in this State more than in her neighbors in the body politic? Why are there more deaths from this disease in one locality than in another? And these are questions of importance if we would hope to lessen this enormous death-rate.

We need to know the haunts and habits of our enemy, his strongholds and weak points, before we can hope to conquer or exterminate him.

Before seeking farther for the answers to these questions, let us consider three of the antecedents of phthisis, which are not, presumably, influenced to any great degree by locality; namely, *age, sex and season*.

The following table shows the number of persons, at the different ages mentioned, out of every 100 persons of all ages dying of consumption in Massachusetts for the twenty-five years from 1863 to 1887 inclusive:

Under 5 years of age	5.45
5 to 10 " "97
10 to 15 " "	1.83
15 to 20 " "	9.28
20 to 30 " "	28.72
30 to 40 " "	19.36
40 to 50 " "	12.56
50 to 60 " "	8.27
60 to 70 " "	7.35
70 to 80 " "	4.46
Over 80 " "59
Age not stated36
<hr/>	
	100.00

If, now, for the same period of twenty-five years, we divide the entire population into classes according to their ages, we find that out of every 1,000 persons living at each age there died from consumption as follows:

Under 5 years of age	17.55
5 to 10 " "	3.19
10 to 15 " "	6.34
15 to 20 " "	31.49
20 to 30 " "	49.36
30 to 40 " "	42.98
40 to 50 " "	36.36
50 to 60 " "	36.45
60 to 70 " "	48.63
70 to 80 " "	62.06
Over 80 " "	44.73

It is from tables, such as the first of these, that there has been derived the popular notion — which has, to some extent, obtained among the profession as well — that the liability to death from consumption is greatest between the ages of twenty and forty, and that after the latter age this liability is constantly decreasing. In point of fact, the table proves no such thing. What it does show is that the actual *number* of deaths is greatest at this period of life; but this may readily be accounted for by the fact that there are more persons living at this age than at any subsequent one, and hence more to die. That this is actually the proper explanation is shown by the second table, whereby we find that the *proportion* of deaths is nearly as great from sixty to seventy as from twenty to thirty, and actually greater from seventy to eighty than at any other period of life. It is very probable, however, that a larger proportion of the deaths attributed to consumption at the later periods of life are from the more chronic forms of the disease, including many cases of chronic bronchitis and chronic pneumonia, and which, at all events, are not dependent upon heredity for their origin.

Passing now to the consideration of *sex*, I find that from 1883 to 1887, inclusive, 29,452 persons died in Massachusetts of consumption, of whom 15,978 were females and 13,474 males — a proportion of about 119 females to every 100 males.

In forming conclusions from this table, it must be remembered that, at all those ages when consumption

is most fatal, the actual number of women living, at least in Massachusetts, is considerably in excess of the number of men. Furthermore, it is probable that the excess of deaths of females from consumption is due largely to confinement indoors, lack of proper exercise, breathing impure air, improper modes of dress, and contagion — from all of which causes women suffer more than men — rather than from the element of sex in itself considered. Give a woman a man's conditions, and there is little reason to suppose that she would suffer more than he from this disease.

As to *month and season*, during the five years aforesaid, the number of deaths from phthisis in the different months was as follows:

January, 2,490	First quarter, 7,745
February, 2,437	
March, 2,809	Second quarter, 7,178
April, 2,601	
May, 2,672	Third quarter, 7,148
June, 1,905	
July, 2,359	Fourth quarter, 7,271
August, 2,407	
September, 2,382	
October, 2,283	
November, 2,292	
December, 2,396	

This table shows that the greatest number of deaths in any one month, 2,809, occurred in March; and the least, 1,905, in June. The first quarter shows the most, 7,745; and the third the least, 7,148; but the difference is so slight, and the distribution throughout the year so uniform, as to make it evident that the season exercises but little controlling influence.

We come now to the consideration of the geographical distribution of the disease, and the study of those elements which determine this distribution — which show why it prevails more in one portion of the State than in another, and by inference, also, in any one locality more than another.

The Registration Report of Massachusetts for the year 1860, I think, contained a paper, prepared by George Derby, M.D., on "The Geographical Distribution of Consumption in Massachusetts." In this paper, the author gave a list of all the towns in the State, with the population of each in 1860, the number of deaths from all causes in ten years, the number of deaths from consumption in ten years, the percentage of deaths from consumption compared with the deaths from all causes, and the average number of persons living each year to one death from consumption. This is followed by a list of the towns having the greatest, and another of those having the least, comparative mortality from consumption. Concerning these last two groups, he says: "We have earnestly endeavored to discover in what respects each of the above groups of towns has common characteristics, and to find broad distinctions, separating one group from the other. That we have failed to satisfy our own mind is, perhaps, not surprising, since the solution of such a question requires an intimate knowledge of a multitude of facts which we do not possess. That causes are in existence for the results given above seems certain, and we commend the comparison of towns and districts to observers throughout the State, confident that what is now obscure will, at some future day which we hope and believe to be not far distant, be apparent to every one."

As I read this paper, it occurred to me that the results might be more satisfactory if we were to begin

at the other end of the problem, and try analysis rather than synthesis; if, instead of contrasting towns having a high mortality with those having a low one, with a view to determining the conditions which give rise to this difference in mortality, we were to compare places possessing certain well-marked and important characteristics and conditions with others possessing opposite conditions, in order to determine what is the effect of these factors upon the mortality.

Acting upon this idea, I proceeded to divide the State into five districts, or groups of towns, upon the basis of topographical features, chiefly *altitude* and *soil-moisture*; and secondarily, atmospheric moisture, prevailing winds, nearness to the ocean, etc. As I was not in possession of data which would enable me to make the distinctions any more exact, I was obliged to make my divisions along the broad lines of the counties. Acknowledging the imperfection and inexactness of these divisions, I shall claim the right to draw only the most broad and general conclusions from the results obtained; and even these results may be looked upon as suggestive rather than determinative.

Having found the proportionate mortality in each group as a whole, for the years 1883 to 1887 inclusive, my results were as follows:

GROUP I.—THE HIGHEST LAND (Berkshire County).

12.95% of the whole number of deaths.
2.17 per 1,000 persons living.

GROUP II.—THE CONNECTICUT VALLEY (Franklin, Hampden, and Hampshire Counties).

12.29% of the whole number of deaths.
2.56 per 1,000 persons living.

GROUP III.—HEART OF THE COMMONWEALTH (Worcester County).

11.86% of the whole number of deaths.
2.89 per 1,000 persons living.

GROUP IV.—THE ATLANTIC COAST (Essex, Middlesex, Norfolk, Suffolk, Plymouth, Bristol, and Barnstable Counties).

15.77% of the whole number of deaths.
3.12 per 1,000 persons living.

GROUP V.—THE ISLAND COUNTIES (Dukes and Nantucket Counties).

11.17% of the whole number of deaths.
2.91 per 1,000 persons living.

WHOLE STATE.

15.15% of the whole number of deaths.
3.03 per 1,000 persons living.

According to these figures, Berkshire County, which consists of the highest land in the State, has the lowest death-rate from consumption, both as compared with the total population, and also, with one exception, as compared with the total mortality.

Next in order, in both respects, stands the Connecticut Valley, with its lower land, but porous, sandy soil, sunny, and well-drained. Then comes Worcester County, midway between the Berkshire Hills and the sea. Highest of all stands the Atlantic Coast Region, with its lower lands, marshy soil, and moist sea breezes.

The island counties present at first sight a seeming exception, in that the proportion of deaths from consumption to the total number of deaths from all causes is only 11.17%, or the lowest of all. But when we turn to the more important comparison with the total population, we find that it is not that fewer people die of consumption, but rather that more die from other causes; for 2.91 deaths from phthisis occur to every 1,000 persons living, which is a larger proportion than in any other group, except the Atlantic Coast Region.

It is quite certain that a part of this difference in mortality from consumption in different parts of the

State is due to other causes than geographical conditions, some of which I shall shortly consider. Nevertheless, it seems to me that both the distinctions made and the results obtained are sufficiently well marked to justify the conclusion, that a moderately high altitude, with dry air and soil, tends to lessen the death-rate from consumption, while the opposite conditions tend to increase it.

The next point I have considered, and one which largely affects the distribution of the disease, is *density of population*. For this purpose, I made two series of calculations. For the first, I made use of the before-mentioned table of Dr. Derby, based upon the census of 1860. Here I again divided the State into five groups of towns, but this time on the basis of density of population. As I was unable to make allowance for the difference in area of the different towns and cities, but was obliged to consider each as a unit, and divide according to the total population, an element of inaccuracy is introduced, which, however, is so slight that I do not think it will in any way affect the general result.

In the first group I put Boston, the only city in the State having over 100,000 inhabitants. In the second group, all cities and towns of from 10,000 to 100,000; in the third, towns of from 5,000 to 10,000; in the fourth, those of from 1,000 to 5,000; and in the fifth, all towns having less than 1,000 inhabitants.

Comparing the yearly number of deaths from consumption in each group with the total population in 1860, the results are as follows:

Group I, 100,000 and over	1 in 229
Group II, 10,000 to 100,000	1 in 249
Group III, 5,000 to 10,000	1 in 295
Group IV, 1,000 to 5,000	1 in 306
Group V, under 1,000	1 in 345

This shows regularly decreasing mortality, corresponding to the decrease in density of population. Not content with this, I proceeded to make a second series of calculations, based upon the Massachusetts census of 1885, and using the same divisions, with the following results:

Group I	1 in 248
Group II	1 in 330
Group III	1 in 362
Group IV	1 in 385
Group V	1 in 427

These results confirm the first, showing absolute conformity to the same general principle. I, therefore, assume the law to be proven, so far as statistics from one State can prove it, that the mortality from consumption increases as the density of population increases.

These two series of calculations, taken together, show one other notable and encouraging result, namely this, that the mortality from consumption in Massachusetts is slowly but steadily decreasing. According to the census of 1860, the average annual mortality throughout the State was 1 in 270 persons living; while, according to the census of 1885, it was only 1 in 326, a most encouraging decrease. Further statistics, taken from Massachusetts Registration Reports, show that the mortality at different periods was as follows:

1853	1 in 234
1854 to 1863	1 in 237
1866 to 1870	1 in 299
1871 to 1875	1 in 304

1876 to 1880	1 in 208
1881 to 1885	1 in 320
1887	1 in 331

These results bear out those before obtained, and encourage us to hope for a still further improvement. They also call our attention to the causes of this improvement, which are well worthy of the attention I cannot give them at present.

To the considerations already advanced as affecting the geographical distribution of consumption, should be added a study of the effects of *occupation* and *nationality* upon the mortality from the disease. But upon these points I have not been able to find any Massachusetts statistics worthy of presenting. I, therefore, merely call attention to them as worthy of further investigation. When the facts are all in, we may hope for definite and uniform conclusions.

INFLUENZA IN THE OUT-PATIENT SERVICE OF THE BOSTON CITY HOSPITAL.¹

BY E. M. BUCKINGHAM, M.D.,
Physician to Out-Patients.

HAVING been upon service in the Out-Patient room during the late epidemic of influenza, it appears proper that I should report the cases seen there, in order to complete the history of the epidemic in the hospital, which has already been made for the wards by Dr. Mason.² In so doing I shall make use of my private cases when convenient, although the two sets of cases ought probably not to be grouped together; since the ordinary run of patients were probably sicker than those coming to the out-patient room. It is true, however, that many of these last had been quite sick, and applied for help only when capable of going out; but before they had forgotten the history of the previous days.

There were in all seventy-four cases of influenza, not including sequelæ; and of these there are very complete records of forty-eight, for which credit is due to the then externes, Drs. Whittemore and Haskell up to January 7th, and Drs. Dwight and Fuller for the later histories. None are recorded as presenting themselves before the fourth day, and in general they ranged from four days to two weeks, when first seen; while many of them did not make a second visit; thus agreeing with the common observations as to the duration of the disease, and as to its greatest severity being during the first few days. There was one case at sixteen days; there were three cases at three weeks, in one of which three, cough, and in another pain, were the only remaining symptoms; and there was one case of insomnia and anorexia at five weeks. Up to the present time, cases not of influenza, but which began as influenza, still show themselves, the patients complaining, for the most part, merely of debility.

It is of great interest with reference to the question, whether the disease is contagious or not, to note the dates of the early cases. I have been told of cases in November. My own first case sent for me on the third of December, having had some soreness since November 29th. My next case dates from December 17th. Dr. Mason states that the first admissions to this hospital were December 10th. Dr. F. C. Shattuck³ saw

his first case on the same day. None are recorded in the out-patient room before December 24th, when there were five cases, one dating from the 16th. It was between December 20th and December 23d, that the number of admissions to the wards rose rapidly, as shown by Dr. Mason. The admissions to the out-patient service, which is open three days in the week, were as follows:

December 24	5 cases.	January 7	6 cases.
December 26	6 "	January 9	5 "
December 28	9 "	January 11	4 "
December 31	8 "	January 14	6 "
January 2	11 "	January 17	1 case.
January 4	12 "		

Many of the later cases were somewhat old; and there were three more cases, one of them being a relapse, and all dating back previous to January 17th. There is nothing in all this comparable to the undoubtedly correct stories of whole ships' companies being attacked on the same day in previous epidemics, a difference which, supposing the disease to be contagious, can be readily understood by any one who has seen the quarters of sailors on men-of-war, and thinks what they must have been without ventilation.

Symptoms. Of the various symptoms, not all of which were present in all cases, nor always at the same time, headache was, perhaps, the most constant and most persisting, existing more or less in almost every case, and being sometimes of great severity. Pain in the back was quite constant, and ranked next in order. Pain in the chest was common, and I think that no part was exempt. I have several notes of a general bruised feeling. Pain was generally an early symptom. It by no means always disappeared with the beginning of convalescence, and it sometimes remained after all other symptoms had gone. Headache may have been sometimes due to coryza, but was occasionally severe without it. Sore throat was far from being as universal as pain in the back and head. At times the tonsils, and at times the pharynx, were inflamed, sometimes severely, sometimes slightly; but it appeared to me that the complaint of sore throat was not infrequently greater than was warranted by the appearance of the parts, and that in some cases it was a part of the general neuralgia quite as much as of an acute inflammation.

There was no complaint of earache in a single case; but this was certainly due to its being a prominent symptom, when it existed at all, thus leading patients to seek the ear clinic. One baby I sent there for examination. Among the forty-nine private cases of influenza that I saw, were two cases of earache, one trifling and temporary, and one dependent on inflammation of the middle ear. There were also two cases of deafness from this cause in patients neither of whom had been sick enough to seek advice, but each of whom had much coryza. They got well slowly, and were advised to seek special advice.

Coryza was very general, but not universal. Dr. De Blois was kind enough to examine one of these patients without nasal discharge, by means of the rhinoscope. He reported very acute congestion. Unfortunately this case did not reappear. It may have developed a discharge later. Epistaxis was present in one case only among the seventy-four, and there was one case of bloody mucous discharge from the nose; the patient had laryngitis, as shown by the voice.

¹ Read at the Boston Society for Medical Observation, May 5, 1890.

² Boston Medical and Surgical Journal, February 13, 1890, p. 145.

³ Boston Medical and Surgical Journal, February 13, 1890, p. 148.

Cough was complained of by about half the patients. Sometimes it was mild, and sometimes very severe, the signs in the chest being also of varying character—from very slight to loud, whistling rales. I cannot, however, recall or find a record of more than one adult whose cough was severe without having something in the chest to more or less explain it. At the same time there may have been such; and possibly the cough may have been out of proportion to the signs in some cases. Certainly the disparity between signs and symptoms did not strike me as in the case of sore throat. Some patients had the expectoration of bronchitis, and others but very little. Cough was quite often a later symptom. It may have depended in part, and probably did in certain cases, upon the condition of the naso-pharynx—such cases, for instance, as the one examined for me by Dr. De Blois, and reported to be intensely congested. At the same time many patients coughed more by night than by day, pointing, perhaps, toward the nervous element in the disease. So far I have confined myself to adults. Among children, but most of the children that I saw were not at the hospital, there were cases of considerable cough, but with absolutely no signs in the chest. I should suppose that here the cough was largely of nervous origin, as has been suggested by Dr. Rotch.⁴

Chill was recorded in a little over a fifth of the cases, and probably existed in others, and was sometimes severe. At times it was the first symptom, but it has begun as late as the fourth day in cases that did not have pneumonia.

Vomiting was recorded once only, and nausea a few times. It did not appear to be worth while to record either in out-patients, except when they were initial symptoms, as they might easily have been due to indiscretion. Both undoubtedly existed in others as purely nervous symptoms. I saw a number of such cases in private.

Delirium was, I think, a not uncommon symptom, especially at night and in children; yet there were not many records of it in this service, probably because it had not been observed by the patient himself, and there was no one to tell his story.

Like other symptoms it sometimes was early and sometimes late; sometimes it was very early. A police-officer told me that he went upon his beat well and hardly knew enough to get home when relieved. Dizziness occurred in a number of cases. A few of my private patients complained of being very faint, but none at the hospital. Anorexia was universal, and insomnia seems to have been so in the last of the epidemic. The record does not so state during the early part. I had not observed this distinction until working up this paper; and I do not understand it, for my private case books show no such difference as to time.

I saw one case of bronchial asthma in a man who had had it before, and in whom it survived the rest of the attack, and one other case of severe dyspnea, apparently of nervous origin.

Prostration was extremely common; perhaps some debility was universal, and it was at times severe. Cases of feeble and intermitting pulse from shock did not come to the out-patient room for obvious reasons, but I have met them outside. One patient whom I saw at his house, fell to the floor from weakness on stepping out of bed in the morning, and yet recovered

enough to go to New York on business at the end of a week. In many cases prostration, however, lasted a long time.

There were a few cases of diarrhoea and two of bloody dejections; one of them probably lost blood from haemorrhoids, but the other had a bloody mucous in the dejection, and probably came from an intestinal catarrh.

Although not a hospital case, I want to refer to a man with vomiting, abdominal pain and tenderness, who made me think of peritonitis, but who had, I think, influenza and nothing else. Recovery was complete in two weeks.

Two of the seventy-four cases had pleurisy, one early in the epidemic: the other has an effusion, and has never been well; although not under observation since his attack of influenza at Christmas, until a few days ago.

Out of the one hundred and twenty-three cases from all sources that came under my observation, four had an eruption, one came and went between two visits so that I did not see it. This patient was taking quinine. The other had an eruption of red papules, with abundant marks of scratching on the breast, and it was said elsewhere. This lady had been sweating freely, and I thought it was a papular eczema from that cause. She was also taking quinine. Yet another woman had an eruption that might have been measles. I only saw her once. She had had no treatment whatever. One man, who had had measles as a child, had influenza two weeks, so he said, and then having nearly recovered, had a severe chill, with prostration, so that he staggered in the street, and an outbreak which was very faint but which resembled measles and had its course, except that there is a doubt as to whether it began on the face or arms. He returned to show that he was getting well, and proved to be desquamating. This looks like a complication of measles and influenza.

The highest temperature was 104° in a baby, increasing to 105° in a week; then the case was sent to the ear-room for examination, and unfortunately I have not its later history. As a rule, temperatures in these out-patients were much lower when I saw them, although many remained slightly elevated for two weeks or possibly more. In general, I think that the severity of the cases is often much greater than is indicated by the thermometer.

Children.—During the whole epidemic, few children were presented for examination; and the Out-Patient Department of the Children's Hospital had a rather light service at this time. This may have been in part due to sickness on the part of parents, but I think not wholly so. The essential difference, so far as there is one, between influenza in children and adults, so far as my own observation went, is that the nervous disturbance is greater in children, although they are not free from catarrhal symptoms.

During the whole epidemic there was an increased number of patients applying for the first time to this department; yet had the influenza cases been eliminated, the number would have been smaller than in the corresponding time a year earlier.

A large number of non-influenza patients had bronchitis. Several cases of chronic bronchitis applied, who were coughing more than usual, but who could not be said to have influenza. Of course, many of them were not seen again, and some of them may have

* Boston Medical and Surgical Journal, February, 1890, p. 156.

been in the initial stage of influenza. Some of the bronchitis starting with this disease was quite persistent.

Pneumonia does not come within the scope of this paper.

Cases with debility and nothing else, continue to present themselves.

The relation of this disease to phthisis is quite interesting. A number of patients with consolidation and symptoms, which symptoms began with influenza, have presented themselves since the epidemic. Whether the bacilli found a prostrated patient, or, on the other hand, a phthisical patient had little power of recuperation, or whether again there is a yet closer connection, does not appear. During the epidemic a few patients applied with influenza and phthisis together, but who had not previously known that they were sick. They were much prostrated. The records are remarkably silent as to the old phthisis patients of the hospital as affected by the epidemic. Possibly some of them are dead, or are now too sick to continue to be out-patients. In this connection I am tempted to add the history of the four phthisical patients of mine outside the hospital, who suffered from the epidemic. One I have not seen since. One, a young man with a small consolidation at the right apex, but no active symptoms for three years, had influenza severely. During the height of it, he had a very few rales only in the old place, together with severe pain in that side. He got over his rales, and assured me last week that he is as well as ever. One gentleman of fifty, with trouble in each lung slowly progressing for I think seven years, had influenza severely, and shortly after had a hemorrhage. He made a slow recovery, and seems about as usual. One girl of twenty, with advanced disease but earning her living, was in bed for weeks, and can now just crawl about.

The only other complication except measles, which I have already spoken of, is cystitis. A patient who had recovered from this had a return coincident with influenza, and began to recover again as that passed off.

There were three relapses with a week of health between. I have seen a larger number outside the hospital, and feel quite sure that there is a greater danger of relapse in those who are imprudent during convalescence. I have seen nothing of the three and four returns which are said to occur. It is well known that the epidemic had a somewhat sudden end, as is usually the case; and as is also usual, there are said to be occasional cases after it. Of this there seems to be no doubt. I myself have not seen them unless I had a case in my own person so late as April 19th. That attack I certainly should have called influenza had it been earlier.

Treatment.—I have given much quinine, and am entirely uncertain whether it controls pain or not. I have thought that it might help support a much prostrated patient, but have in those cases generally given alcohol as well. It certainly seems to be of service during the weakness of convalescence. Salicylate of sodium, which I stumbled upon through mistaking an early case for rheumatism, has, I believe, a good effect upon the pain. Antifebrin was only used in a few of the later cases. It seems to be of some use in controlling pain. The earlier headache, and, perhaps, the earlier sleeplessness, seem to be helped by bromide of potassium. I think that Dover's powder is useful, not only in relieving pain, but in relieving cough. Sul-

phonial seems to secure sleep to some patients who would not otherwise have had it. A few patients had taken more or less active cathartics before coming under my observation. The late Dr. Austin Flint was of opinion that in young and strong patients a "brisk purge seems to be useful." I have, therefore, given a purge, not particularly brisk, to a few patients with stuffed heads, and at the beginning of the disease. I must add that it sometimes seems to be useful, but not always; nor is the good effect always permanent, while it is not a treatment that I have cared to repeat in so debilitating a disease.

LATERAL DEVIATION OF THE SPINE AS A DIAGNOSTIC SYMPTOM IN POTT'S DISEASE.¹

BY ROBERT W. LOVETT, M.D., BOSTON.

LATERAL deviation of the spinal column as a symptom of Pott's disease, up to the present time, has been allowed very little significance or importance. Rarely spoken of at all, when it has forced itself upon the attention it has been considered as an occasional symptom of no especial significance, occurring rather uncommonly, and probably due to the wearing away of the vertebral bodies more on one side than on the other. The only article which deals with the subject at all as its importance warrants is the one by Dr. Bartow, in the *Annals of Surgery* for July, 1889, to whom I am indebted for most of my ideas in the matter. He called attention to the existence of lateral deviation of the spine in most cases of dorsal and lumbar Pott's disease, insisting particularly upon the presence of rotation of the spine. And he made the characteristics of the deformity very plain by a series of admirable illustrations.

In the last nine months I have examined with regard to the existence of lateral deviation nearly every case of Pott's disease that I have seen, and I have been able to secure detailed and accurate measurements of some thirty cases. It is the results of these observations that I shall have the pleasure of briefly presenting to you.

The striking fact that at once presented itself in the observation of these cases was that lateral deviation of the spine was amazingly common. In fact it seemed, in all stages of the disease, to be almost universal in some degree. The notable exception being cases that were progressing particularly well under conservative treatment, and certain cured cases where evidences of active disease had ceased. But in the cases taken as they came first to the clinic, before treatment was begun, the presence of lateral deviation was universal.

Cases of cervical disease showed the least characteristic deformity; although inasmuch as the head was generally held obliquely to one side or the other, a certain compensatory twisting of the trunk was necessitated, but it lacked the characteristic features of the deviation when the disease was lower down in the spinal column.

I am aware that in asserting that a perceptible degree of lateral deviation of the spine is a uniform symptom of early dorsal and lumbar Pott's disease, I run the risk of awakening scepticism, and I can only ask that you will carefully examine cases with this in

¹ Read before the American Orthopedic Association at Philadelphia, September 18, 1890.

view. The kyphosis, the antero-posterior curvature, is so much the more important matter that attention is apt to be directed solely to that, and lateral deviation naturally enough escapes attention, except when it is so severe that it becomes difficult to fit a brace or the attitude is notably unsymmetrical.

But if the child be stripped and inspected from in front, when standing as squarely as he can hold himself, it will be found that a perceptible degree of deviation of the spinal column is present. On account of the sharper and more definite outline which the front aspect of the body presents, any deviation is much more noticeable to an observer standing in front of the child than when behind him. So that when from behind it seems scarcely noticeable, from in front it becomes a marked deviation of the whole trunk.

The characteristics of the deviation are not like those of rotary lateral curvature. The whole aspect of the trunk is different, it has not so much the look of sinuous distortion as of a distinct leaning of the body to one side or the other. Rotation is not a prominent factor.

In the larger number of cases, for some reason or other, the inclination of the trunk is to the right rather than to the left, although not overwhelmingly so. Possibly it may be associated with the more constant use of the right arm.

This lateral deviation would seem to be one of the earliest symptoms of Pott's disease. In two or three of the cases observed it was distinctly recognizable when the other symptoms were slight and ill marked, and was associated with a very slight degree of muscular rigidity, which alone would have been altogether insufficient to establish the diagnosis of Pott's disease.

By the kindness of some of my assistants at the Children's Hospital, particularly Dr. Goldthwaite and Mr. Lund, I have been able to measure accurately some thirty cases of Pott's disease, which were taken consecutively as they came to the out-patient clinic, and were not selected for the existence of lateral deviation, or for any other reason. They represent unselected cases, mild and severe, at all stages of the disease.

The apparatus by which the measurements were taken was a very simple one, consisting of an elastic steel pelvic band which was buckled about the pelvis at the level of the anterior superior spines, and to the middle of this at the back just over the sacrum, was attached by a pivot a movable steel upright which could be placed in the line of the deviated column, and its divergence from the perpendicular noted on a graduated arc attached to the pelvic band. Rotation of the spinal column was measured by a horizontal arm revolving on this upright, the two ends of which were placed against the ribs, and the deviation of the plane of the chest from that of the pelvis read on another graduated arc.

In all of these thirty cases, with one exception, the deviation was enough to be easily measured by the instrument, reading in degrees. In the one case mentioned, although asymmetry was perceptible, it was so slight that the instrument did not record it. In no case was a lateral deviation of more than eight degrees from the perpendicular found, and that was so much of a distortion that it seemed as if the children would lose their balance and topple over sideways in walking. In only four cases of the thirty was there as much divergence as eight degrees, and even this must

be an accidentally large proportion of such severe instances of the deviation.

A divergence of five or six degrees was decidedly noticeable, so much so that it gave decided difficulty in fitting braces on account of the inequality of the two sides when the child stood up. Cases which were progressing well showed only a divergence of two or three degrees, which would not be noticed except on careful inspection, but which is enough to be distinctly perceptible when the child is regarded from in front without his apparatus.

Of course, it is purely arbitrary to speak of the matter in degrees as measured by this instrument; but it serves as some sort of a standard in the comparison of cases, and it afforded the means of keeping record of the progress of individual cases.

A particular interest attached to the question of rotation in connection with the lateral deviation. It was easily measured by the horizontal arm of the apparatus; but it proved to be a variable and uncertain affair, following no especial rule, but present to some degree in the majority of cases of Pott's disease in connection with the lateral deviation. It was never very marked, not being in any way comparable to the rotation of true scoliosis; and in no case had the column rotated through an arc of more than seven or eight degrees. This was, however, enough to be distinctly noticeable.

The most interesting fact about the rotation was the fact that it did not follow the same rule as in scoliosis, that is, rotating backward on the side of the convexity of the curve. More often than not it did follow this rule, but in at least a third of the cases measured it rotated in the other direction. One would expect to find in a large dorsal curve to the right that the right side of the chest had rotated backward, but in these Pott's disease cases it was just as likely to have rotated forward without disturbing the symmetry of the lateral curve.

As a check to the observations made on lateral deviation as occurring in Pott's disease (to anticipate the possible criticism that a common asymmetry of the growing body had been mistaken for a pathological condition), I was enabled to have measured in this regard one hundred healthy boys from one of the city institutions, by the kindness of the Post Physician, Dr. Coggeswell. These boys were all stripped, and carefully measured by Mr. Lund, who had taken most of the pathological measurements under my supervision. The same apparatus was used as that which was employed in the pathological measurements.

These boys were from nine to fifteen years old and may be taken as representatives of healthy, well-developed boys in general. Sixty-two were perfectly symmetrical, two had short legs from injury, and were not counted. Thirty-six showed slight but perceptible asymmetry, in only three cases reaching as much as four degrees; most of them showed only one or two degrees of lateral deviation, which would not be noticeable when they were dressed, and even when they were stripped would escape any but the closest inspection. An interesting point, however, in this connection was that slight rotation was a constant accompaniment of the lateral deviation, and followed the same rule as in scoliosis, cases with a right dorsal curvature showing a backward rotation of the right side of the chest.

To return once more to the lateral deviation in Pott's disease. The symptom is much more noticeable

ble in the standing than in the lying position, in which it becomes very much diminished or disappears only to reappear again when the patient stands on his feet. It is this variation in the deformity which makes it so difficult to apply a brace to a child who has this lateral deviation severely. The brace may fit perfectly when the child lies on his face, but in the standing position it may be thrown so markedly to one side that it fails to afford the proper support.

Although in certain cases, especially the late ones, the distortion is undoubtedly due to the unilateral destruction of bone, it is in general a symptom of muscular irritability. Often associated with a severe degree of pain, it is to be regarded as analogous to the distortion of other diseased joints. Just as in hip-disease, for some unknown reason, the irritation of the diseased joint-surfaces produces a reflex muscular spasm of the muscles controlling the joint, and the leg is stiffly held in a position of adduction. So in Pott's disease undue irritation of the inflamed intervertebral articulations causes rigidity of the columns and lateral distortion.

That it is a phenomenon of this sort in most cases is shown by the fact that it tends to disappear in the recumbent position, that it increases progressively if the children go about without proper support, and that it improves so rapidly under suitable treatment that the idea of a structural cause for it is not tenable in most cases.

Two cases which I have recently had the opportunity of observing very closely will serve to show how rapid is the disappearance of the deformity under favoring conditions.

A girl of ten appeared at the Children's Hospital with a lateral deviation of eight degrees occurring in dorsal Pott's disease, being an exceptionally severe case. She was put to bed with weight and pulley extension to the spine, and weekly measurements were taken in the standing position. The deformity diminished progressively from the first, and in five weeks has been reduced from eight to two degrees, which is an amount scarcely perceptible.

A boy of five seen at the same time, with an equal amount of deformity, was treated in the same way at the Samaritan Hospital, and after five weeks of recumbency and extension showed a reduction of the deformity from eight to three degrees.

These cases were treated so long by recumbency, not because it was entirely necessary, but in order to note the rapidity of improvement under the most favorable conditions.

It thus would seem proper in most cases to class the deformity as an irritative muscular symptom rather than as a unilateral loss of bone, and to treat it in the same manner that one treats the malpositions of other irritated joints. The rapidity with which it responds to the sedative measures of fixation and perhaps traction applied to the seat of the disease is the strongest advocate for this sort of treatment.

Treatment by recumbency and extension to the spine (applied by means of weight and pulley extension to both legs, and a Sayre's head sling pulling also by a weight and pulley from the head of the bed) is undoubtedly the quickest and most efficient method of reducing the local irritation, and with it the deformity; but it is a method which is not always available or acceptable, and the deformity is not one which requires such radical and immediate measures as im-

pending paralysis or threatened abscess. So that although the deformity may be most quickly reduced in that way, efficient treatment by braces or jackets will in most cases suffice to accomplish the same end more slowly. In all the cases observed no class showed so little lateral deviation of the spine as those cases which were progressing favorably under treatment by the Taylor back brace.

The objection to the treatment of these cases by a brace has been already stated in the difficulty of accurate adjustment. In even the worst cases, however, by special pains the brace can generally be made to afford efficient support if the two uprights be bent to fit the different curves of the two sides of the back.

The plaster jacket affords a still readier means of correcting the deformity. Suspension diminishes or effaces the lateral deviation so that by the application of a series of accurately fitting jackets a comparatively normal position is restored to the spine.

The method of Dr. Bartow is more rapid and equally efficient, who shapes a leather jacket to a corrected cast of the deviated trunk, and applies a comparatively straight jacket to the distorted column.

From the efficiency of these methods it must be evident that treatment need not necessarily be addressed to the lateral deformity as such. Any measure which modifies the pressure of the diseased vertebrae and fixes the spinal column tends to quiet the local irritation, and acts as a corrective measure to the disease and all its symptoms, including the lateral deviation. In a word, the treatment of Pott's disease is the treatment of the lateral deformity. In the severest cases, however, the importance of recumbency and extension cannot be overestimated.

In attempting in some way to sum up what I have tried to call to your attention, it is first necessary to insist upon lateral curvature of the spine as an exceedingly common, if not a uniform symptom of Pott's disease in the lumbar and dorsal region. This deviation is generally accompanied by a certain amount of rotation, which does not follow the same rule as in scoliosis.

The lateral deviation is for the most part a symptom of muscular irritation reflex to joint inflammation, and belongs to the same class as the malpositions of other diseased joints. It yields readily to treatment, and is most rapidly reduced by rest in bed and spinal extension, although the ordinary treatment of Pott's disease is generally sufficient to overcome the lateral deformity if efficiently carried out.

Finally, I would call your attention to the importance of extending and verifying these observations, in the hope of adding in lateral deviation, a new and simple diagnostic symptom by which the early detection of Pott's disease may be rendered less difficult.

— Considerable agitation having been caused by the refusal of a Doctor Saalfeldt, in Chicago, to sign a death certificate of a child dead of diphtheria until the father (poor man who had just lost three other children from the same disease) should have paid the doctor's bill, it now appears that the "doctor" was not registered, and had no right to practise at all. The registrar of vital statistics, by the way, sent an order to Saalfeldt to make the certificate, which he refused again to do. A warrant was therefore issued for his arrest. Thereupon he signed the required certificate.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

T. F. SHERMAN, M.D., SECRETARY.

REGULAR Meeting, Monday, May 5, 1890, DR. BOLLES in the chair.

DR. E. M. BUCKINGHAM read a paper on INFLUENZA IN THE OUT-PATIENT SERVICE OF THE BOSTON CITY HOSPITAL.¹

DR. MCCOLLUM: I have been very much interested in Dr. Buckingham's paper. His experience agrees with mine. At the jail there were about 150 cases during the epidemic. The suddenness of the onset was a matter of surprise to me. One day on making my visit I found five or six cases; the following day perhaps twenty-five cases, and for the next ten days I saw twenty-five or thirty patients a day. There was no attack of pneumonia following the influenza, which was different from my experience elsewhere. The moment a man was sick he was not exposed to the weather in any way, and that I think had a great influence upon the course of the disease. In most of the cases to which I was called, there was marked prostration at the beginning of the disease in those who were robust and strong. Trouble with the ear followed in two or three cases, in one case there was disease of the middle ear. This case recovered, however, after a while. In the 150 cases I noticed an eruption in perhaps twenty-five, and in many instances where there was absolutely no eruption, there was a great deal of itching, and in these cases not dependent upon quinine because in many of the cases the men complained of the itching or eruption before they had taken quinine; so that I think the eruption was much more common in this epidemic than was generally supposed. The cause of it I suppose was some disturbance of the nervous system. One remark of Dr. Buckingham's impressed me particularly as to the effect of the disease upon phthisical patients. A large number of such patients who might have lived four or six months were carried off by the influenza. During the epidemic I saw perhaps twenty-five to thirty consumptive patients who were stricken down with the influenza, and died apparently from prostration, not from pneumonia or any extension of the disease itself. They were debilitated by phthisis, and unable to bear up under the two diseases.

DR. BOLLES: I would like to ask Dr. Wadsworth whether he noticed any eye symptoms accompanying the disease.

DR. WADSWORTH: Not an inconsiderable number of patients complained of infra- and supra-orbital pain, but there seemed to be no especial affection of the eyes in the cases I saw. A certain number of cases had conjunctivitis in connection with the influenza, as is to be expected with any disease that affects the mucous membrane of the respiratory tract.

DR. IRWIN: There are two points in connection with this subject which seem to me of very great interest: one of them is the possibility of this epidemic being contagious, and the other its resemblance to dengue fever. I happened to be in Charleston in 1879 when there was an epidemic of dengue fever, there being 5,000 to 6,000 cases in the city at one

¹ See page 343 of the journal.

time. To me the two diseases seem strikingly alike. The eruption was so far as I saw it exactly the same, somewhat like measles and characterized by great itching, and relieved frequently by the use of ointments. In regard to the contagious character there was one circumstance which I noticed at the Marine Hospital. In the surgical ward of about twenty patients, the disease passed from bed to bed quite as regularly as I have ever seen in cases of erysipelas. First one patient had it, and in forty-eight hours the next, etc., until every patient in the ward had it. In regard to its effect on patients with phthisis: I saw about twenty cases of phthisis with influenza, and I failed to see that it modified the disease in any form. They passed through the influenza and got well of it, and went on with the phthisis as usual. I think this was probably due to the fact that they were not exposed at all, but were kept in their wards.

DR. BLODGETT: I am especially grateful to Dr. Buckingham for rounding out the history of this epidemic in the City Hospital. The report by Dr. Mason, which was rendered before the Clinical Section of the Suffolk District Society, embraced everything, I think, within the hospital; and I am extremely obliged to Dr. Buckingham for the completion of the report of that institution which, I think, will now stand as comparatively full in this respect.

I have been quite struck by several cases in which I think there was no doubt of the recurrence of the disease after it had gone a long distance on its way to recovery from the primary infection. One case of that kind has been particularly interesting to me. A lady first took the disease in the latter part of December, and did not recognize its nature until ill some days. She remained in her room three weeks before she ventured to go out at all. She was prostrated by another attack through which she carried herself by domestic remedies. A third attack followed in about two weeks accompanied by great swelling of the right side of the face involving all the glands from the ear to the middle of the space beneath the chin, requiring opening in several places. At length a large abscess formed beneath the chin which required lancing. The lady made a recovery after this attack, and I think has been well since.

The absence of any mention of two, at least, of the more commonly prescribed remedies in this affection struck me quite forcibly; for almost every one who has spoken of the disease has had more or less to say of phenacetine or substances of that character. I found it necessary to use opium in some cases for the extreme pain and headache not relieved by the common remedies. In one or two cases insomnia would yield to nothing else, and I was obliged to resort to it, and I was also obliged to use it in a number of cases in which the influenza was followed by symptoms not mentioned here. In one of these cases there was a swelling in the region of the left ovary, apparently an ovaritis. There was an eruption upon the chest but not upon the abdomen. The nurse was quite sure it was a case of typhoid fever which had given no other evidences of that disease, excepting profuse diarrhoea for a number of days, which I think was an accidental affair. Following the painful affection of the abdomen was a milk leg which ran its course, and she has at present recovered from all the complications. This case also presented a very high pulse — 140 sometimes with a distinct mitral regurgitant mur-

mur during the height of the disease, which subsided as soon as convalescence took place. It may have been a pure haemic murmur, but at the time I was inclined to suppose that it had its origin in some organic defect, but the fact that it has very nearly disappeared, leads me to think I was mistaken.

DR. AYER said: Dr. Blodgett has just spoken of the use of morphine in the last epidemic. I relied upon it more than all the antipyretics put together. I felt that I knew how morphine would act. I did not give antipyrine or phenacetin a full trial as most of the gentlemen have done.

DR. O. F. WADSWORTH read a paper on

THE INSUFFICIENCY OF THE OCULAR MUSCLES.²

DR. H. W. WILLIAMS: I quite agree with Dr. Wadsworth that the time has not yet arrived when we can acknowledge the exaggerated claims that have been put forward with reference to this subject, the ultimate results cannot be judged of in so short a time as has yet elapsed. Unquestionably there must be something of good in efforts which are made so zealously and on so large a scale as this experiment has been tried, but I very much doubt if we shall realize all the benefits claimed for this procedure.

The subject of asthenopia has been an interesting one. Before we had our knowledge of the way in which the eye-mechanism was carried on; before we had the discoveries of Donders, which came to us like a gospel, and which have never been improved upon to any great extent since he first announced them; before that time and since, the whole subject has been extremely interesting. When Donders announced the mechanism of accommodation, much was added to our knowledge of the conditions under which vision was carried on. We understood refraction infinitely better after what he gave us in regard to the frequency of astigmatism, for instance; and at the same time accommodative action being explained, we had an explanation of the pains complained of in and around the eye after various kinds of use. We found that vast numbers of these were relieved by the correction of these errors of refraction; and there is no reason why we should not find a great amount of relief also from the correction of the accommodative mechanism which we have been dealing with in the same way, correcting by various means and with inestimable advantage. But I think that because some persons who have chorea, hysteria or epilepsy, have asthenopia, that the general disease depends on this condition of the eye, is altogether too much for us to accept. The author of these theories seems to forget that these things may be coexistent, that the state of the nervous system may affect the ability to use the eye, as we found before we had this knowledge of which I have spoken. Before that time we recognized that in persons of nervous temperament, whose nervous energy was exhausted from one cause or another, there would be temporary and permanent difficulties in using the eyes for ordinary purposes; those we have learned sometime ago to correct by tonics, as was described at one of the early meetings of the American Ophthalmological Society. The cases were not all cases where refraction and accommodation were disturbed as a permanent condition, but a temporary condition where accommodation and refraction could not be carried on very well because the nervous tone was low.

² Publication deferred.

As observers have compared their ideas, there has been a wonderful advance, as we all know, within the last generation. Our former knowledge of ophthalmology would be considered as very slight compared to what we have at present. There has been so great an advance, through the aid of the ophthalmoscope on the one hand and through those researches so carefully made by Donders and others on the other hand, that we have at command means we had not before; and we find many of these conditions are temporary — many of these slight degrees of aberration from the absolutely accurate standard in regard to astigmatism and in regard to insufficiencies of the muscles — and that some of these conditions may be neutralized by the eyes. An ophthalmologist at the last meeting of the Heidelberg Society, and also others in other places have presented very accurate papers showing that the eye is capable of neutralizing certain degrees of incapability. If we make careful examination, we can detect this disability; but the eye itself can overcome that in a state of health. When the health is depressed from one reason or another, especially from disturbances of nerve action, there will be a greater difficulty in performing these delicate nervous functions; and I think we must feel that there is reason for looking in other directions than in operating on the eye for the cure of all these things that have been laid so much stress upon as being cured by section of the muscles, and especially when we see the results. I have watched the process of reasoning which has been carried on in New York, and the assertions made of success, with a great deal of interest, for my attention was drawn more particularly to them by seeing cases which had evidently been injured by these operations pretty soon after they were announced. According to my observation, it does not seem as though the large number of operations performed, had been any more successful in restoring the normal balance of action than previously existed in a great many instances. I have seen several cases in which, after a large number of operations had been done on the muscles of the eye, there was still no rectification of the considered abnormal action; and some of those cases had never complained at all before. They had had their eyes examined, but the examination was not made because they complained of anything about the eyes. I think we do not give quite regard enough probably to the effects on such temperaments of constant training and practice. They are told that a certain thing is going to be of great benefit, and are very willing to accept it. They are willing to assert in the most positive manner that they have had benefit. We can test that benefit and ascertain whether it has been derived or not. Some of these cases have been positively damaged in their comfort in using the eyes. The results, it seems to me, are likely to be very small as compared with the predictions set forth.

DR. KNAFF: I have not had the opportunity of following out a great many of these cases of refractive trouble. I have seen very distinct benefits from tenotomy in one or two cases of severe headache in patients who had some refractive error combined with muscular insufficiency. In some of these cases there has been a history of other causes acting besides those mentioned, as care, anxiety, overwork; in some of them the special predisposing causes, other than neurasthenia, seem to have been absent. The relief that has been obtained by tenotomy has been quite marked,

so that I think that we must admit, from the neurological standpoint, that there are certain cases of persistent headache and of various neurasthenic symptoms which can be relieved by tenotomy. Curiously enough a good many of the text-books on nervous diseases do not say a word about refractive errors causing headaches. The fifth edition of Strümpell does not mention that hypermetropia or astigmatism or muscular insufficiency can cause headache. But going beyond these cases, I am rather sceptical as to the effect of eye-strain as a cause. As it happens, this year, during which my attention has been more particularly directed to it, I have seen rather fewer cases of chorea than usual. A certain proportion of these cases I have sent to Dr. Wadsworth for examination; and either he or Dr. Kilburn have examined them, and fitted them with glasses; and other cases which have not been sent seem to me to be getting along just about as well as the cases that had their refractive errors attended to. I recall now some four or five choreas that I have under treatment; two of them that I had fitted with glasses seem to be rather obstinate cases. Two more that have not had their eyes examined, seem to be getting on rather faster than those who have glasses. I don't know that that has anything to do with the matter, however, because there was that same distinction in the cases before I had the eyes of any of my cases examined. The epileptics I am not prepared to say anything about. I have had one or two cases of epilepsy examined, and the eyes pronounced to be all right. Other cases I have sent to oculists, and they are still under treatment. Almost all of the cases of epilepsy in which I have paid special attention to the muscular error, have been cases that I have seen during the past year, so that it is too soon to say anything whatever in regard to it.

DR. WADSWORTH: I agree in general with what Dr. Knapp has said. The subject of refraction I did not mean to touch upon this evening. My personal experience does not show any remarkable benefit from the use of glasses in chorea patients, as he has said.

DR. MCCOLLOM reported

A CASE OF LEPROSY.

The patient is a woman about forty-five years of age; is the mother of seven children, who are in this country. She states indirectly that the first symptoms appeared about seven years ago, fourteen days after the birth of her youngest child. She nursed the child a year, the disease meantime increasing in severity. At the end of that time the family came to this country, and left her behind. The children at the present time show no symptoms of the disease at all. They are well nourished. In her case the disease has gone on quite rapidly for the past four or five years. When her husband and oldest daughter saw her they seemed very much surprised at her appearance. They had not seen her for about three years. The case is of the tubercular kind. The bridge of the nose is entirely gone, and the lip has that thickening due to the deposit of tubercles under the skin. The ears are somewhat increased in size. There are two or three large tubercles over the eye-lids; also a large ulcer at each elbow, irregular in shape, three or four inches long, and one and a half to two inches wide. The ulcer contains no pus, but the tissues evidently break down without forming pus. There is also an ulcer on each knee, and the fingers are covered with a deposit

of matter which you can hardly call pus, and on the feet there is the same condition of things. One toe is just commencing to slough off. On the body there is no eruption at all. There is quite an eruption in the mouth and also on the fauces. The eruption is very peculiar, and not likely to be mistaken for anything else. She has a very peculiar, husky voice—the "voice of the leper" as it is termed by some writers. This peculiar huskiness one would recognize after having heard a leper speak two or three times.

This is the first case of leprosy in Boston for some time. There was a case here some time ago, which finally escaped, and all trace of him was lost. He had had the disease about five years when seen. There was a case at Salem a few years ago—a sailor from the west coast of Africa.

DR. JEFFRIES briefly alluded to several cases of leprosy which had come under his observation. In reference to the element of contagion, Dr. Jeffries thought that was overestimated.

DR. FARLOW showed a large

NASAL POLYPUS

removed from the nostril of a man. The whole of the growth is not yet removed; and from the fact of his age, and the rapid growth, he suspected the element of malignancy.

AMERICAN GYNECOLOGICAL SOCIETY.

THE Fifteenth Annual Meeting of the Society was held in the lecture-room of the Buffalo Library, September 16, 17, and 18, 1890. After the roll-call, the following gentlemen were asked to take part in the proceedings as invited guests: Dr. Roswell Park, Dr. Tremaine, of Buffalo; Dr. George Keith, of Buffalo; Dr. W. H. Buckmaster, of New York; Dr. J. A. Temple, of Toronto; Dr. Rosebrugh Hamilton, of Ontario; Dr. Fredericks and Dr. Mynter, of Buffalo; Dr. Carpenter, of Cleveland.

DR. ROSWELL PARK, on behalf of the physicians of Buffalo, delivered an Address of Welcome, after which the Society proceeded to carry out its programme. **DR. JOHN P. REYNOLDS**, of Boston, presiding, and **DR. JOSEPH TABER JOHNSON**, of Washington, Secretary.

The morning of the first day was devoted to the **DISCUSSION ON THE DIAGNOSIS, PATHOLOGY AND TREATMENT OF EXTRA-UTERINE PREGNANCY**, which was opened with a paper by **DR. A. W. JOHNSON**, of Cincinnati.

Dr. Johnston said that the ameboid state is the first picture in the life of viviparous animals. From the first segmentation, immersed in a proper nutrient fluid, all alike go on to the formation of the life-producing membranes. It is only required of the mother that she should furnish this nutrient fluid. In the human being the "rut" is semipaternal, and the endometrium is ever ready to pass into the myeloid state. Pregnancy can, therefore, occur at any time.

Dr. Johnston stated that he did not believe that extra-uterine pregnancy ever occurs with a perfectly normal genital tract. He believes that such a thing as ovarian pregnancy, if such a thing exists, must be due to certain peculiar conditions.

In regard to diagnosis, the practical question is,

How often is the diagnosis made before rupture? Every colicky pain means a giving-way of some part of the tube. Sometimes the first pain gets a large blood-vessel, but more generally the bleeding is not alarming until the second or third.

When extra-uterine pregnancy is discovered, all there is left to do is to remove it. Electrical treatment should be condemned, as the growth of the gestation sac cannot be arrested until the placenta is killed. The death of the child does not, necessarily, mean the death of the placenta, for the latter has a separate existence. Electrical treatment is dangerous in practice, wrong in principle, and disastrous in its final results.

Dr. Johnstone referred to a specimen presented by Dr. Mann, in 1888, and claimed that this was a dermoid cyst, and not an ovarian fœtation, as Dr. Mann had claimed.

Dr. Johnstone's paper was followed by one by DR. MATTHEW D. MANN, of Buffalo.

Dr. Mann said that the view that the union of the male and female elements must take place in the uterus is erroneous. In the case of an extra-uterine pregnancy, the union must occur in the tube or beyond it, and most ectopic pregnancies are primarily tubal. In regard to abdominal pregnancy, the question is still *sub judice*. There is no possible doubt as to the occurrence of ovarian fœtation. The specimen exhibited by Dr. Mann, in 1888, was unquestionably one of ovarian pregnancy; and he thought that Dr. Johnstone was not in any sense justified in assuming that it was a dermoid cyst, especially as all the evidence was to the contrary. A dermoid cyst does not contain placental tissue.

When rupture into the abdomen has taken place, the only rational treatment is to open into the abdomen. Electricity is ordinarily of greatest value. With the death of the embryo the danger of rupture ceases.

DR. CHARLES JEWETT, of Brooklyn, presented a report of

A CASE OF RUPTURED TUBAL PREGNANCY.

This case occurred in the practice of Dr. F. A. Jewett, and was seen by him on August 22, 1890. The patient was unmarried, twenty-nine years old, and gave a history as follows: At the last menstrual period she had only a slight flow, which lasted two hours. She attributed the suppression to having taken a bath a day or two before the flow was due. She had no pain nor subsequent hemorrhage. On the day when she called her physician, while at dinner she was seized with an attack of syncope, to which she was subject. On regaining consciousness, she complained of general abdominal pain, which seemed to radiate from a point above the umbilicus, and near the median line. The abdomen was somewhat tender on pressure, and slightly tympanitic. Vomiting occurred frequently during this night. Morphia was given to relieve pain.

In the morning of the next day, August 23d, she had sharp, colicky paroxysms. In the evening, the pains had been relieved, but the pulse was 96, and the abdomen was tender on pressure. At night, the pains were, for the first time, referred to the pelvis, and radiated down the thighs. There was a slight flow of blood from the vagina, and as the catamenia were due the next day, the pains were supposed to be dysmenorrhœal. There was no marked pallor or other sign of internal hemorrhage.

August 24th, at 10 o'clock in the morning, the pulse was 120, and the temperature 100.4 F. The patient went into collapse at 11 o'clock, and died three hours later.

An autopsy was made by Dr. C. E. Barber. The abdomen was found to be full of blood; the omentum was attached to the fundus uteri by adhesions; the left ovary was partially prolapsed, and fixed to the uterus by old, firmly-organized adhesions, just without the left fold of Douglas; the right side of the pelvis, posteriorly, also showed evidences of old pelvic peritonitis; the isthmus of the left tube contained a gestation sac, of about five or six weeks' development; the tube had ruptured at a point about three-quarters of an inch from the cornu, near the middle of the posterior aspect of the tube, and the opening, which was elliptical, measured, in its long diameter, about four millimeters; the ovum remained *in situ*.

Dr. Jewett considered this a case in which the diagnosis of ectopic pregnancy was not suggested by the symptoms, prior to collapse.

DR. J. M. BALDY, of Philadelphia, continued the discussion on

ECTOPIC PREGNANCY.

He stated that he would take as a base for argument the supposition that conception had taken place in a Fallopian tube. He did not wish to be understood as denying the possibility of an ovarian or abdominal pregnancy, but he proposed to confine his remarks to the earlier stages of the condition, to a period when the symptoms were practically the same and differential diagnosis most difficult, if not impossible.

As symptoms of ectopic pregnancy, the following may be classified as significant, or, at least, strongly suggestive:

(1) A spurious flow, simulating menstruation, which is at first lighter and afterwards darker in color than the normal menstrual discharge, and which contains clots and shreds.

(2) Pain, intermittent and cramp-like and becoming more severe and more frequent. Its situation is almost invariably pelvic and low down in the abdomen, and it may be so severe as to cause syncope. This peculiar pain, which usually is the symptom which leads the patient to seek the advice of her physician, in conjunction with the pseudo-menstrual flow, may be accepted as pointing forcibly towards the possibility of ectopic gestation.

(3) Discharge of shreds of decidua, with or without clots.

(4) General signs of pregnancy, such as gastric, vesical and rectal disturbances, and the breast symptoms.

(5) Occasionally the history of a sterility, subsequent to a miscarriage or a normal labor.

(6) The vaginal discoloration is as in normal pregnancy.

(7) The cervix uteri is sometimes enlarged and soft and the os patulous, but this is not invariably the case.

(8) The fundus of the uterus is enlarged and softened and crowded either far forwards against the pubic bone or is pushed to one side. It is more or less immovable, and has a feeling of softness. As in the case of the cervix, these conditions are not constant.

(9) The uterine appendages sometimes show a cyst on one side, while the examination of the other side

may be negative. The cyst, if it be a pulsating one, does not make certain the diagnosis.

(10) The patient's belief as to whether she is or is not pregnant is of considerable value.

(11) In some cases, elevated temperature and accelerated pulse.

(12) At the time of rupture, great pain, collapse and all the signs of concealed hemorrhage.

Dr. Baldy said that three propositions were justified by his experience and the experience of other physicians :

(1) In a certain proportion of cases of extra-uterine pregnancy, in the early stages, the diagnosis is easy and unmistakable.

(2) In a certain (quite large) proportion of cases, sufficient symptoms are present to more than warrant a diagnosis of extra-uterine pregnancy, such a pregnancy not being present.

(3) In a certain other proportion of cases, the symptoms, until rupture has occurred, are entirely wanting or of such dubious character as to in no wise warrant such a diagnosis.

The writer cited a number of cases occurring in his practice, and reviewed cases reported by others. He said that he believed that many cases of extra-uterine pregnancy go on to a spontaneous cure ; that in some other cases there was death of the embryo, and subsequent partial or complete absorption of the resulting hematocoele, embryo and membranes. A very large number of cases terminate fatally, which renders expectant treatment sometimes hazardous, and necessitates active measures to prevent disaster. Where diagnosis is reasonably certain, laparotomy is preferable to electricity. The gentlemen who, a year ago, were among the most ardent admirers of the electrical treatment seem to have changed their minds, and now advocate laparotomy.

DR. A. J. C. SKENE, of Brooklyn, believed that it was highly important that a diagnosis should be made in all cases of extra-uterine pregnancy with equal certainty, whether the treatment contemplated be that of electricity or laparotomy, in order that patients *in extremis* could be intelligently cared for. He hesitated somewhat in expressing his views in regard to the importance of diagnosis, a subject about which so much has been said, but stated that he was firmly convinced that extra-uterine pregnancy is as easily diagnosed as any known affection of the female pelvic organs — as pyo salpinx or ovarian cyst — if there be no complication of other pelvic disease. Of course, if the case is complicated like the one mentioned by Dr. Jewett, where the anatomy of the pelvic organs undergoes an entire change, diagnosis will be more difficult, but that is true of affections of any part of the body. It is very true, however, that patients very often do not come to us until after rupture occurs, and then, of course, a diagnosis cannot be made.

The doctor referred to a case of pregnancy in one horn of a uterus bi-cornis, in which he had treated the patient for dysmenorrhea, the pregnancy occurring subsequently. The sac was soft, fluctuating and movable and lay in the region of the right tube and had every appearance of a tubal pregnancy, which he should have diagnosed as such had he not been familiar with the previous history of bi-lobed uterus. This condition of pregnancy in one horn of a bifid uterus, he held to be the *only* one which could not be differentiated from tubal pregnancy with certainty, and that excluding

this one condition, the diagnosis of ectopic-gestation was as easy and certain as any other form of disease.

In regard to the treatment of these cases by electricity, the speaker expressed the regret that such an important subject should have been so heatedly and doubtfully discussed, and that it should have received such merciless condemnation from the advocates of laparotomy and he believed that such acrimonious discussion between the electricians and laparotomists would never lead to the determining of the true value of either method of treatment and he hoped there would soon be an end to it. He had seen no evidence that electricity was especially dangerous and believed that it could be employed with entire safety, and failing to cure, did not prejudice in the least the resort to the more conservative method of laparotomy. The laparotomists say that their operation must be done by "competent hands." Considering that the cases for laparotomy are emergency cases, perhaps if they examined the histories of the cases that have been operated upon by *presumably* "competent hands," they would not be so ready to condemn electricity.

DR. W. W. JAGGARD, of Chicago, thought Dr. Johnstone's statement in regard to the spermatozoa determining the site of the fecundated ovum, did not throw any light on the general point of fecundation ; and that to attribute the cause of labor to the cessation of the influence of the spermatozoa was carrying the action of the ferment a little too far. He was sure ovarian pregnancy has been definitely proved, and was not a discussible point, and that it was useless to discuss the case referred to by Dr. Mann as the presence of decidua and villi had not been demonstrated microscopically. He thought it looked like a tubal pregnancy rather than a dermoid cyst, but he did not think it wise to take cognizance of the observations of an unfamiliar observer in a case of this kind. Many things look like and are called *fetuses* that are not fetuses.

The speaker called attention to the fact that a great many cases of so called tubal pregnancy, are simply hematomas of the tubes, and that many cases of hemato-salpinx are really tubal pregnancies. A. Kellar reported several cases in which villi of the chorion were found in these blood tumors of the tubes.

The natural history of tubal pregnancy has three terminations : (1) death before rupture, (2) rupture, (3) going on to term.

When the tube ruptures, the following sub-terminations may be observed : (1) Rupture into the broad ligament, with formation of hematoma of broad ligament — favorable termination. (2) After rupture ovum may remain *in situ*, and plug it up, acting as a tampon — favorable termination. (3) It may rupture with formation of retro-uterine hematocoele — favorable termination. (4) Rupture into the abdomen with intra-peritoneal hemorrhage. With the exception of the last, all of these are favorable terminations ; and, as a rule, ruptured tubal pregnancy will recover if left alone.

He agreed perfectly with Dr. Skene in regard to diagnosis being easy in uncomplicated cases, and cited a typical case of tubal pregnancy (seen recently with Dr. Bonner, of Chicago) diagnosed and operated on before rupture, with removal of fetus intact, the patient making good recovery. The points in the diagnosis were : slight bluish discoloration of the anterior vaginal wall ; softening and compressibility of the

lower uterine segment (Hegar's sign); uterus displaced to the left, retroflexed, enlarged and of a peculiar, soft, doughy consistency; to the right of the median line well-marked, small, almond-shaped, non-fluctuating tumor, resembling somewhat an ovarian cyst. This woman was thirty years old, and had three children; two were born at regular intervals of about two years, and there was an interval of three years between the third and fourth pregnancies, which latter was on the right side; and it should be noted that the typical cases of extra-uterine pregnancy occur in old multiparae going a long interval between pregnancies, or in primiparae who have been sterile for a long time. The evidence in favor of laparotomy, where diagnosis is made before rupture, is conclusive.

Dr. Veit's article on the "Diagnosis and Treatment of Early Tubal Pregnancies," including some ten cases, diagnosed before rupture, and operated upon with but one death, was referred to, as being the best result obtained by any method of treatment.

He makes the following objections to the use of electricity: (1) Danger of rupturing the sac; (2) uncertainty in diagnosis; (3) after the eighth week it is hopeless to expect resorption of the fetus or placenta. He agrees, however, with Dr. Skene, that it is well to be temperate in the condemnation of electricity.

The universal proposition that every case of ruptured tubal pregnancy is an indication for laparotomy, is an erroneous one, and has proved most disastrous in practice. The principal indication for laparotomy is where there is a free intra-peritoneal hemorrhage. In the event of haematomata of the broad ligament, broad ligament pregnancy; rupture of the tube, the clot acting as a tampon, the indications are all strongly against laparotomy.

DR. H. P. C. WILSON, of Baltimore, was entirely in accord with Dr. Skene. He believes extra-uterine pregnancy is very frequent, but that ovarian pregnancy is very rarely met with; that if ectopic pregnancy can be diagnosed in its early stages, electricity is the proper treatment. He would adopt three months as the limitation for the application of electricity to destroy the fetus rather than four months as advised by Dr. Mann, and has succeeded a number of times in destroying the fetus before the end of the third month. Failing in that he would resort to surgical measures, which he estimated to be fully as valuable under the proper indications, as electricity. In the early stages of ectopic pregnancy, the women are usually in good health, and cannot believe that such a serious thing as cutting into the abdomen is necessary, and you can rarely get their consent to such a procedure, hence the resort to electricity. In hospital cases you may operate at the beginning, but not in the better class of patients. Should the case, however, go on beyond three months, to cut in and remove the fetus is the manifest duty of the gynecologist.

(To be continued.)

— "Chiropodist and Female Beautifier" is the professional title adopted by a man of California, who is charged with criminal malpractice in causing the death from peritonitis of a pregnant woman. It is to be hoped that fetuses are not to be classed generally among the blemishes which come within the scope of the "female beautifier."

THE BOSTON Medical and Surgical Journal.

THURSDAY, OCTOBER 9, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMREL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

OLD PHYSICIANS OF HARTFORD.

An interesting pamphlet on the Physicians of Hartford in 1820 and 1837 contains two papers of reminiscences: one, a reprint of an article by Dr. George Sumner, read before the Hartford Medical Society in 1820, the second by Dr. Gurdon W. Russell. The first paper contains sketches of physicians who obtained their early training in the War of the Revolution, and goes back to a time when the practitioners of the now busy city numbered but eight.

The physicians of that older day seem to have partaken of the earnestness of the times; and these reminiscences speak of their political beliefs and the ways in which their actions and their practices were influenced thereby. They had their professional differences also, and divided the city into *bleeders* and *stimulators*. They made their influence felt beyond the confines of their State also in their good works.

Dr. Mason Fitch Cogswell was the promoter of a school for deaf-mutes which was the nucleus of the American Asylum, and became the model of other schools for the deaf and dumb. Dr. Cogswell's daughter Alice was a deaf-mute. The interest in his own child led him to make inquiries respecting the number of deaf and dumb persons in the State, with a result that created great surprise at the unexpected frequency of the affliction. His appeal to his friends to aid him in introducing into this country methods of instruction already favorably known in France was successful, and led to the beneficial results already mentioned.

Dr. Todd brought before his professional brethren at a society meeting the difficulties in the treatment of the insane in their own homes, and gave the impetus to the foundation of the Hartford Retreat for the Insane. The name "Retreat" was chosen instead of "Asylum" because the school for the deaf and dumb had already appropriated the term "asylum." Physicians educated in that school were afterwards called to inaugurate other insane hospitals in Boston, Worcester, Brattleboro, and Utica.

Perhaps distance throws an enchantment over men of previous generations; but there seems to be a picturesque element in many of these Hartford doctors that would be hard to find at the present time. Dr. Sylvester Wells caused the bells to be tolled while the Hartford Convention was in session, and sent an old soldier marching with muffled drum through the streets; conduct which brought upon him angry remarks and poetical squibs.

The two Doctors Beresford must have been marked men. The father was a British Army Surgeon from 1804 to 1817, who was wounded at the last capture of Guadeloupe and put upon the half-pay list. Resigning his connection with the army he came to Hartford from Berbice, British Guiana, with a retinue of negroes, monkeys and parrots, which created quite a stir in the part of the town where he settled. He was a large, fine-looking man, commanding in appearance, accustomed to say no more than was necessary, and to speak to the point. It was the common impression that what he said must be obeyed. "In making his visits or when walking in the street, he was usually accompanied by his son, and as both were large, broad-shouldered men, they readily drew attention. It made some of the younger men smile . . . when, entering the sick-room, they both drew out their watches, and each seized an arm to feel the pulse of the patient." The Hartford hospital owes the son a debt of gratitude for a devotion which went so far as the neglect of private patients for public duties.

These are but meagre details from an interesting subject, but the Connecticut Society, which will celebrate its centennial in 1892, may well be pardoned if it dwells somewhat at length on some of the topics which are mentioned here.

THE REGULATION OF THE PRACTICE OF MEDICINE IN NEW JERSEY.

An act was passed by the Senate and General Assembly of New Jersey last May for the regulation of the practice of medicine, which is just going into operation, and which contains some features worthy of note. The execution of the law is vested in a board of nine members, appointed by the Governor for terms of three years. It is provided that the board "shall consist of five old school, three homeopaths and one eclectic," and further that "no member of any college or university having a medical department shall be appointed to serve as a member of said board." The new regulations apply only to those who commence practice in the State after the passage of the act, preceding practitioners being already registered under a previous law.

All examinations are to be in writing and both "scientific and practical, but of sufficient severity to test the candidate's fitness to practise medicine and surgery." "If the applicant intends to practise homeopathy or eclecticism, the member or members of the board of those schools shall examine said applicant in *materia medica* and *therapeutics*." A license shall not

issue unless the applicant passes an examination satisfactory to all the members of the board.

A somewhat peculiar feature of the law provides that any applicant refused a license by the board "for failure on examination may appeal from the decision of said board to the appointing power thereof, who may thereupon appoint a medical committee of review consisting of three members, one from each school of medicine, who shall examine the examination papers of the said applicant, and from them determine whether a license should issue and their decision shall be final: if said commission by an unanimous vote reverse the determination of the board, the board shall thereupon issue a license to the applicant: the expense of said appeal shall be borne by the applicant."

The board may by a unanimous vote refuse to grant a license for the following causes: "chronic and persistent inebriety, the practice of criminal abortion, conviction of crime involving moral turpitude or for publicly advertising special ability to treat or cure diseases, which in the opinion of said board, it is impossible to cure."

The power of the board is evidently very great, but it would be difficult to arrange a greater number of safeguards. In fact, it may be a question whether the safeguards against possible injustice are not so great as to hamper the action of the board.

MEDICAL NOTES.

— According to the daily press, Assistant Secretary Spaulding has informed the collector of customs at Boston that a recent importation of merchandise described as "ligature silk," is in no sense silk thread, or sewing silk, and is clearly dutiable at the rate of fifty per cent. *ad valorem*, as a manufacture of silk.

— The report of the Pennsylvania State Board of Health as to the number of registered medical practitioners in that State has just been issued. There are 8,318 practitioners, of whom 641 are of foreign birth, every nation, with the exception of Spain, being represented. The report contains the names and residences of each practitioner, with the name of the college and the length of time they have been practising.

— One physician of Buffalo has brought suit against another for \$25,000 damages for calling him a quack. The chief interest in the case lies in the fact that this much-used and often-abused word is now likely to be defined judicially. The plaintiff had called the defendant in consultation on a case of hernia, which he had treated by electricity. The relations between them became strained, for the plaintiff says that at a meeting of the County Medical and Surgical Society in the Iroquois Hotel on September 2d, the defendant spoke of him thus:

"The use of electricity is now practised by a notorious quack of Buffalo for the cure of hernia. This quack pronounced the patient cured of hernia after treating him, and a few days afterward the patient was taken with symptoms of strangulation."

The words were reported and published in the Buffalo *Medical and Surgical Journal* by the secretary of the meeting. For these words the plaintiff wants \$25,000 damages, and says he will sue the *Medical and Surgical Journal*, which published the words in its October issue. Both parties in the suit are regular practitioners of medicine.

BOSTON.

— The special committee of the Board of Overseers of Harvard College, on changes in the academic department and in its relation to the professional schools, made their report to the Board Wednesday, October 8th, at the conclusion of which the passage of the following votes was recommended :

Voted., That the Board of Overseers concurs with the Corporation in its approval of the fourth proposal of the College Faculty, "that a student may be recommended for the degree of Bachelor of Arts in the middle, as well as at the end, of the academic year."

Voted., That the Board of Overseers concurs with the Corporation in its approval of the third proposal of the College Faculty, provided it be amended by striking out the words "the foregoing requirement of sixteen courses," and substituting therefor the words "the requirements for the degree of Bachelor of Arts," so that it shall read as follows: "That when a student enters College there shall be placed to his credit towards satisfying the requirements for the degree of Bachelor of Arts (1) any advanced studies on which he has passed in his admission examination beyond the number required for admission, and (2) any other college studies which he has anticipated."

Voted., That the Board of Overseers does not concur with the Corporation in its approval of the first and second proposals of the College Faculty.

(1) That the requirements for the degree of A.B. be expressed, under suitable regulations with regard to length of residence and distribution of work, in terms of courses of study satisfactorily accomplished.

(2) That the number of courses required for the degree be sixteen.

Voted., That the Board of Overseers recommends the modification of the present Regulations of the College Faculty in accordance with the following proposition:

That a Senior intending to enter the Medical School and to take the full four years' course therein may, under proper supervision, include in the requirements for the degree of Bachelor of Arts the courses on physiology and anatomy required in the first year of the Medical School, each of said courses to count as one full elective course.

NEW YORK.

— The monthly bulletin of the New York State Board of Health reports that during the month of August, 10,002 deaths were recorded. This is 1,080 less than in July, and 630 more than in August, 1889, which was an unusually healthy month for the season of the year. The number of deaths reported represents an annual death-rate of 21.80 per 1,000 of the population. Of the total mortality 48.8 per cent. occurred under the age of five years; which is higher by eight per cent. than in August, 1889, three per cent. higher than the average for August, and two per cent. lower than in July. In each thousand deaths 292.70 occurred from zymotic diseases; being 35 lower than in July, and 37 lower than the average for August, for the preceding five years. The mortality from diarrhoeal diseases is about the same as the average for August, having fallen four per cent. from that of July. Of the 2,139 deaths from this cause,

1,310, or nearly sixty per cent., occurred in the five large cities of the State. Typhoid fever caused 162 deaths, just the average for the past five years for August; being an increase of 58 over July. There were 60 less deaths from diphtheria in August than in July, and 88 less than the August average. Whooping-cough and measles show an increasing death-rate, while other zymotic diseases are below the average.

— A case of small-pox, from which others are likely to arise, turned up at the Barge Office on September 26th. The patient, a young Irish woman, landed at Boston, September 16th, from the steamer *Nestorian* of the Allan line. She felt ill and feverish at the time, but the next day came on to New York, and on the 21st, an eruption made its appearance on her body. She had no idea that she was suffering from small-pox, and the discovery was not made until the 26th, when a Roman Catholic priest brought her to the Barge Office to have her examined. The examining physician, Dr. Guiteras, at once recognized the disease, and the diagnosis having been confirmed by Dr. Dillingham of the Board of Health, she was at once sent to the hospital on North Brother Island, and precautions taken, as far as possible, to prevent a spread of the infection.

— At the opening of the regular session of the Medical Department of the University of the City of New York, September 30th, Professor William H. Thomson delivered a lecture on the "Medical Aspects of Mental Discipline."

— On the 29th of September, 947 policemen specially selected for the purpose, began the retaking of the census of the city; continuing at the work from 8 A. M. to 6 P. M., with an interval of an hour for dinner. Twenty clerks from the Health Department assist in doing the tabulating. It is somewhat unfortunate that the new census should not have been left until a little later in the season, as many residents are still abroad or in the country.

— Coroner Hanly, with a jury composed chiefly of electricians, held an inquest on September 30th, on the case of Kopp, the lineman of the United States Illuminating Company who was killed by an electric shock while making repairs to a lamp at 35th Street and Broadway. The testimony went to show that the porcelain knob on the top of the lamp, which was an insulator, was cracked, and that Kopp, although considered one of the most expert linemen in the service of the company, failed to take the requisite precautions against accident. He had neither rubber coat, boots or gloves, and his pliers were not insulated. Manager Brown testified that the company furnished rubber gloves to all its employees, and that men were discharged for not wearing them when at work upon the wires. After the testimony was all in, the coroner called the attention of the jury to the action of an undertaker's assistant, who had injected an embalming fluid into the body of Kopp before the autopsy was made, and asked them to make some recommendation in regard to the matter. This was not done, however.

The jury, after deliberating for two hours, rendered a verdict that Kopp would not have lost his life if he had exercised proper care; but that "while said August Kopp did not exercise proper care, it has appeared in evidence that the defective insulation which existed at various arc lamps was a necessary factor in causing his death; and that the existence of such defective insulation was countenanced by the Board of Electrical Control. It is the opinion of this jury that the operation of high tension electric circuits in such condition, is a dangerous practice."

—The 18th of October, Deputy Health Commissioner Young, of Brooklyn, estimated the population of that city from the records of the Health Department, as 880,225, while the result of the United States census in June, placed the number of inhabitants at 804,000. On September 30th, Mrs. Mary McKenna, a native of Ireland, died in Brooklyn at the advanced age of 104. Her husband died in 1870 aged 85.

—At a convention of delegates from the various societies in the State for the prevention of cruelty, held at Albany, October 1st, a resolution was adopted recommending that all lying-in asylums and all institutions for the care of children, should be licensed and under the inspection of local health boards.

Miscellany.

STATISTICS OF THE BOSTON DISPENSARY.

The statistics of the Boston Dispensary for the year ending September 30, 1890, are as follows:

The number of new patients treated at the Central Office was 24,456, classified as follows:

Medical Department.—Men, 3,163; women, 5,359; children, 2,872; total, 11,374.

Surgical Department.—Men, 2,113; women, 1,007; children, 674; total, 3,792.

Department for Diseases of the Skin.—Men, 685; women, 431; children, 299; total, 1,415.

Department for Diseases of the Nervous System.—Men, 650; women, 476; children, 74; total, 1,200.

Department for Diseases of the Throat and Nose.—Men, 788; women, 724; children, 533; total, 2,045.

Department for Diseases of Women.—Women, 785; total, 785.

Department for Diseases of the Eye.—Men, 309; women, 315; children, 292; total, 916.

Department for Diseases of the Ear.—Men, 170; women, 203; children, 227; total, 600.

Department for Diseases of the Genito-Urinary System.—Men, 1,114; women, 31; children, 3; total, 1,148.

Department for Diseases of the Rectum.—Men, 123; women, 70; children, 5; total, 198.

Orthopedic Department.—Men, 27; women, 21; children, 43; total, 91.

Dental Department.—Men, 216; women, 269; children, 407; total, 892.

The number of visits made by patients, old and new, at the Central Office is 58,978, classified as follows: Medical, 20,956; surgical, 38,022; total, 58,978. The

number of patients treated in the Districts is 15,122 (including 449 cases of midwifery), classified as follows: Men, 2,944; women, 6,104; children, 6,074; total, 15,122. The results of treatment in the Districts are as follows:

Discharged, cured or relieved	39,578
The number of cases of midwifery attended during the year	449
The number of cases of midwifery attended since July, 1856	6,166
Whole number of patients since October, 1796	1,072,993
Whole number of patients since July, 1856	954,190
Average daily attendance at the Central Office	190
Largest number present any one day, March 10	323
Smallest number present any one day, June 13	80
The number of recipes put up at the Central Office during the year	60,883
The number of house recipes	48,265
The number of district recipes	12,618
Largest number of recipes put up in one day, December 30	447
Smallest number of recipes put up in one day, December 4	96
Number of paid recipes	54,780
Number of free recipes	6,103
Number of paid dental patients	849
Number of free dental patients	43

The list of medical officers for the ensuing year is as follows:

Surgeons: Drs. Edward O. Otis, William M. Conant, Frederic M. Briggs, Arthur K. Stone. Physicians: Drs. Robert Disbrow, John Dixwell, Thomas M. Rotch, Claudius M. Jones, Harold Williams, George M. Garland, Edwin M. Buckingham, Vincent Y. Bowditch, William C. Emerson, Robert B. Dixon, Russell Sturgis, Thomas F. Sherman, James S. Howe, William F. Temple, George E. Richards, Henry Jackson, Henry C. Baldwin, Robert W. Greenleaf.

Department for the Diseases of the Skin.—Drs. Francis B. Greenough, Abner Post.

Department for Diseases of the Nervous System.—Drs. William N. Bullard, John A. Jeffries, Elliot G. Brackett.

Department for Diseases of the Throat and Nose.—Drs. John W. Farlow, J. Payson Clark, Algernon Coolidge, Jr., Frederic C. Cobb.

Department for Diseases of Women.—Drs. Francis H. Davenport, John B. Swift, Rufus A. Kingman, George Haven.

Department for Diseases of the Eye.—Drs. William D. Hall, Edwin E. Jack.

Department for Diseases of the Ear.—Drs. George A. Leland, William S. Bryant, Wallace Preble.

Department for Diseases of the Genito-Urinary System.—Drs. George H. Tilden, Francis S. Watson, Hayward W. Cushing, Gardner W. Allen.

Department for Diseases of the Rectum.—Drs. Walter J. Otis, William D. Hodges.

Obstetric Department.—Dr. Charles M. Green. Assistant Physicians, Drs. Edward Reynolds, Charles W. Townsend.

Orthopedic Department.—Dr. Charles L. Seudder. Pathologist.—Dr. Edward M. Greene.

Dentist.—Joseph E. Waitt, D.M.D.

District Physicians.—Drs. Willis B. McMichael, George A. Sargent, Augustus Thorndike, William S. Thayer, William S. Boardman, Chauncey R. Burr, Samuel Breck, Paul Thorndike, Edward L. Twombly, James R. Draper, Charles D. Fillebrown.

Apothecary.—Frederick H. Dudley. Assistant Apothecary, Joseph S. Lang.

WILLIAM H. H. HASTINGS, *Supt.*

CASES OF ERYSIPELAS OF THE PHARYNX.

The Annals of Surgery, September, 1890, refers to two cases of the above affection described in a pamphlet by K. G. Sennander (*Upsala*). Two cases were observed by him in the surgical clinic of Upsala, the clinical course of which rendered the diagnosis beyond a doubt. Two students of medicine who were serving in the clinic, fell sick, one soon after the other; they had been in the surgical as well as in the inner clinic, where several cases of erysipelas had been under treatment. The disease commenced with rigors and intense reddening of the mucous membrane of the pharynx, with sore throat and difficulty in swallowing. There was disturbance of the general condition, continuous high and remitting fever, swelling of the glands at the angle of the lower jaw, and then violent pain in the ear with following perforation of the tympanic membrane, when some bloody pus was evacuated. This perforation was followed by an erythema of the integuments of the external meatus; from there a characteristic erysipelas passed over onto the corresponding part of the face, where the vesicles developed on the forehead up to the boundary formed by the hair. The aural disturbances, as roaring in the ears, difficulty in hearing, and perforation of the membrane, disappeared under the proper treatment.

In addition to these two observations the writer communicates several cases of pharyngeal erysipelas which were treated at the same time in the inner clinic of Professor Henschen. In one case the extension of the disease over the neck rendered tracheotomy necessary; another one complicated with pleuritis and peritonitis, ending fatally, while in a third case an otitis media developed.

MUMPS AND INFLAMMATION OF THE LACHRYMAL GLAND.

A SHORT time ago a paragraph appeared in the *British Medical Journal* on certain affections which make their appearance during epidemics of mumps, and are presumably allied to that disease. At a meeting of the Société Vaudoise de Médecine in June, according to the same journal, M. Dufour exhibited a drawing which represented a case of acute inflammation of the lachrymal glands, occurring during an epidemic of parotitis in the district where the patient dwelt. A gardener was attacked with rigors and feverishness on the day after hard work under a hot sun. The eyelids began to swell, next day there was a distinct swelling in each upper lid, which continued for three days. At the end of that date the lachrymal gland, enlarged to the size of a cobnut and hard as cartilage, could be felt on each side. The palpebral cleft was triangular, with the apex at the inner canthus; the symmetrical character of the affection was

marked. Two days later all fever had passed away, the tumors had diminished in size; at the end of three days they were of the dimensions of a small bean, the lids had resumed their normal aspect. A fortnight later, three weeks and four days after the initial rigor, a rough body the size of a pea could be felt under each upper lid, at the outer canthus. The patient was in good general health. Professor Hirschberg, of Berlin, described two similar cases which occurred during the past spring at Berlin. Dr. Epéron noted that, whilst inflammation of the orbital portion of the lachrymal gland is rare, the palpebral or lower portion is more frequently inflamed, constituting an affection doubtless mistaken, in many instances, for a sty in the outer part of the upper lid.

EARLY MARRIAGES IN INDIA.

THE case of child-wife murder, reported in the *Journal* of October 2d, has attracted wide attention in India to the subject of the nubile age of females in that country. An editorial article in the *Indian Medical Gazette* of September, 1890, says:

"The appearance of menstruation is held by the great majority of natives of India to be evidence and proof of marriageability, but among the Hindu community it is considered disgraceful that a girl should remain unmarried until this function is established. The consequence is that girls are married at the age of nine or ten years, but it is understood or professed that the consummation of the marriage is delayed until after the first menstrual period. There is, however, too much reason to believe that the earlier ceremony is very frequently, perhaps commonly, taken to warrant resort to sexual intercourse before the menstrual flux has occurred. This came out clearly at the recent trial, and was indeed advanced in extenuation of the prisoner's 'rash and negligent act' by his counsel, and from evidence which we have gathered since the trial, it may be accepted as true that pre menstrual copulation is largely practised under the cover of marriage in this country.

"From this practice it results that girls become mothers at the earliest possible period of their lives. A native medical witness testified that in about twenty per cent. of marriages, children were born by wives of from twelve to thirteen years of age. Cases of death caused by the first act of sexual intercourse, are by no means rare. They are naturally concealed, but ever and anon they come to light. Dr. Cheverys mentioned some fourteen cases of this sort in the last edition of his 'Handbook of Medical Jurisprudence for India,' and Dr. Harvey found five in the medico-legal returns submitted by the Civil Surgeons of the Bengal Presidency during the years 1870-71-72.

"Reform must come from conviction and effort as in every other case, but meantime the strong arm of the law should be put forth for the protection of female children from the degradation and hurt entailed by premature sexual intercourse. This can easily be done by raising the age of punishable intercourse which is now fixed at the absurd limit of ten years. Menstruation very seldom appears in native girls before the completed age of twelve years, and if the 'age of consent' were raised to that limit, it would not interfere with the prejudices and customs which insist on marriage before menstruation."

ETHER INTOXICATION.

We can bear out from personal observation, says the *Lancet* for September 20th editorially, many of the statements which are now going the round of the public press in reference to the habit of ether drinking in some parts of Ulster; for, in fact, some of the paragraphs are nothing more than copies of what we have reported in years gone by. The practice came into use about the year 1841-42, and was at first a kind of reaction against the great temperance movement which had been inaugurated by Father Mathew. Ether, at that time of the ethyl type, probably not very pure, was substituted for whiskey, and the habit, commencing in or near to Drapers Town and spreading over a small surrounding area, is continued up to the present day. The order of drinking, as we witnessed it during a visit to the district named, is singular. The ether purchased at open shop and at stores was doled out in wineglasses. The drinker first washed out his mouth with a draught of cold water, and after that tossed off a wineglassful of ether "nate," as it was said, drinking it quickly, almost at a gulp. Both men and women took part in this indulgence, and were speedily brought into a state of intoxication, more or less complete. The intoxication differs from that produced by alcohol. It is more rapidly induced, and more rapidly dispelled; in fact, the effect of one dose may be developed and cleared off in a quarter of an hour or twenty minutes. The delirium is sharp, the stupor, for a brief period, deep, and the excitement, so long as it lasts, hysterical.

We gathered particulars from a trustworthy medical source of several instances in which the narcotism caused by the ether had proved dangerous, calling for the employment of artificial respiration; and we found evidence of four actually fatal intoxications, either from an excessive dose or from asphyxia caused by the entrance of some of the fluid into the glottis, with succeeding spasm or obstruction. We gathered, at the same time, that tolerance to the effects of ether was much less marked than tolerance to alcohol; and we learned further, that organic disease from the habitual taking of ether was exceedingly small compared with the ravages and degenerations which alcohol leaves in its train. The explanation of these facts is not difficult; alcohol is so soluble that it enters the blood freely, pervades, with the water of the blood, all the tissues, and is readily retained by them to work out those serious osmotic changes which demonstrate its action as the most potent of degenerators. Ether, on the other hand, is comparatively insoluble, and as it boils at the temperature of the body and is diffused nearly as fast as it is introduced, it leaves few marks of mischief, except when it destroys life directly. Occasionally it gives rise to dyspepsia and to gastric irritation, with free eructations of gases mixed with etherial vapor. But these symptoms belong to ether tasters of a hardened sort, and soon pass off when the habit is abandoned.

Of late years the use of the cheaper methylated ether has taken the place to a considerable extent, of the ethyl variety, and some think with more injurious effects; but on this point there is no evidence strictly trustworthy. Officers of the Government have at various periods made inquiries in order to see if, by legislative action, the habit could be controlled or prevented, but as yet nothing has been suggested that

has promised success, and the excise officers are helpless, inasmuch as the spirit from which the ether is made has paid the usual duty previously to the manufacture.

Correspondence.

CRYPTORCHIDISM.

BOSTON, October 4, 1890.

MR. EDITOR:—I beg leave to communicate the following report of a case seen within the past few days. This instance of a rare condition—as to anatomy and physiology—naturally belongs with those already published, under title "Puerile Genitalia," in the *Boston Medical and Surgical Journal* of October 15, 1888:

The man is a native of Connecticut; aged twenty-six years; of robust frame, with unusual muscular development in general; complexion, fair; eyes, light blue; hair, brown and thin; markedly hirsute over front of trunk; weight, 147 pounds; height, five feet six inches; chest measure, 36 inches; voice, rather high-pitched.

There is congenital absence of both testes, scrotum and phallus appearing to be normal. Thorough examination failed to reveal any sign of missing "witnesses" in or about canal or abdominal walls. The parts about the lower portion of the trunk and thighs were unusually firm, no looseness or flabbiness of structure anywhere. He states that coitus has been normal, with usual sensations. He also says that he recently passed five days in a small boat at sea, without food and water, showing great endurance.

Query for the medico-surgical public: What would be the prognosis in event of injury or disease?

Very respectfully,

F. B. STEPHENSON, Surgeon U. S. Navy.

ANTISEPTICS AND ETHICS.

SALEM, October 3, 1890.

MR. EDITOR:—When Lord Lytton wrote, "the pen is mightier than the sword," he doubtless did not imagine that later on a Strasburg professor would extol the virtues of ink in the healing of wounds. If the aniline colors, recently introduced as antisepsics under the name of "pyoktanin," are not identical with the aniline inks with which we have been unpleasantly familiar for some years, they are, at least, cousins-german to them.

Unless the alleged remarkable antisepctic action of pyoktanin should receive the confirmation of clinical experience, it is hardly likely to be generally employed, and chiefly because of the conspicuous staining that invariably attends its use. At present, according to the *Annales d'Oculistique* (juillet-août), doctors abroad differ as to its merits; and they do not by any means assent unanimously to all that is, somewhat extravagantly, claimed for it. On the contrary, in many cases, they find the salts of mercury and of silver are more reliable.

However, after a while pyoktanin will have found its place.

As to another matter:

On the label of a tincture bottle (price one dollar), bought in New York, appears (in questionable taste, according to our ideas) "Unter Kontrole von Prof. Dr. F. Stilling," which leads one to surmise it is (like Dr. Knorr's antipyrin) a proprietary article.

In contrast, cocaine, the value of which is universally recognized, was generously given (?) to the world by its discoverer, Dr. Koller (who is now living in New York). In this country, in which charlatans flourish so luxuriantly, it is assuredly creditable to us that our qualified medical men freely and unselfishly bestow their professional inventions for the benefit of mankind, possibly remembering that *noblesse oblige*.

DAVID COGGIN.

REPORTED MORTALITY FOR THE WEEK ENDING SEPTEMBER 27, 1890.

Deaths reported 2,783; under five years of age 1,160: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 573, consumption 322, acute lung diseases 370, diarrhoeal diseases 273, diphtheria and croup 121, typhoid fever 83, whooping-cough 66, malarial fever 25, scarlet fever 13, cerebro-spinal meningitis 8, measles 6, erysipelas 5, typhus fever 4.

From whooping-cough, Brooklyn 7, New York and Baltimore 6 each, Chicago 4, Philadelphia 3, Quincy 2, St. Louis, Boston, New Orleans, Washington, Nashville, Lowell, Salem and Taunton 1 each. From malarial fever, New Orleans 9, New York 6, Brooklyn 5, Baltimore 3, Nashville and Charleston 1 each. From scarlet fever, New York 3, Brooklyn and St. Louis 2 each, Chicago, Boston, New Orleans, Worcester, Lowell and Lynn 1 each. From cerebro-spinal meningitis, New York 3,

Brooklyn 2, Chicago, Washington and Quincy 1 each. From measles, New York and Springfield 2 each, Brooklyn and Baltimore 1 each. From erysipelas, New York 2, Chicago, Brooklyn and Washington 1 each. From typhus fever, Philadelphia 3, and the two chief greater towns of England and Wales with an estimated population of 9,715,550, for the week ending September 20th, the death-rate was 19.1. Death rate reported 3,650: acute diseases of the respiratory organs (London) 187, diarrhoea 373, measles 76, whooping-cough 72, diphtheria 63, fever 49, scarlet fever 47.

The death-rates ranged from 12.9 in Derby to 35.7 in Preston, Birmingham 19.0, Bradford 14.1, Hull 23.7, Leeds 21.9, Leicester 17.9, Liverpool 22.1, London 16.2, Manchester 31.6, Newcastle-on-Tyne 26.6, Nottingham 15.8, Sheffield 25.2, Sunderland 27.9, In Edinburgh 16.7, Glasgow 24.0, Dublin 19.4.

The meteorological record for the week ending Sept. 20, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:-

Week ending	Barometer.	Thermometer.			Relative Humidity.			Direction of Wind.		Velocity of Wind.			State of Weather.*		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 27, 1890, TO OCTOBER 3, 1890.

In view of the abandonment of Fort Gibson, I. T., to which post he is at present assigned for station, Captain W. O. OWEN, Jr., assistant surgeon, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Fort Sill, I. T., and report to the commanding officer for duty. S. O. 135, Department of the Missouri, St. Louis, Mo., September 27, 1890.

In view of the abandonment of Fort Crawford, Col., to which post he is at present assigned for station, Captain J. L. PHILLIPS, assistant surgeon, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Fort Logan, Col., and report to the commanding officer for duty. S. O. 135, Par. 1, Department of the Missouri, St. Louis, Mo., September 27, 1890.

Leave of absence for twenty days, to take effect when his services can be spared by his post commander, is granted Captain LOUIS S. TESSON, assistant surgeon, Fort Sidney, Nebraska. S. O. 72, Department of the Platte, Omaha, Neb., September 25, 1890.

By direction of the Secretary of War, leave of absence granted Captain JOHN L. PHILLIPS, assistant surgeon, in Special Orders No. 164, July 16, 1890, from this office is extended two months. S. O. 228, Par. 3, A. G. O., Washington, September 29, 1890.

Leave of absence for one month, to take effect about October 1, 1890, is granted Captain LOUIS W. CRAMPTON, assistant surgeon (Fort Sheridan, Ill.). S. O. 80, Par. 2, Division of the Missouri, September 30, 1890.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, October 13, 1890, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Dr. F. B. Harrington will read a paper on "The Value of Primary Anesthesia in Minor Operations." Dr. E. G. Cutler will show a case of Multiple Neuritis due to Arsenic, and a case of Pseudo-Muscular Hypertrophy in an Adult.

G. G. SEARS, M.D., Secretary.

CORRECTION.

In the JOURNAL of September 25th, on page 302, near the end of the page, before the words "I have two very interesting cases" should have appeared "Dr. Broughton said." As it was printed the remarks which follow were apparently made by Dr. Bolles.

OBITUARY. MONTROSE A. PALLEN, M.D.

Dr. Montrose A. Pallen died in New York, on October 1st. He was born January 2, 1830, in Pittsburgh, Pa. His father, a Virginian, was professor of obstetrics in the St. Louis Medical College for twenty-seven years. Dr. Pallen received his medical education at the St. Louis University, from which he graduated in 1856. He spent two years in the medical schools and hospitals of London, Paris and Berlin, and then settled in St. Louis, where he remained till 1874, when he was called to the chair of gynecology in the medical department of the University of the City of New York.

During the war Dr. Pallen was medical director of Gen. Henry A. Wise's Legion in 1861, of Gen. William J. Hardee's army corps in 1862, and later of the Department of Mississippi until February, 1863. Subsequently he was sent to Canada by

the confederate government to report on the condition of the confederate prisoners on Johnson's Island. He returned to Richmond in 1864, went to Paris, and obtained surgical and medical supplies for the confederate army there. He was sent to Memphis again, but was compelled to return home back to the South, and held on parole in New York until the end of the war. He was professor of gynecology in the Humboldt Medical College in 1866-67, adjunct professor of obstetrics in the St. Louis Medical College 1867-68, professor of gynecology in the St. Louis College of Physicians and Surgeons 1869-70, professor of anatomy in the Missouri Medical College 1871-72, and professor in the medical department of the University of the City of New York 1874-82. In 1885 he assisted in forming the Post-Graduate Medical College. He also served as surgeon to the Charity Hospital.

OBITUARY. E. HUGGINS BISHOP, M.D.

Dr. E. Huggins Bishop, one of the oldest residents of New Haven, Conn., died at his home on October 2d. He was born in New Haven on February 11, 1807, and was therefore in his eighty-fifth year at the time of his death. He was a graduate of Yale, class of 1826, and of the medical department of the college in 1829. Most of his life he spent in the practice of medicine in his native city, and was for several years president of the New Haven Hospital Society. He retired from active practice ten years ago.

OBITUARY. PROCTOR THAYER, M.D.

Dr. Proctor Thayer, a prominent physician of Cleveland, O., died in that city on October 1st. Dr. Thayer was born in Williamstown, Mass., on October 16, 1823, but has lived in Ohio since his eighth year. He graduated from the Cleveland Medical College in 1843. In 1845 he became a member of the faculty, and four years later professor of anatomy and physiology in the Western Reserve Medical College. When the war broke out he entered the army as a surgeon, and served at the reduction of Fort Sumter, Moultrie and Wagner, and was afterwards placed in charge of a large hospital at Beaufort, S. C. Dr. Thayer was in the battles of Pittsburg Landing and Corinth, and from the latter he brought three hundred wounded men, distributing them on the way to Cincinnati. He was honorably relieved from further service, and returned to Cleveland. He resumed his connection with the Western Reserve Medical College, and did much to the growth and progress of that institution. Of late years he was professor of surgery and of medical jurisprudence, but he resigned last winter, because of failing health. His resignation was accepted only so far as concerned the chair of surgery, and he consented to retain his professorship of medical jurisprudence. He was then made emeritus professor of surgery.

Dr. Thayer had been in ill health for several years, but until last March he did not retire from active practice.

OBITUARY. JEROME WILMARTH, M.D., M.M.S.S.

Dr. Jerome Wilmarth, of Milford, died on October 7th. He was born in Montague fifty-nine years ago, and graduated from the Harvard Medical School in 1866. He was for many years a resident of Upton, but for the last few years has lived in Milford. He leaves a widow and three children.

DEATHS.

Died in Boston, September 22, 1890, John Cauldwell Sharp, M.D., M.M.S.S.

Charles L. Hubbell, A.M., M.D., M.M.S.S., died suddenly in his office, in Williamstown, of heart disease on October 7th.

Original Articles.**A READY METHOD FOR COUNTER-EXTENSION AT THE KNEE.¹**

BY HENRY LING TAYLOR, M.D., NEW YORK.

If the knee-joint is, from its position and structure, peculiarly liable to acute and chronic inflammation, it is also favorably situated for examination and treatment. Experience has shown, however, the obstinate and serious nature of many cases of synovitis and arthritis of the knee, and the frequency of grave sequelæ, unless treated with the utmost care and precision.

We endeavor to put the parts at rest and to prevent friction, by immobilizing the joint in the more or less flexed position instinctively assumed by the patient, and to abolish harmful pressure on the surfaces by counter-extension in the lines of the tibia and femur. Properly applied, counter-extension, with fixation and recumbency, usually affords prompt and often marvellous relief to the intense suffering in the active stage of the trouble, and at the same time provides conditions favorable to the proper nutrition of the joint, and the subsidence of the inflammatory process. I have seen a young man who had been in such agony for months from a synovitis of the knee, that narcotics were freely administered with only slight mitigation, breathe a sigh of relief the moment the straps of the

counter-extension splint were tightened, and remain free from suffering from that time, with coincident subsidence of the inflammation. Fixation alone or simple traction by means of the weight and pulley, however useful in an emergency, give by no means the same results, and I am convinced that the early application of some form of counter-extension is of extreme importance in surgical inflammations of the knee-joint. My object is to indicate one or two ways in which counter-traction may be effectively applied without elaborate apparatus, remembering always that, in mechanical as well as operative surgery, the success of any procedure depends strictly upon the care and skill of the operator, and that no amount of theoretical acquirement will compensate for the lack of exact and dexterous manipulation of details.

The patient being put to bed, the first step in the dressing is the application of adhesive plasters to each

side of the leg and thigh. To get a firm and even grasp of the limb, we use a three-tailed or five-tailed plaster made as follows: four pieces of yellow adhesive plaster, about an inch and a half wide and eight inches long for an adult, have firmly sewed to one end a piece of webbing six inches long, and two strips of rubber plaster three-quarters of an inch wide and about twenty inches long, in such a manner that the webbing prolongs the yellow plaster, while the strips of rubber plaster make with it an angle of sixty degrees, as seen in the cut (Fig. 1). We now have four three-tailed plasters with webbing attached.² Two of these are applied to the leg below the knee, one to each side, the webbing starting about four inches above the ankle, and falling towards it; the narrow strips of rubber plaster are wound spirally around the leg slanting towards the knee. The two remaining three-tailed plasters are similarly applied to the thigh, the webbing starting a few inches below the level of the crotch and falling towards the pelvis. When in place the plaster is retained by a light bandage; it is thus seen that when the four ends of the webbing are doubled on themselves and buckled over the edge of some form of fixation splint, reaching beyond the plaster in both directions, traction is exerted upon the knee both above and below.

It is necessary to apply the plasters to the leg and fasten the webbing to the splint in such a manner that no prying or twisting force falls upon the knee, or pressure will be increased instead of relieved. The splint must be rigid to provide fixed points for the traction, and must immobilize the knee laterally and antero-posteriorly, without pressing upon the joint. If flexion is moderate, two straight strips of wood like laths or window-shade sticks, cut the proper length and provided with buckles near each end, will do very well. The strips are well padded with cotton or folds of fabric above and below the knee and at the ends and securely fastened in place each side of the limb by bandaging them together over the top of the thigh, behind the knee, and above the ankle; after this additional bandages may secure the whole. We now have to draw the pieces of webbing over the ends of the side splints as tightly as we wish, and fasten them into the buckles provided (Fig. 2). Our simple counter-extension splint is now complete, but it is usually desirable to attach five or six pounds to the lower end of the apparatus by the ordinary cord, pulley and

FIG. 1.

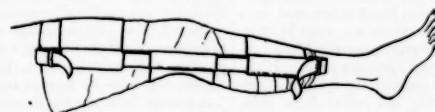

FIG. 2.

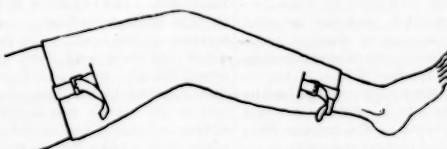

FIG. 3.

¹ Read at the meeting of the American Orthopedic Association, Philadelphia, September 16, 1890.

² If we wish to use strong traction we may use a five-tailed plaster by sewing another pair of rubber plaster strips just above the first.

stirrup arrangement, the knee being carefully propped and supported in the flexed position by hard cushions or in a sling. If much flexion is present, a tracing of the leg should be taken on paper, and wooden side-splints with a corresponding angle and perhaps hollowed at the knee, can be prepared by the carpenter. This dressing³ has worked well and given prompt relief in a number of cases, but it occurred to me last summer, that the ordinary plaster-of-Paris splint reaching from above the ankle to near the crotch, might be utilized for the same purpose and prove more convenient in an ambulatory case. I have used such an arrangement with satisfaction in a number of cases, of which one was a bad old case of osteitis of the knee, with nearly ninety degrees of flexion, for whom I was preparing and have since applied, a more perfect steel splint. The plasters were applied to the limb as before, bandaged in place, and the knee covered with cotton; over this was placed a light plaster-of-Paris splint with strong edges, over which small pieces of cardboard were bent where the webbing was reflected. Buckles attached to bits of webbing were bandaged into the plaster on the outer and inner side of the limb at each end, and to these the plaster webbing was fastened (Fig. 3).

If the patient is small a stiff tin or zinc posterior splint could be bent to correspond to the angle of flexion, and turned up at the sides for lateral support and to receive the buckles near the ends. Whatever the form of apparatus we use for fixation and as a fixed point for our counter-traction, we must be careful, let me repeat, that no leverage, especially no prying or twisting force is exerted upon the joint. If the counter-traction acts in the lines of the deformity, we should in most cases speedily get relief from pain, diminution of tenderness, heat and swelling, relaxation of the flexor muscles and an improved general condition of the patient. As the mechanical conditions are favorable, the amount of traction need not be great, not nearly so great as is required at the hip, but it should be constant, definite and in the proper direction. Even in our steel splints ratchet-traction is not required, as merely drawing the straps into the buckles by the hand, gives a sufficient pull. After a few days or weeks motion will be freer; as the muscles relax the splint is straightened, and counter-extension in the improved position continued. The later stages toward recovery may present indications for different management, and the ultimate result will depend upon an exact apprehension of the physiological requirements of the joint at each stage, and precision in meeting their demands.

A CASE OF COMPOUND DISLOCATION OF THE HIP, WITH RECOVERY.

BY JOHN W. PERKINS, M.D.

I SAW the following case while interne at the Children's Hospital, Boston, during the service of Drs. Langmaid and Cabot, by whose permission it is published. The notes were taken by me, daily, at the time.

Ella S., aged eight years, admitted April 17, 1885, under Dr. Langmaid. Her physical development was excellent, her mind unusually bright. Although suffering somewhat from shock, she related very clearly the

³ Used by Dr. C. Fayette Taylor since 1871.

manner of the accident. An hour and a half previously, while she was sitting on the edge of the sidewalk, a heavy brewery wagon drew in suddenly, close to the curbstone. In her hurry to get out of the way, she fell on her stomach, so that her body rested obliquely on the edge of the curb, her knees in the gutter. One wheel of the wagon passed between her legs and across the back of her left thigh (from within outward) as shown by an ecchymosed band, nearly coinciding with the gluteal fold. She was brought on a stretcher to the hospital at once, without having undergone any manipulation which would have altered the relation of the parts.

When placed on her back upon the table, her left thigh was flexed, abducted and rotated outwards, so as to lie perfectly flat along its outer aspect, upon the table. A widely gaping wound some eight inches in length extended diagonally across Poupart's ligament, from a point an inch above and inside the anterior superior spine, to the inner and posterior aspect of the thigh. The muscles directly under the wound were severed, the adductor longus completely, the pectenous, psoas and gracilis, partially. The adductors, contracting, formed a well-marked swelling about midway down the thigh. The head of the femur with the whole of the round ligament presented near the middle of, and close to Poupart's ligament. The lower portion of the abdominal muscles, nearly the whole length of Poupart's ligament, and the unsevered muscles of the thigh for a considerable extent, were exposed by the retracted skin. Haemorrhage was considerable, so that it became necessary to pack the wound with sponges, pending the arrival of Dr. Langmaid. The femoral vessels could not be seen or felt in the wound.

An hour later the child was etherized. Under the spray, and with antiseptic precautions, the wound was carefully cleaned, and the dislocation reduced by Dr. Langmaid. The reduction was easily accomplished at the first attempt, by flexing the hip and making direct pressure on the head. The femoral artery and vein, which had been held down outside and beneath the cervix femoris, were now found in their normal position, exposed by the laceration of the sheath. The rent in the capsule was anterior. The tendinous insertion and about two inches of the adductor longus, which was almost free in the wound, were removed. No bleeding points were found, drainage-tubes were inserted, the skin brought together with silk, and a dressing of iodiform gauze applied, with a waterproof covering. The child was placed upon a Cabot hip-splint,¹ which was found to be of the greatest assistance throughout the subsequent treatment, not only in maintaining the leg in good position, but in handling the child. On it, she was easily raised, to renew the dressings or to change the bed—a consideration of great importance in view of the incontinence which followed.

An aseptic condition of the wound was not maintained. Attempts to have all urine passed by catheter were unsuccessful. Frequent involuntary passages saturated the dressing, in spite of its mackintosh covering. The left labium major, and the abdominal wall covering the left iliac fossa became red, swollen, painful. Enemata, and even the introduction of a thermometer into the vagina caused pain. The urine and stools were never bloody. The temperature and pulse rose steadily until the third day after the acci-

¹ Described in Boston Medical and Surgical Journal, vol. ex., p. 6.

dent when the temperature reached 104.5° F. Pus appeared in the wound and the febrile condition declined. On the fifth day secondary hemorrhage occurred, from the upper end of the wound, about eight ounces by estimation.

The child, who previously had become very nervous, now became exceedingly fretful and irritable. Night screams, similar to those occurring in the early stages of tubercular joint disease, were of frequent occurrence. She lost flesh rapidly. The wound gaped. Three days after the first, a second hemorrhage took place, about the same amount as before. The flow on both occasions was quickly discovered by the nurse and checked by immediate compression. There were no more hemorrhages.

Following this second mishap, the child's condition became very trying. Restless and irritable before, she was now almost unmanageable, at times wildly delirious. Her temperature fluctuated between 100 and 102° F. daily—her appetite was feeble, her physical condition daily grew worse. Bed-sores formed in spite of every precaution. The skin sloughed wherever the splint pressed. Intense pain in the hip and knee were constant whenever the leg was disturbed.

At the end of the second week, by Dr. Cabot's direction, a second splint, similar to the first was applied, having slightly different curves and dimensions, thus altering the points of pressure upon her body and leg. In addition, an anterior splint, similar to a "Smith" was made, by means of which extension was applied to the suspended leg. From this time on, her condition improved; the wound healing rapidly although frequently soaked with urine. The leg took on the peculiar condition not infrequently seen in paraplegics; pallid and edematous throughout, its vitality was so low that the pressure of the most carefully padded splint produced sloughs in a night.

Six weeks after the injury, the wound had almost closed, the bed-sores healing, and her general condition greatly improved. The leg was still swollen, even larger than before, the thigh measuring thirteen inches, the calf nine and three-eighths inches. There was slight motion at the hip-joint. She convalesced rapidly and at the end of three months she could walk without the aid of crutches, the foot being considerably everted.

A year and a half after the injury I carefully examined the child—noting the following:

The left hip was completely ankylosed, the joint absolutely without motion. The thigh was slightly abducted, somewhat rotated outward and flexed on the body at an angle of about fifteen degrees. Lordosis marked when the thigh was brought parallel with the table. The pelvis was not tilted. There was no difference in the length of the two legs. The left thigh measured one-half an inch less in circumference than the right, but the left calf measured one-half inch more than the right. The left foot was ordinarily held much everted but could be brought to the median line but not inverted beyond this point. Extreme eversion was greater with the left than with the right foot. The gluteal fold was about three-quarters of an inch lower on the left than on the right side, the left glutei muscles being noticeably flattened. The cicatrix extended from one inch inside the anterior superior spine directly along the fold of the groin six and one-half inches, to a point on the upper thigh, on a level with the

perineum. The child walked easily, with much everted foot and a limp, a slight jog, quite noticeable, but which did not inconvenience or weary her in the least. There was no pain or tenderness about the joint. Her physical condition was excellent.

Remarks.—Compound dislocations of the hip are certainly rare. Malgaigne wrote that it had probably never occurred. Sir Astley Cooper had never seen one, but in his work "On Dislocations," Mr. Bransby Cooper gives a case of his own and records a second related by a former pupil, Dr. Walker of Charlestown, Mass. Hamilton adds one recorded by Wm. Taylor, and Stimson gives four others. These cases, briefly, are as follows:

CASE I. A healthy boy aged seventeen, attempted to kick a stone out of the way of his wagon-wheel. The wheel caught his left foot, forced him to the ground and passed over his right hip. The following day at Guy's Hospital, Mr. B. Cooper² found the head of the femur in the right groin, placed to the inner side of the femoral vessels, which he describes as "very unusual." An extensive lacerated wound was situated just below Poupart's ligament, a little to the inner side of the centre. The dislocation was reduced with pulleys, aided by the usual depletives. The wound became sloughy, suppurated profusely and the patient died in twenty days.

CASE II. Walker's³ patient was a very muscular man who fell from a wagon "laden with many tons of manure," upon his hands and knees. While in this position the wagon passed over the posterior part of his pelvis and right thigh, forcing the head of the femur out of the acetabulum upon the groin, and pressing the head through the integuments. After several vain attempts at reduction by extension, Dr. William Ingalls replaced the head by flexing the thigh on the pelvis, abducting and rotating inward, assisted by direct pressure on the head, with the thumb in the wound. "The reduction was effected with the greatest ease and elegance." Extensive suppuration again proved fatal to the the patient at the end of three weeks.

CASE III. A third case of compound pelvic dislocation is reported by a German military surgeon, name not given.⁴ An artillery man, galloping, fell with his horse in such a way as to bend his left leg forcibly backward, until the heel lay against the back of the shoulder. The head of the bone, with a portion of the round ligament, projected through the skin of the groin. The femoral vein was ruptured and bled profusely. He died the following day.

CASE IV. Taylor's⁵ case was a boy aged seventeen, who was engaged in sawing down a tree when it suddenly fell, pinning him to the ground. He extricated himself, and was found to have a dislocation of the hip with a lacerated wound of the perineum nearly two inches in length. Through this, the head of the femur was plainly felt lodged in the obturator foramen. The dislocation was reduced with some difficulty, and pelvis and leg fixed by a long straight splint. The method of reduction is not stated. The wound suppurated. A large abscess formed in the neighborhood of the hip, which was opened there, and which also discharged through the perineum. The wound healed well, and

⁵ W. F. Taylor: *Lancet*, 1881, p. 732.

at the end of five months he had left the hospital with the joint, as Taylor supposed, in a satisfactory way towards ankylosis. Eight months later, however, he met his patient riding on horseback seated in bushman style on a large colonial saddle. He could mount and dismount with ease, and suffered no inconvenience from the hip excepting a little occasional stiffness.

CASE V. Moxon's⁶ case was a railway porter knocked down violently by the train, while closing a door. Accounts of the accident varied. Some said he was caught between the train and platform; others that he was doubled up in some indescribable way. He was taken to Guy's Hospital, bleeding from a wound in the perineum, and died shortly after admission. It was said he had lost a great deal of blood. The left lower extremity was much swollen and discolored throughout its whole extent. The limb was in the position of dislocation onto the dorsum ilii. The wound was large, admitting several fingers, just under the fold of the gluteus maximus, its position corresponding to the junction of the left sacro-sciatic ligament with the tubus ischi. The head of the bone had escaped between the quadratus femoris and the obturator internus, and lay half an inch outside the great sciatic nerve, free under the remains of the glutei. A portion of the head with the round ligament was found in the socket. Besides a scalp wound there was nothing else discoverable. Death was attributed to hemorrhage and shock.

CASE VI. Woodward's⁷ case was also a railway accident. A boy aged twelve years was rolled over and over in front of a moving freight car, the wheels not passing over any part of his body except one toe, which was crushed. The head of the right femur projected about four inches through a wound two inches long on the inner side of the thigh, two and one-half inches below the angle of the pubes. The ligamentum teres had been torn away from the head of the bone. There was no fracture of femur or pelvis and the great vessels were not injured. Haemorrhage was slight. The patient had sustained other injuries, however, including several fractures, and died of shock in five hours. After death the dislocation could not be reduced, owing to the muscular attachments falling over the acetabulum.

CASE VII. Macouchy's⁸ case was a boy aged fourteen, who fell from the mast of a vessel to the deck, sixty feet. He was found sitting on the deck with the head of the femur appearing between his legs through his trousers, as if it protruded from the anus. The head, neck and great trochanter had protruded through the integuments covering the posterior third of the tuberosity of the ischium, the head resting on the posterior portion of the opposite ischium. Reduction had been tried and failed. The head was sawn off and the shaft replaced. The patient had sustained a fracture of the base of the skull in addition, and died two days later with the usual symptoms of compression.

We have in all, eight cases, five of which occurred between the ages of eight and seventeen years. Four of the eight died within forty-eight hours — two uncomplicated from haemorrhage, and two complicated with other injuries, from shock and compression of the brain. Of the remaining four, two died from the effect of prolonged suppuration — in eighteen and twenty-

one days — and two recovered, one with completely and one with partially ankylosed joint.

Four of the eight dislocations were of the pubic variety, two obturator, one dorsal and one ischiatic — a ratio⁹ exactly the reverse of what is generally accepted as the relative frequency of the uncomplicated varieties. This result is perhaps to be expected from the fact that the thinnest covering of the joint lies towards the pubes. In both the posterior dislocations as well as in both the obturator cases, the violence was certainly very great; as witnessed by the fact that three of the four died within two days of the immediate effect of their injuries, and in two of them the head of the bone was protruded four inches or more through the integument. It is worthy of remark that three of the four pubic cases were produced in identically the same way — namely, by the passage of a wagon wheel over the back of the thigh near the hip. The resulting hyperextension of the joint, and stretching of the integuments must have been important factors in producing this dislocation and in rendering it compound. It is not probable that the same degree of force applied to the front of the thigh would have rendered a dislocation compound posteriorly, if indeed the resultant of the forces produced a dislocation at all.

The occurrence of severe haemorrhage in four of the cases, with two deaths directly due to that cause, suggests the importance of ascertaining the position of the dislocated head with reference to the femoral vessels, especially in the pubic form, where they come in close proximity. In the case reported, the vessels were caught under the head, so that they might easily have been torn by rotating the head outward. The degree of difficulty, which may result from their close association, is well illustrated by the following set of cases of pubic dislocations, not compound:

(1) Sir Astley Cooper¹⁰ records the case of a man, aged thirty-six, knocked down by a cab, who sustained a dislocation of the left femur upon the pubes. "The head of the bone could be felt on the pubes, pressing Poupart's ligament upward, and was placed upon the femoral artery, so as to stop the pulsation."¹¹ No difficulty was experienced in this case, the pulsation returning after extension for about a quarter of an hour, the dislocation was ultimately reduced, and the patient made a perfect recovery.

(2) Stokes¹² was not so fortunate. His patient, a young man aged twenty-seven, had sustained a dislocation onto the pubes by falling off his team. Ether was administered, and the dislocation reduced. The patient died, at the end of the operation, of pulmonary embolism. At the post-mortem, a clot was found in the femoral vein, which had apparently been formed in consequence of the traumatism, and been detached by his efforts at reduction.

(3) The third case is that of Goldsmith:¹³ a man aged forty, in whom the head of femur was thrust under Poupart's ligament, over-riding the margin of the pelvis in such a way as to underlie the femoral artery. It remained unreduced for two months, when he came under observation with a diffused swelling occupying

the groin, filling the iliac fossa, and extending to the middle of the thigh; feeble pulsation, tumor appearing a few days after the accident; pain severe; diagnosis aneurism; treatment ligature of the common iliac artery; death on the fifth day. At the autopsy the femoral and external iliac arteries were found perforated to the extent of an inch on the postero-external aspect; the head of the femur lay in the cavity of the aneurism.

In view of the occurrence of such results, the importance of clearly ascertaining the relation of the dislocated head to the femoral vessels is manifest; and Stokes's case emphasizes the necessity of ascertaining the position before any attempts at reduction, and not after. I do not find any constant relation in the pubic form, although it has been so formulated by various writers. Sir Astley Cooper¹⁴ stated that in the ordinary pubic dislocation, "the head is situated upon the pubes, above the level of Poupart's ligament on the outer side of the femoral artery and vein." This observation was based on an autopsy in an old case of unreduced pubic dislocation. Of the ten cases of pubic dislocation which he quotes, the position is not noted in six. In one of the remaining four (the autopsy just referred to) the head lay to the outside; in the second, it lay to the inside — "very unusual" — he comments. In the third "the head of the bone had taken a course behind the femoral artery and rested in a space between the psoas and pectenous muscles"; and Mr. B. Cooper remarks that the position is "much more to the inner side than is usual in this dislocation, as the head of the bone is more frequently placed to the outer side of the femoral artery." In the fourth case, the head lay under the artery, stopping the pulsation, as already described. Of these ten cases, then, in one, the position of the head was noted to be on the outside, in one under the artery, and two on the inside, so that from the Cooper's own statistics, the inside position does not appear to be so "very unusual," and this is confirmed by other cases, demonstrated post-mortem, namely: In one, Aubrey¹⁵ found the head lying between the psoas and pectenous, raising the latter muscles, and with it the vessels. In a second¹⁶ the head was thrown upward resting against the outer side of the ilio-pectineal eminence, and had displaced the artery outward, so that it lay curved outwardly, below Poupart's ligament. In a third¹⁷ the vessels were found crossing the head, and in a fourth¹⁸ an old case, in which the neck of the femur had been fractured, the head was found on the inner side of the vessels.

From the cases quoted, then, it appears that (1) in pubic dislocation, a considerable danger may threaten the patient from injury to the femoral vessels; that (2) the relative position of the vessels and dislocated head are of interest with especial reference to efforts at reduction; but (3) their relative position is not constant; and (4) the position of the dislocated head with reference to the normal position of the vessels should give rise to no inference as to the actual position of the vessels, for, the head lying outside the normal situation of the vessels, may still have the vessels outside it.

It may be inferred that the careful location of the vessels should be the indispensable preliminary to any attempt at reduction, and that the primary manipulation should be directed towards freeing the vessels and head from a dangerous relationship.

REPORT OF FIFTY CATARACT EXTRactions BY A NEW METHOD.

BY DR. H. B. CHANDLER,
Assistant Surgeon Massachusetts Charitable Eye and Ear Infirmary.

BROADLY speaking, the operation for the removal of the cataractous lens may be divided into two distinct methods; with and without an iridectomy, modified to a certain extent by the will and pleasure of the operator. In my limited experience as an operator and observer, neither method has resulted altogether satisfactorily; but in many cases, far from it.

Those advocating an iridectomy claim that the mutilated iris and resulting coloboma forms no particular objection, as the lid covers it, and that the lens and cortical can more easily be removed, and that there is less tendency to iritis and loss of vitreous. On the other hand, promoters of simple extraction maintain that an operation allowing spherical aberration, and at times a large and distressing amount of light to enter the eye, is far from ideal.

There can be no doubt in the minds of those who have operated by both methods, that so far as the removal of the lens and cortical are concerned, it is just as satisfactory under one method as the other, if the operator takes the precaution of following the expressed lens by the cortical before the iris becomes replaced. There is also less danger from loss of vitreous in simple extraction, that is, so far as I have observed, the reason being obvious.

It is not, however, the loss of vitreous, difficulty with the lens, etc., which has induced some of our best operators to abandon the operation of simple extraction, but the far more important and decidedly unsatisfactory accidental complication of prolapsed or incarcerated iris.

To have a patient, more especially a private one, complain of irritation and gritty feeling in the eye, and on examination to find a prolapsed iris is, to use a mild expression, very annoying, not that the prolapsed iris and necessary excision results in any particular danger to the ultimate success as regards sight, but our simple extraction has proved a failure, and the moral effect on the patient of a second operation is bad, leaving out of consideration the disturbance of a partially united wound and a second chance of septic infection.

If we are fortunate in escaping a prolapsed iris, there is a chance of incarceration which, although not as unsatisfactory as prolapse to the operator, may eventually prove more so to the patient.

Very little has been written about this mishap. Even a small incarceration which shortly after an operation seems of trivial importance may be the source of irritation to an eye in after months. I have seen patients whose anterior synechiae were looked on as no particular misfortune, return with a misplaced pupil, and a tale of woe as regards irritation, and in some cases of considerable ciliary neuralgia.

The operation I now propose for your consideration, is one which I have attempted in fifty, and performed

in forty-seven cases without any selection of cases. Three of these, on account of numerous posterior synechiae necessitated an iridectomy. Although the number of cases is not large, I think it is sufficient to justify my claim, that simple extraction can be performed without any danger of subsequent prolapse, or incarcerated iris, leaving a round, central and movable pupil.

The operation is performed in the following manner: After making a corneal cut, exactly at the cornea-scleral junction, a very small piece of iris about one or two millimetres from the periphery is caught up, either by means of a fine iris forceps with teeth situated on the lower portion of the blade as near the point as possible, or by means of a sharp hook, the bent portion being at right angles and about one millimetre long, and gently drawn out, is cut horizontally as close to the gripping instrument as possible; this leaves a small round opening not more than one to two millimetres in diameter. The lens and cortical are now pressed out in the usual manner, particular care being taken that the cortical shall follow the lens before replacement of the iris takes place.

After removal of the pressure the iris usually replaces itself, if there is any difficulty, a Daviel's spoon or any other suitable instrument can be used for its replacement. A one per cent. solution of atropine sulphate is instilled and applied at each subsequent dressing. This small opening I have found amply sufficient to prevent prolapse or incarceration, and is invisible, except under careful examination.

The reason for making a small opening is to allow the free escape of the aqueous which collects behind the iris, otherwise when a sufficient quantity has been secreted, any movement of the eyeball inducing a gaping of the wound, is followed by a rush of aqueous and a washing out of the iris in some cases; for where the iris has some tone and the circular fibres strength to resist, it will not happen. The irides becoming prolapsed, or incarcerated are to be regarded as in a flaccid or limp condition.

The phenomenon may be practically demonstrated by performing simple extraction, allowing the anterior chamber to be partially refilled, and applying gentle pressure.

If, after reducing the iris a second time a small opening be made, no change in the condition of the iris will take place.

I remember a case some time ago in which a piece of steel had become imbedded in the tissue of the iris, and it was impossible to remove it without bringing the iris with it. I found I could not replace the iris, and after several futile attempts I was about to excise the prolapsed portion, when in place of doing so I made a small peripheral incision, after which I had no trouble in returning it, leaving a cosmetically perfect eye.

I have dwelt perhaps at length on the theory of the cause of prolapse. My reasons for this are, that it has been doubted as to whether the aqueous had any direct or indirect cause in its production.

The result obtained from this operation during convalescence has been much more satisfactory than those obtained from modified Graefe.

I have been pleasantly surprised at the slight amount of irritation and injection found on removal of the compress.

Slight secondary iritis has been the exception rather

than the rule, while the reverse has been my experience with the modified Graefe.

No tabulated statement has been deemed necessary in this article, as all were senile cataracts, the ages of the patients ranging from forty-five to eighty-four. Nothing abnormal took place either at the time of operation or during convalescence, except in a few of the cases as mentioned below.

Atropine was not instilled in the first fifteen cases until the third or fourth day, and as a consequence, the majority had two or three small filiform posterior synechiae which, although not interfering with the position or symmetry of the pupil, were readily revealed under a mydriatic.

In the later cases, atropine was used immediately after the operation and at each subsequent dressing, and although a few have had synechiae, the majority were perfectly free from any adhesion.

In one patient suffering from rheumatic arthritis, iris supervened on the fifth day, and although the result was satisfactory regarding direct vision, the pupil was small and the field so contracted, it was thought best to do an iridectomy. In another case atropine was omitted through a misunderstanding which resulted in blocked pupil. The patient has not returned for secondary operation.

In another case a small prolapse took place after union of the wound. This exception, however, rather proved the rule. On account of the restlessness of the patient it was doubtful whether an opening had been made, as I was unable to get the patient to look down; subsequent examination during convalescence revealed no opening.

The resulting vision tabulated below was taken in the majority of cases and at the time of discharge, two or three weeks after the operation, no second test having been made for improvement of vision. Subsequent examination would have doubtless given better results.

3 cases	Graefe's operation done.	

50

Secondary operation was performed in seven cases, and antiseptic precautions taken in all.

This operation, thus far, commends itself to me as liable to fewer accidents than any method at present employed, while furnishing as good results.

— A daily paper in Chicago announces that a practice tending to demoralize an important branch of the city service has been stopped. The Health Commissioner has issued an iron-clad order that henceforth all vaccination by the health inspectors shall be done upon the arms and not upon the legs. This action was found necessary because of the constantly increasing applications of young women who desired to be vaccinated upon the legs to avoid the slight scar on the arm, which would be visible on dress occasions.

Clinical Department.

A CASE OF HYDROPHOBIA.

IN THE SERVICE OF C. F. FOLSON, M.D., Visiting Physician, Boston City Hospital.

REPORTED BY H. G. WILBUR, M.D., House Physician.

A GERMAN, John K., aged fifty-three, a hortler, was admitted to the hospital September 3d. He was bitten by a dog in the thumb of the left hand on July 4th, two months previous while trying to separate two dogs that were fighting. A small cicatrix marked the site of the wound. The dog was not known to be rabid, but shortly afterwards it killed several pigs, and was shot by the owner of the pigs.

He is said to have been more or less worried about the bite, and feared that he would have hydrophobia. He was as well as usual, however, until the morning of September 3d, when he could eat nothing. On attempting to drink, he could not swallow. Later on he went to work in the stable, but in putting his hand into a pail of water to reach for a sponge, he started back exclaiming that the water frightened him.

On entering the hospital, nothing unusual was found; the physical examination was negative. Temperature normal, pulse slow and full. There was some difficulty in giving him his bath, he was so frightened at the water. He refused food. On giving him some milk he seemed frightened at the sight of it; we assured him that he could drink the milk. He took a little, and, on attempting to swallow, it came out of his mouth as if the pharyngeal muscles closed with a spasm and expelled it. His hands trembled, and there were violent movements of the arms and body with every effort to swallow. He was very thirsty, and with every effort to drink came these spasms; and he could, after repeated trials, swallow but very little of the milk.

The convulsions occurred with every effort to drink; they were not characteristic of any one thing. There was no retraction of the head, no especial movements, except trembling of the hands, rigidity of the abdominal muscles, and a few quick, involuntary motions of the body, and rapid respiration.

He was given an enema of bromide of potassium three times during the night, but he slept very little. On the morning of September 5th, I was called, and found the patient wildly excited and delirious. He wanted to get away; said that some one was going to kill him. Attempting to restrain him, he became furious, and the spasms were more frequent and violent. His lips were dry, and he complained of frequent thirst. The temperature then was 102°, respiration 34, pulse rapid, but of good strength, mouth and tongue extremely dry. Water was given him frequently, which he drank, but always with great effort and violent trembling. It was not possible to restrain him completely, and keep him in bed. It was noticed that he walked with great effort, his gait was very unsteady. From 6 A. M. until 4 P. M., when he died, the spasms increased in frequency and violence.

At ten o'clock he began to vomit, and there was a frothy exudation from the mouth, which was occasionally streaked with blood. He was delirious most of the time. He fancied he was driving a team or taking care of horses. As the spasms increased in violence, he was given:

Chloroform.	3 ss.
Chloral.	gr. xv.
Bromid. potas.	gr. xxx.

Every three hours, by enema.

The convulsions seemed to be excited by talking to him, as well as by the effort to drink. He vomited, at intervals of ten minutes, from about eleven o'clock until three. The vomitus, which at first was whitish and watery, became dark and granular — coffee ground — in appearance. It was frothy, and an occasional streak of fresh blood. Under the microscope the granular substance was shown to be blood. Free hydrochloric acid was shown by the Smaglgruin and the Tropaeolin tests.

The frothy and sticky exudation from the mouth and fauces became more abundant; the expectoration frequent and profuse. It was accompanied by a short, hollow cough. The mouth closed frequently with a quick snap. Several times he tried to bite the attendants as they wiped the froth from his mouth.

At one o'clock the temperature was 102.5°, pulse fairly full, but irregular and intermittent.

With each convolution there were tonic spasms of all the muscles; the abdominal muscles were very hard and resistant. The face was congested and bathed in perspiration. He was given brandy and water to drink; he swallowed with less effort than at first. There was frequent grating of the teeth. The delirium towards the end was continuous, there were no lucid moments. A peculiar smile was frequently repeated. The hands were markedly cyanosed and cold, and the spasms less frequent, one hour before death. The vomiting also gradually ceased; the temperature went up slowly, pulse became small and intermittent, and he laid down exhausted, no longer able to retain the upright position which, up to this time, he had kept. He had complained frequently of weakness and loss of power in the left arm. It was noticed that in the writhings and convulsive movements of the body and extremities, the left arm was quite powerless. Just at the end, the face became markedly cyanosed, and there were clonic spasms of the muscles of the jaw.

An autopsy, by Dr. H. F. Sears, assistant pathologist, on the following day revealed nothing except slight congestion of the medulla and rupture of small blood-vessels in the stomach.

On the same day, September 6th, Dr. Harold C. Ernst, of the Harvard Medical School, inoculated two rabbits with some emulsion made from the medulla. One rabbit died on the next day, from the wound made in trephining. The second showed on the 20th, fourteen days later, well marked symptoms of rabies, namely, paralysis of the posterior extremities, and, finally, paralysis of all the muscles, including those of deglutition and digestion. These are the characteristic symptoms of rabies in rabbits, and since they came on within fourteen days, the virus must have been especially powerful.

— Doctor (to patient). — "What ails you?"

Patient. — "Indeed, I don't know. I only know that I suffer."

"What kind of a life do you lead?"

"I work like an ox, I eat like a wolf, I am as tired as a dog, and I sleep like a horse."

"In that case I should advise you to consult a veterinary surgeon." — *Paris Paper*.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY,
SUFFOLK DISTRICT.
SECTION FOR CLINICAL MEDICINE, PATHOLOGY
AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

REGULAR Meeting, Wednesday, April 9, 1890, DR. A. L. MASON in the chair.

The Secretary read letters from Dr. Valentine Mott, and Dr. W. A. Dolan, of Fall River, Mass., expressing their regret at not being present. The latter gentleman had seen three cases of rabies within the year.

DR. HAROLD C. ERNST introduced the subject of

RABIES

by reading the following from the publications of the Pasteur Institute:¹

On the first of July, 1889, there was held at the Mansion House, under the presidency of the Lord-Mayor of London, a meeting for the discussion of the measures to be taken to prevent the spread of hydrophobia in England. After the reading of letters from the Prince of Wales, Stokes, Tyndall, Huxley, etc., the meeting adopted the following resolutions:

(1) The meeting is convinced of the efficacy of the anti-rabic treatment devised by M. Pasteur.

(2) The meeting desires to express to M. Pasteur and his collaborators, the thanks of Great Britain and Ireland for their generous aid to more than two hundred English, bitten by rabid dogs.

(3) The meeting requests the Lord-Mayor to start a fund for the double purpose of offering a suitable gratuity to the Institute Pasteur, and for the purpose of paying the expenses of British subjects who are unable to pay their own way to Paris.

(4) The meeting, whilst recognizing the value of the treatment of M. Pasteur, and taking measures for providing treatment for those bitten by rabid dogs in this country, are of the opinion that rabies may be made to disappear from these islands, and invites the Government to present without delay, a bill requiring the simultaneous muzzling of all dogs, — after the plan of the society for the suppression of rabies, and the establishment of a reasonable quarantine for all imported dogs.

(5) The meeting desires to offer its cordial thanks to the Lord-Mayor for the great interest that he has taken in this important work, and for having presided upon this occasion.

Dr. Ernst presented the views of Dr. Charles Schaffer, of Budapest, as follows:

After the period of incubation and the period of prodromes the manifestations of rabies are suddenly developed, during which, the following phenomena successively appear:

(1) In the first place appear the symptoms of inflammatory irritation of the spinal cord and the medulla oblongata: the inspiratory dyspnea, the dysphagia, the salivation, the spasm of the larynx, and the ariophobia, though they may all be very light. The pupils are at this time more dilated than normal, and react readily. At the moment when a peripheral irritation reaches them by the auditory nerve or from the surface of the skin, they dilate, and afterward

quickly contract, and this double movement repeats itself two or three times before it ceases. I have observed this phenomenon in many cases of rabies. It is chiefly manifested at the moment when the inflammatory irritation of the spinal cord, and of the medulla oblongata is most marked. Besides this the reflexes of sensorial character and those of the skin are much augmented. The pulse is frequent, as is the respiration, which is also irregular. The patient has hydrophobia, and turns and tosses without repose in his bed.

(2) The intelligence, which has till this time been undisturbed, is clouded, the patient has hallucinations of painful character, and is often violent. When he believes himself pursued he assumes an attitude of defence, or is even aggressive. He hears the voices of his friends, converses with them, etc. This is the period of delirium and it is not at all doubtful that during this time there predominates an irritation of the cortex of the brain. During the first and second periods, the general reflex irritability is found to be increased, as is indicated by the activity of the reflexes of the skin and the senses.

(3) After the delirium, that is to say, after the disturbance of the intelligence, appear the defects in the domain of motility. The patient has difficulty in walking, stumbles often; the legs can no longer bear up the weight of the body, and they fall. The picture is that of lumbar paraplegia, and this form of paraparesis betrays in the clearest manner its spinal origin. The irritability, which has increased until now, begins to diminish but does not disappear until the commencement of the fourth stage.

(4) Then appear the convulsive phenomena, accompanied by abundant salivation and frequent vomiting, during which the consciousness is lost. The patients pass urine involuntarily, and now and then the respiration takes the character of Chyne-Stokes, and in the midst of these manifestations which accompany the augmentation of the convulsive phenomena, and sometimes true tetanus, death occurs. It is plain that the convulsions correspond to cortical lesions when they present the form of clonic or general spasm.

In order to complete the picture, it is necessary to allude to the temperature in rabies. Ancient and modern authors agree in the opinion that rabies is a febrile affection. The fever presents no typical form, but is accompanied by morning remissions and evening exacerbations. There is a sudden rise in temperature previous to the exacerbation which ushers in the lethal ending of the disease. In a general way the occurrence of convulsions is one of the immediate precursors of a fatal ending of the disease.

These considerations allow the grouping of the phenomena of rabies into the following classes:

- (1) Period of incubation.
- (2) Period of rabid prodromata.
- (3) Period of nervous irritability (augmentation of the reflexes), comprising (a) manifestations originating in the spinobulbar region; (b) delirium (impairment of the cerebral cortex).
- (4) Period of termination, of death (reflexes diminished), comprising (a) paraplegia (cord), (b) convulsions (cerebral cortex).

Statistics obtained from the "Annales de l'Institut Pasteur" were given.

Class A includes those bitten by animals shown to

¹ Meeting at the Mansion House. Ann. de l'Inst. Pasteur, III, 303.

be mad by inoculation, or by the appearance of the disease in other animals bitten. Class B includes those bitten by animals shown to be mad by veterinary autopsy or by the symptoms. Class C includes those bitten by suspected animals.

Among the persons submitted to the treatment, many died immediately afterwards (in a day or two), and might fairly be taken out of the statistics, but are not. It would be fair to take from the statistics all those who developed symptoms before fifteen days after treatment, because this time is that required for the appearance of the disease in dogs after trephining.

Up to the time of the regular publication of the results in the "Annales de l'Institut Pasteur," the statistics of those inoculated run as follows:

	Bitten.	Died.	Per cent.
Class A	233	4	..
Class B	1,931	25	..
Class C	518	2	..
Total,	2,682	31	1.15+

	Bitten.	Died.	Per cent.
Class A	89	1	..
Class B	357	11	..
Class C	127	1	..
Total,	553	13	1.73+

This difference may possibly be ascribed to the longer time that those coming from foreign countries, passed before coming under treatment.

Combining all the cases reported, we have the enormous number of 8,666 persons who have been treated by this method, with 109 deaths recorded: that is, a mortality of 1.25% for the whole number treated. Total cases, Class A, 1,347; deaths 23, a percentage of 1.707+. Total cases, Classes A and B, 7,193; deaths 106, a percentage of 1.47+. Total cases, Class B, 5,846; deaths 83, a percentage of 1.419+.

Bordoni-Uffreduzzi's report to the Syndic of Turin, "Two Years of Pasteur's Cure,"² contains the following:

	Bitten.	Died.	Per cent.
Class A	162	6	..
Class B	137	4	..
Class C	23	0	..
Total,	322	10	3.10+

	Bitten.	Died.	Per cent.
Class A	79	0	..
Class B	108	0	..
Class C	22	0	..
Total,	209	0	0
Grand Total,	531	10	1.88

The same sort of comparative statistics can easily be worked out with the figures given by Pasteur, but it would have required a much longer time than it was possible to give to the preparation of this paper.

Certain Comparative Statistics of the "Simple" and "Intensive" Treatment.

Bites on the Head or Face.

Simple treatment . . . (A and B) 136 bitten 9 died = 6.61%

Intensive " . . . " 50 " 0 " = 0%

All Cases under Treatment.

Simple treatment . . . (A and B) 1,610 bitten 24 died = 1.48%

" . . . (C) 409 " 1 " = 0.24%

Intensive treatment . . . (A and B) 515 " 5 " = 0.97%

" . . . (C) 109 " 1 " = 0.91%

Statistics in regard to the Fatality of Bites without Pasteur's Treatment.

Twenty per cent is an altogether moderate estimate of the death-rate for persons bitten by rabid animals, except wolves, taking the cauterized and non-cauterized altogether.

The death-rate after wolf-bites is to be put down at sixty-five per cent., and the percentage after bites on the face and head, as high as eighty-eight per cent.

In July, 1886, Grancher made an extremely interesting comparison between the vaccine viruses of small-pox, splenic fever and rabies.

Small-Pox. Deaths before Jennerian vaccination, 500 in 1,000; after, 23 in 1,000. Preservative power of vaccination, 21.70%.

Splenic Fever. Figures gathered from over two hundred veterinary surgeons. Deaths before Pasteurian vaccination, 120 in 1,000; after, 5 in 1,000. Preservative power of vaccination, 24%.

Rabies. Statistics from Leblanc and Pasteur. Deaths before Pasteurian vaccination, 160 in 1,000; after, 7 in 1,000. Preservative power, 22.85%.

The duration of the immunity produced by these preventive inoculations, is a matter of much interest, and has been partially determined by Pasteur himself,³ who speaks of an experiment where fourteen dogs were inoculated by trephining with the full virus, after having been "protected" a year before; eleven of these resisted the inoculation. In another similar experiment, four out of six dogs resisted the same method of inoculation after two years from the protection of the method.

Pasteur also believes that the virus diminishes in quantity not in quality, and that the diminution of its effects is due to this fact and not to the gradual diminution in its intensity.

The duration of the period of incubation in rabbits or dogs after inoculation by trephining, is fifteen days — on very rare occasions it is as low as eleven days; then it diminishes after several series to eleven days; then to ten, nine, eight (after about eighty to one hundred series) and, finally, at the one hundred and thirty-third series (December, 1885), it had got down to seven days.

Hoegyes, of Buda Pesth,⁴ speaks of spontaneous cure as possible, on the ground of having seen one dog recover after the appearance of slight paralytic symptoms. He also thinks that immunity may be hereditary, because of his failing to produce the disease on the young of a dog upon which the protective inoculations had been practised.

To come nearer home. In the Legislature of this State, a short time ago, an offer of five hundred dollars was made for the proof of a single genuine case of rabies. At that very time four rabbits were dying in my care from inoculation with virus from a Newfoundland dog that was shot for rabies last January at Harvard Square. This animal bit six dogs, a horse and possibly a man. Two of the dogs came to me after they, too, had died, and both furnished proof of rabies. Last June another case came to my notice. The original rabid animal was shot, and the dogs it had bitten were killed by their masters. It would be better for the cause of medical science if animals suspected of rabies were not killed, but were kept con-

⁴ Ann. de l'Inst. Pasteur, III, 429.

fined and submitted to examination by a veterinarian or a physician. Lately the brain and cord of a man supposed to have died from rabies in Lowell were submitted to me. An emulsion was made and injected into a rabbit just two weeks ago. To-day the animal exhibited signs of dulness, which precede the true symptoms of rabies.

Dr. Ernst emphasized the need of precautions to prevent street curs from spreading rabies, which he feared was epidemic in this vicinity.

DR. RECORD, of Wollaston, reported a fatal case which came under his own care. On December 16, 1889, an Irish setter dog bit the boy who was in the habit of carrying the daily paper to the house. The owner, hearing of this, came home, and, while chastising the dog, was himself wounded; he does not think the dog bit him, but that he pushed his hand against his teeth.

After this the animal was chained, and on the following morning a neighbor, Mr. White, was bitten by the same dog. The accident occurred in this way: Mr. White came over at the request of his friend to help drive the dog into his kennel and nail him up. He was not afraid; and on his approach the dog barked, wagged his tail as usual, and seemed pleased to see him. After patting him he passed on up the steps; then the dog seized him, inflicting a deep wound in the palm of the hand one and one-fourth inches long, and one tooth-mark on the back.

These three persons came to me immediately and had their wounds cauterized.

The owner, a practical man, in fear lest his dog might be suffering from rabies, went to the city and consulted Mr. Watts and also visited the Harvard Veterinary School, located on Village Street. From the symptoms present he received the opinion at both places, that the dog was probably suffering from an inflamed stomach.

This man did not go to these places to satisfy an idle curiosity. He had heard of the treatment of Pasteur for the prevention of hydrophobia, and told Dr. Lyman of the Veterinary School, that he wished to subject himself to that treatment if the dog showed any of the symptoms of rabies. He was told that the symptoms did not in any way point to rabies—that he might keep the dog and await symptoms, or if the dog troubled him by barking, as there were no symptoms of rabies, he could kill the dog and send it to them for examination. The dog was troublesome. Where to shoot the animal was then the next question. The advice given again was that, the brain symptoms being so indistinct, and the stomach symptoms so distinct, the dog be shot in the head, and thus the stomach and bowels be preserved for examination. This was done, and the opinion previously expressed as to the inflamed stomach seemed to be substantiated, and this diagnosis was confirmed.

The man who was bitten was satisfied that there was no need of his being inoculated to prevent rabies.

The dog's history is this: a dog always cross, snapping at children whenever he came near them. Both his master and Mr. White noticed that some two weeks before the accidents, any little patting on the sides caused the animal to cry out as though he were hurt. On Sunday he refused food, and possibly water, certainly refused water Monday.

From Sunday to Wednesday evening, when he was shot, he refused all nourishment, being about four

days. He was on his chain until Wednesday morning, when he was driven under the porch where his kennel was, and nailed up. I saw him Tuesday night. There was nothing unusual in his appearance, except that he was uneasy and would drag himself along a little as though in pain, perhaps; no howling, no snapping, no paralysis, no frothing. When nailed up Wednesday morning he began to howl, and tried continually to dig himself out. His master says he would have done this at any time. Wednesday, about an hour before he was shot, his owner spoke quick to him and told him to get into his house; the dog immediately made a spring at the door and hit against it with great force. The post-mortem held at the Veterinary School proved to their satisfaction the opinion previously expressed. The alimentary canal was empty of all solid or liquid, except masses of the dog's own hair scattered throughout the intestines, and in the stomach a mass about four inches in diameter. It was thought that this must have been a long time in accumulating.

To recapitulate: a dog living four days, neither eating or drinking, no paroxysm of great fury, no saliva flowing from the mouth, no paralysis, and pronounced by good authority to be suffering from inflammation of the stomach.

To continue with the case of Mr. White: His wound healed kindly, and in due time he returned to his work.

On Wednesday, March 12, 1890, I was summoned to see him. He was bitten, you remember, December 17th, nearly three months before. On the Monday afternoon previous, while at his work in the shop, he went to the faucet for water, and found himself unable to drink—the first distinct symptom then was an inability to drink water. That afternoon or night he was taken with a pain in the right hand, (the seat of the wound), which ran up the arm, and had been more or less severe until I was called Wednesday morning. At this time he appeared somewhat excited, perfectly rational but talkative. He told me he could not drink water. I brought a glass to him and told him I thought he could drink it; but when I carried the glass towards him, he shuddered and asked me to wait. When he would start towards the water he seemed to be in a hurry. I quieted him, and finally I got him to take a number of swallows. It seemed, however, to bother him; and as he could take water from a spoon, we fed him in that way. At his suggestion, we got a straw for him to take water through, and they said he made this go very well. At this time, as I remember, he had practically no fever; his temperature was not above 100°, and his pulse not above 75.

Thursday and Friday his condition was about the same—simply an inability or difficulty in drinking water from a tumbler, excitement and loss of appetite being present; but I think every day I made him drink water from a tumbler. I know that Thursday or Friday night, a neighbor who had considerable influence over him induced him to drink from a goblet, by encouraging him, three swallows of water; which he did quietly and set the glass down.

I diagnosed the case as one of nervous hydrophobia. I have never seen a case of rabies; but I thought I found in Bryant's "Surgery" an exact description of the case under consideration. He says: "What Troussseau has called nervous hydrophobia—that is, true dysphagia brought on by a dread of rabies—may,

however, be mistaken for true hydrophobia; but the sudden invasion of the complaint, generally coming on through the person's recalling to mind or hearing the relation of a case of hydrophobia, and the duration of the dysphagia over a period of four days, are amply sufficient to characterize the complaint, and to enable the practitioner to persuade the patient that he is suffering from mere nervous symptoms, which will vanish as soon as he ceases to fear. Besides, in nervous hydrophobia there is dysphagia only, but no general convulsions, the spasm affecting the pharynx alone, while the breathing goes on with regularity."

Saturday morning there was a slight increase in the rapidity of the pulse, not going above 84, and the fever rose to 101°, other symptoms about the same; no desire for food, and more excitement. Saturday night, Dr. Gordon, of Quincy, was called in consultation. The patient then was greatly excited, talking continually but connectedly. Temperature 101°, pulse 85 to 90. The same symptoms that I have related existed — aversion to water, loss of appetite, excitement evincing itself in continual talk, no convulsions on attempt to drink, no violence, no appreciable amount of saliva, no sputation. The doctor concurred in the opinion I had given, and pronounced it a case of nervous hydrophobia.

Through Sunday and Monday the patient remained about the same, growing weaker but with no fever. He certainly took more or less liquid every day and some toast. Monday night his sister, who had just arrived and was a great favorite with him, induced him to eat the larger part of a cracker. There was then no fever Sunday and Monday, and his nurse thought there was none through the night Monday. Of this we cannot be sure. He was noticed towards morning to become more excited and grow feverish.

At my morning call Tuesday, he had a temperature taken under the tongue of 104°, and a pulse of 120, and was continually talking and excited. At this turn of affairs, I stayed with him for perhaps an hour. He became quiet; in fact there never was a time during his sickness when I could not calm him. At this time I fed him a slice of toast a third as large as the hand, made him drink from a tumbler two-thirds of a glass of milk and half a glass of water containing twenty-five grains of the bromide of potassium. I left him and he was quiet until I called again at two o'clock when I fed him as before about the same amount, but with less difficulty.

The symptoms thus far, and to the end, were not different from what they were at first or when Dr. Gordon saw the patient, except that there were greater prostration, higher fever, more excitement. The shuddering at the attempt to drink was not so great as at first. When he was forced to drink there was no asphyxia, but the trouble was with the pharynx, and also he would move his head from side to side and throw the water from his mouth, this not happening from a convulsion but appearing to be in a measure voluntary. I was led to this conclusion from the fact that, when the tumbler was held to his mouth he drank all its contents. There was no saliva in or about the mouth that ever attracted my attention, no spitting and no convolution.

Dr. Wm. B. C. Fifield of Dorchester, appeared in consultation at about five o'clock Tuesday, and pronounced the case one of true hydrophobia. The general symptoms appeared to me no different at this

time, except that it was evident that the man would probably die. The temperature under the tongue was 104°.

From this time there was a gradual failing until his death at five o'clock Wednesday morning, no salivation, spitting, or convulsion appearing even to the end; the symptoms present being aversion to water, pain in the hand, mania, death. The post-mortem performed by Dr. A. N. Blodgett, of Boston, showed no adequate cause for death, and the brain and spinal cord were immediately transferred to the bacteriological department of Harvard College.

Autopsy, twenty-nine hours after death. External temperature below freezing. Body of man about thirty-three years old, well developed and nourished. Rigor mortis well marked. Post-mortem lividity on dependent portions of body. A pale cicatrix, hardly visible in palm of right hand, following one of natural lines of the palm. A punctiform cicatrix on back of right thumb, with slight lividity in centre. No swelling or any pathological appearance on right hand or arm. Abdomen distended, resonant. No other external pathological appearances. Calvarium removed; translucent; nothing remarkable; membranes not engorged; dura reflected; no adhesions; nerve firm; rather less moisture than normal. Cord uncovered without rupture of membranes. No pathological appearance noticed *in situ*. Cord removed, from medulla to beginning of cauda equina without injury. Dura opened longitudinally; nothing remarkable noted. Body opened. Muscles well developed. Intestines filled with flatus. Lungs entirely collapsed; no fluid in pleural cavities. Stomach contained small amount of fluid. Spleen slightly smaller than normal. Pericardium contained about four drachms of fluid. Heart small, contracted, flabby, soft and friable; appears fatty; valves all right. Kidneys normal.

DR. A. N. BLODGETT: I feel that some apology is due to the Society for the very brief account of the autopsy, and I would state that it was made under circumstances which did not allow a sufficient time for so careful an examination as would under other circumstances have been made.

The appearances upon the body of the man, and those which were disclosed during the autopsy, were not indicative of any pathological process that I could discover, and I do not remember that any one present noticed the indications of any disease whatever; with the single exception of the appearance of the heart, which has been mentioned. The cause of death was not discovered at the autopsy. The condition of the heart was not sufficient, in my opinion, to produce a fatal result; and there were no other sufficient appearances evident at the autopsy (which was confined to the gross examination of the organs) which were sufficient to account for the death. The amount of cerebro-spinal fluid was less than ordinary, but I think that this can be accounted for by the diminished amount of fluid which the patient had taken during his sickness. This was the single, other pathological or unusual appearance which I noticed at that time.

DR. GEORGE H. THOMAS presented the following brief account of a case in Lowell, as it was observed by himself and others:

"Early one February morning before daylight, the patient, while going to the barn to feed a horse, was bitten quite severely on the hand by a stray dog which was not afterward seen. The wound was not dressed

by a surgeon for several hours, but eventually healed nicely. On a Thursday, some six weeks later, the man began to feel under the weather, but kept on with his work. Friday morning he complained of a tightness or constriction across the chest. Later in the day a choking sensation was felt upon swallowing. At first he could swallow a cracker better than he could liquids, and liquids better through a tube than in any other way. In the evening every attempt at swallowing set up severe laryngeal spasms, and, all of a sudden, the patient began to strike at his physician, trying to bite, and uttering unearthly screeches. These spells occurred at intervals through the night until, by the combined effect of exhaustion and medicine the patient became quiet. On Saturday he was suffering greatly from an increased secretion of saliva, which he could not swallow, and could only spit out with difficulty. At each attempt of the attendants to wipe the saliva from off the lips and chin, the patient would snap his jaws and would strike and kick as far as his bandages would allow. Any sudden noise in the room would produce these symptoms. The patient died from exhaustion on Saturday night after being confined to the house only two days.

"I should have added to the foregoing that the patient never feared the disease as a result of the bite, that during the illness there was hyperesthesia of the skin, that there were no tetanic symptoms and that the patient's mind was clear in the intervals of the paroxysms. Several physicians saw the case, and even those who were most skeptical went away convinced that it was a genuine case of rabies."

DR. JAMES B. FIELD, of the Lowell Board of Health: "Perhaps my own impressions on seeing Dr. Thomas's case the afternoon prior to his death may be interesting. I went there with the idea that it was not a case of rabies. I came away convinced from what little knowledge I had of the subject that it must be a case of rabies. I found this man lying back in the easy chair, confined there, mouth full of increased secretion of saliva; at all events on trying to swallow this he would have a spasm of choking, a sort of spasm of the larynx. On attempting to spit the saliva out of his mouth he made a noise which some people liken to the bark of a dog. It was not like that, nor like anything one usually hears. He could spit with difficulty, could get the saliva out on his lips or on his beard and attendants would then try to wipe it off. They would take a long piece of bandage and wipe carefully. Even on doing that he would snap at it involuntarily. At no time when I saw him was there any lock-jaw or suspicion of tetanus or anything of that nature. When the swab was inserted into the mouth to wipe out saliva he would snap his teeth on it. Any sudden noise in the room or motion of the body would start him to strike out with the hand, or to involuntarily snap the teeth together. I had known this man for several years; he was not of a nervous make-up, but rather of phlegmatic disposition. I don't think he had any false hydrophobia or could be scared into anything of the kind. All the doctors who saw him were extremely skeptical as to the diagnosis of the case and I think they all came away convinced that it was rabies.

"In a small city like Lowell, rabies produces more stir than in Boston. People say to me as a member of the Board of Health: 'What is the Board of Health going to do about it?' We came to the conclusion which Dr. Ernst has stated to-night that if anything

was to be done it could be done better by the Veterinarians than by any other way. They tell me that lately they have noticed several cases of what seemed to be true rabies in dogs. In one instance a lady was nursing a sick dog in her lap. A veterinary surgeon was called and found what he supposed to be rabies in the paralytic stage. If we could compel people to report sickness in dogs as in human beings, perhaps we could get something done."

DR. J. J. PUTNAM: I think we owe a great debt to Dr. Ernst for bringing so clearly before us the investigations of Pasteur. The whole study of rabies, as it seems to me, has entered on an entirely new stage. So far as I know the views of Pasteur are accepted by a very large proportion of men eminent in this department. Gowers, who has studied hydrophobia carefully and made microscopic examinations in many cases, has adopted them; and I have recently had the opportunity of talking with Dr. Welch of Baltimore, who certainly stands very near the head of our specialists in bacteriology in this country, and he fully believes in them.

What interests us as practical physicians are the diagnosis and the treatment of this affection. One or two points in the Wollaston case are, I think, interesting. It is said that straw and material of that sort was found in the dog's stomach. Gowers mentions that as one of the diagnostic marks of this condition in animals, — this peculiar tendency in the early stage of the disease to eat things of this kind. With regard to the inability to swallow water. That, I think, may be mentioned in connection with the general subject, the strongly marked mental disturbances and the peculiarity of the mental conditions in cases that are liable to be brought to our notice are certainly such as to mislead, and they have misled many observers and given rise, I feel sure, to the diagnosis of false hydrophobia in many cases. That is the opinion of Dr. Gowers, and he says persons do not very often die of insanity or hysteria in two or three days. In the case I wish to report I was misled and fancied that the disease was probably not one of hydrophobia.

Dr. Putnam then mentioned a case in East Cambridge, to which he was called in August, 1889. The patient, a boy, exhibited symptoms of hydrophobia. He was nervous and excited, complained of pains about the left shoulder and arm and the heart, refused food and drink, and died the same night in fearful agony. There was no record of his being bitten, but he was said to have played not long before with a strange Newfoundland dog. A small scar was found on his left wrist.

PROF. C. P. LYMAN: I wish to refer a moment to the Wollaston case. I regret very much that I am not able to give further particulars and more precise details than I am, but as I explain the matter you will perhaps not wonder at it. When first I knew of this case I heard a man describing with some degree of excitement, a case that had happened at his home; as a result of which he had been bitten, and also a neighbor of his, and altogether I gathered from the general manner that he was very much alarmed, I asked him to come to my office and relate the case. In his relation there was nothing which led me to believe that this was a case of rabies, except the fact that two men were bitten, and we know that dogs bite people when they are not mad. After talking to the man some time he believed, I think, that it was not rabies, but

at the same time he believed that he wanted to kill the dog at once. I urged him rather to lock him up in some secure place, telling him if he did so we could tell better whether it was rabies or not. I understood afterward that he confined him in the kennel and nailed him up. The dog barked a good deal and bothered him, and he shot him the next day or day after. Having shot him through the head with a rifle or revolver, he brought the carcass to the hospital. The head was so thoroughly shot that it was of no use to us. The stomach and bowels we found to be practically empty of all food. There was in the stomach a collection of hair, purely hair, I think. I believe I asked the question whether there were any sticks or straws mixed, and was told there were not. I believe there was in the stomach a hair-ball which is not a very unusual matter, perhaps, of egg shape about three and a half inches in its long diameter, and something like one and a half or two inches in its shorter diameter. Throughout the bowels there were scattered similar collections of hair. One in particular was in the rectum just at the anus, another higher up in the upper one-third of the rectum, and a small one somewhere about the duodenum. A little mucus was in the bowel. There is nothing about a post-mortem of that kind that would absolutely lead one to know that a dog had died of rabies. I may say that in addition to the hair-balls, etc., the mucous membrane of the stomach and intestine was very much reddened, that of the stomach particularly. It is true that in certain cases of rabies in dogs, after death the mucosæ will have the general appearance which it had in this case, will be found much injected. That redness is supposed in rabies to be especially prominent upon the folds of the membranes of the stomach.

So far as the presence of rabies in this neighborhood goes, I will say that ever since February or March of last year it has been within our knowledge at the hospital that something of the sort was among the dogs here about. In one of those months a pointer dog was brought in, exhibiting symptoms which led us to believe he might be rabid. He was put into a room by himself, and quickly developed more or less furious symptoms of rabies. He died in the course of three or four days. Since that time there have been brought to the hospital a great many dogs showing symptoms which would lead one to suppose they were affected with one or the other forms of rabies. I can't say, not having had time to look up the matter, how many dogs were treated, but I don't think there are less than thirty, and there may be considerably more than that. During all of that time there have been a number of cases which have had very interesting episodes connected with them. One is that to which Dr. Ernst has referred. He has given you the history of the Cambridge outbreak. This dog of whom no one knew anything went into the butcher's shop, was eating a bone very comfortably on the sidewalk. When he had finished with the bone, as I understand the matter, he raised himself up, looked about and fastening his eye, so to speak, upon a dog at some distance across Harvard Square, ran across and bit him, and went to another and another. Six dogs were bitten altogether I have heard at that time and I understand, though I did not get it as directly as I got the rest of the story, that a horse was bitten at the time. I did not understand that any man was bitten. The difference between my under-

standing and Dr. Ernst's was that there was no interval between the finishing the bone and commencing the biting. That is immaterial, however.

Of the dogs bitten by that dog, four came to us. The owner of two of them came to my office in the morning and related the history and said: "Do you think that dog was mad? If he was I want to do something to my dogs to make them safe." I told him there was nothing in the history to lead me to know he was rabid, but to set doubt aside he had better bring the dog to the hospital, and let us keep it until such time as the disease might show itself. He said he would do that and went away, but came back and said a policeman had shot the dog, and they buried it. I told him the best thing was to dig the dog up and send it to Dr. Ernst, and see if he could do anything with it, if things had not gone too far. To go on with the dogs brought to us. There were two of them at first. They were both sent to a farm where they had special care and treatment. A little while after that, another man, one of whose dogs were bitten, wanted us to take care of the dog, and see if anything came of it. He was advised to send the dog to Lincoln, Mass., but wanted us to keep him in the hospital. I think it was on the twenty-ninth day after he was bitten that he commenced showing symptoms of rabies, and died rabid a few days afterward. One or two days afterward the first dog which was a terrier died, his owner came into the office and said his other dog, a setter, showed symptoms which made him uneasy, and he wanted us to watch him. At the time his little dog was bitten, he asked his man whether the setter was bitten, and he said he was sure he was not. When the setter was taken sick, the man was asked again, and said that there was once when the dog went out a moment into the Square and he lost sight of him and that was the only time. However, the setter dog developed symptoms of rabies and died. The carcass of the terrier and setter were both sent to Dr. Ernst. He made inoculations from the brains of both of them, and they were profitable of result I think. The dogs that were sent to Lincoln were sent to a man who understands dogs and knew what sort of dogs he was taking under his charge, and he was given orders to report any illness of whatever nature, as soon as it occurred. He has not yet made any such report, that is to say, they are apparently well. I understand that the other two dogs which were bitten in Harvard Square, have died, exhibiting symptoms of rabies.

The period of incubation seems to have been in the terrier twenty-nine days, and in the setter thirty-eight days. In another very well authenticated case which has recently come to my knowledge, the incubation was forty-five days from the time of the bite until the first expression of the rabid symptoms. Speaking of the period of incubation from the statistics of one hundred and thirty-one cases, the disease appeared after the bite in twenty-five within thirty days; in thirty-one it appeared between the thirtieth and sixtieth days after the bite; in seven between the sixtieth and ninetieth days; in five between the ninetieth and one hundred and twentieth days, that is to say, sixty-eight out of one hundred and thirty dogs bitten by dogs known to be rabid, died. The rest at the end of four months were all apparently well.

I think veterinary surgeons generally regard forty-five per cent. as being about the number of escapes of

dogs bitten by animals known to be rabid. Of course a great many things have to be considered. In the case of human beings, if the bites are upon the hands or face, a much larger percentage are fatal than if the bites are made through the clothing. With dogs, those with thick heavy coats are much less apt to contract the disease, than those with thinner hair.

With regard to the popular opinion that warm weather produces rabies more abundantly than cold, all the statistics not only here, but elsewhere, show the opposite to be the case. Somewhere in February or March is the most prolific time.

So far as the symptoms of rabies in animals go, there seems to me to be some further need of description than is commonly found in relation to the matter to-day. It seems to me, that the symptoms as they are shown in dogs, clearly divide themselves into four heads instead of two. The division heretofore has been into *furious rabies* and *dumb rabies*. My own opinion of the matter is this: That certain animals develop rabies without any premonitory signs. Generally the first thing that we know is that the animal bites something or somebody and this form is quickly followed by death. I can illustrate that by relating a case that came to my knowledge two months ago. A man in Cambridge had a collie dog which was playing with his sister. She was throwing a ball to it, and he was bringing it to her, when instead of giving her the ball he bit her hand very slightly indeed. The teeth hardly went through the kid glove and made only an impression upon the skin. The man started to town with the dog, taking the precaution to order his carriage to follow behind him. He walked along the street, the dog following closely. He got along very well as far as the bridge. In passing a couple of men whom he said were tramps, the dog sprang at one and bit him in the leg through his trousers. The owner said: "I am sorry my dog has bitten you. Here are five dollars. Will that be enough?" The man replied: "Yes; I would be glad to be bitten again at that price." As he got into the carriage the dog made a grab for the owner. The owner grabbed the dog on each side of the neck and held him until he got to the hospital. When they got to the hospital I happened to be there and went out and saw a man with a very anxious face holding a dog. The man very quickly related the story. We got proper appliances and took the dog into the hospital placing him in a large stall where he could be conveniently watched. He would look out through the grate, wag his tail, his whole expression seeming to be "come and pat me" and if anything was put through he would grab it most furiously. He was full of agility and died without any premonitory signs. At six o'clock the second morning he was seen to be just the same as usual and at eight o'clock he was dead. During all that time he had not eaten.

The second form comes nearer to that described in the book. The dog begins by being dull, gets out of the way in a dark corner, snaps at imaginary objects in the air, and that goes along for a little while until finally the rabid state comes on and he goes about and bites various articles he comes in contact with. He won't always bite. After a period of frenzy in which he will bite he lies down and keeps still quite a while and then gets up and has another rabid attack and this continues until the dog becomes exhausted and paralyzed and dies.

In the next form there is simply dulness with loss of appetite, the ordinary symptoms of indigestion with paraplegia. Indigestion with paraplegic symptoms is not uncommon in dogs. The dog has a disposition to bite but bites very weakly indeed and has to be urged considerably to bite, has to be roused and then in biting he takes hold in a very half-hearted way.

In the fourth form there is loss of appetite followed by drooping jaw, barking. They will bite furiously at articles thrust at them. General paralysis and death from exhaustion follow.

It would seem to me that the term *paralytic rabies* would be very much better than dumb rabies, because in a number of cases of dumb rabies I have found the animals quite paralyzed.

As to this form of dumb or paralytic rabies the percentage of cases with us is very much greater than in the dumb condition of the furious form. In this last outbreak I think there were at least thirty animals. Of these there have only been three that were furiously rabid. The rest have had one or other of the paralytic forms of the disease. This experience is different from the European statistics. They give the dumb form in fifteen to twenty per cent. of the cases. You will realize that any dog that is paralytic is not as dangerous as one that is not; both being equally venomous. It may be that the slow spread of the disorder among our dogs as compared to what I suppose the spread to be in other countries may be accounted for in this way, that we have such a large percentage of the paralytic form of the disease.

Something has been said here regarding the management of rabies when an outbreak exists, as it undoubtedly now does. Who shall manage it? It has been suggested, on the one hand, that the Board of Health should do so. On the other hand, it has been suggested that the veterinary surgeons should do so. I would remind the gentlemen that veterinary surgeons are merely private individuals, and they do what they can in a quiet way to prevent ill results. I don't think any of us are disposed to go about and make much noise in the matter. Quietly, I think we do what we should do to prevent ill results coming from dogs of this kind. There seems to be a law in this State which would make it rather probable that the handling of this matter should be taken up by the Board of Cattle Commissioners. It would seem to me that they would form the proper authority to undertake, in the first instance at any rate, the management of this matter.

I should like to ask Dr. Putnam if he knows anything regarding the dog that bit this person whose case he reports?

DR. PUTNAM: The dog was a stray cur, and disappeared afterwards.

DR. ERNST: Of six dogs, which this dog in Harvard Square was known to bite, four are known to be dead. It would not be at all difficult to comprehend that this may be the continuation of the same virus.

DR. CUSHING: I understood Dr. Ernst to say that without treatment twenty per cent. of the cases die. Did he mean twenty per cent. take the disease, and all who take it die?

DR. ERNST: What I meant was that twenty per cent. of those bitten by animals known to be rabid die, not that twenty per cent. only take the disease and that all die, but twenty per cent. of those bitten die without reference to how many took the disease.

DR. CUSHING: How many cases proportionately do recover?

DR. ERNST: That is a point upon which I should pay no regard to the statistics published. Personally I feel that it is impossible to make an absolute diagnosis of rabies without the Pasteurian inoculation.

DR. PUTNAM: I would like to ask if one can't be as certain as in the great majority of diseases with which we have to deal, taking cases where death occurs in a few days?

DR. ERNST: I think that is very likely, but I think if you ask me such a question as that, I should have to say that our diagnosis from clinical signs is one of the most uncertain things with which we have to deal. I am speaking from the scientific point of view. We have a method of absolute certainty, and I believe that is the only absolute method.

DR. MASON: If there is to be an alarm in case of rabies, it seems to me we ought to know the number of cases this year as compared with previous years.

DR. ERNST: I only know the quoting of the statistics in reference to the muzzling of dogs, stating that there had been no deaths for twenty years, and Dr. Wolcott informed me that those were chosen years to prove a point. I do not wish to be understood as trying to start a scare. I have seen more cases this year than I have seen before, but I doubt whether there are many more cases. I think that medical men should be aware that there is such a disease. I know some of them do not believe in the existence of such a disease, and scoff at the question, and say that any dog which died of rabies died of indigestion. Now I think that any man who believes that ought to have the facts presented to him, and ought to have sufficient encouragement to stamp out the disease in ways much more efficient than by starting a scare.

PROFESSOR LYMAN: So far as the disease among dogs goes, I can say the hospital started about 1883, and that there was nothing simulating a case of rabies until February or March of last year. The outbreak I saw before was in 1876 or 1877, or in both years.

I am surprised to hear that veterinarians hold to the idea that rabies is a disease that exists in the imagination only. I have never known but one veterinarian who held to that idea, and he seemed to have pretty good reason for it. Several years ago he started for Europe with children bitten by a dog supposed to have been mad, and found, on his return, that the dog was well and hearty.

DR. MASON: Hydrophobia seems to be very rare in this community at present, but in 1875 or 1876 there was a slight epidemic, and I believe at that time there were, perhaps, three cases within a year or two occurring in this vicinity. I think since the City Hospital was inaugurated, twenty-five years ago, there has not been a single case inside the hospital, or in the out-patient department. It is to be hoped that the present epidemic will last no longer than the previous one to which Dr. Lyman referred.

—"School Life in Relation to Growth and Health" is the title of a paper by Prof. Axel Key, of Stockholm, to be published in the November *Popular Science Monthly*. Professor Key maintains that the studies of children, as now ordered, do not allow enough time for rest and growth, and urges a reform in this respect.

AMERICAN GYNECOLOGICAL SOCIETY.¹

CONTINUATION OF THE DISCUSSION ON ECTOPIC PREGNANCY.

DR. HOWARD A. KELLY: of Baltimore, referred to Mauriceau's case of extra-uterine pregnancy in 1669, described as follows: "History of a woman in whose abdomen there was found, after death, a small fetus about two and a half inches long, together with a great quantity of coagulated blood." The woman had borne eleven children at term, but in the twelfth pregnancy at two and a half months, the uterus dilated in the direction of the right horn and ruptured. It was thought by many to be a true tubal pregnancy, and cited as an instance of retention of an ova in the tube, becoming fecundated, but subsequently going on to gestation within the tube, and final rupture. Mauriceau called it a hernia from the uterine body proper, and was much opposed to its being called a tubal pregnancy, which it was not. It was plainly a case of pregnancy in a rudimentary cornu uteri demonstrated by a small bridge of tissue between the fetal sac and the uterus; decidedly not a tubal pregnancy, because the round ligament of the right side was displaced downwards.

In the last century there was much excellent work done in this direction. The best plates ever published on abdominal extra-uterine pregnancy, were by Deutsch, in 1792, showing the fetus, life size, in the belly of the mother, attached by the cord to the placenta which is implanted low down in the abdominal cavity.

The speaker believed it was possible to recognize the following forms of extra-uterine pregnancy: (1) Interstitial, (2) tubal, (3) tubo-ovarian (doubtful), (4) ovarian (proven beyond a doubt by the cases of Gottschalk in the *Centralblatt* 1886, Patenka, Leopold and Spiedelberg), (5) primary abdominal (remaining to be proved). The tubal may be divided into (a) isthmal; (b) isthmio-ampullar; (c) ampullar, according to their relative position in the tube.

The critique of ovarian pregnancy: an extra-uterine fetal sac, which must have the same relation to the uterus as the ovary maintains; the tube must remain intact, and the ovarian ligament connecting the side of the sac with the uterus, must be present. The ovarian ligament is as important to the establishing of ovarian pregnancy, as the round ligament is to that of interstitial pregnancy.

In a case five months beyond term, recently operated upon in the Johns Hopkins Hospital, by Dr. Robb, which proved beyond question to be an unruptured tubal pregnancy, ovarian tissue was present in the sac wall, which goes to show that the mere evidence of ovarian tissue in the walls of the sac is not conclusive of ovarian pregnancy.

It is interesting to note how the men, who claimed no diagnosis could be made, have shifted their ground since so many positive diagnoses have been made, and now say that diagnosis cannot be made before rupture. Very few cases are seen before rupture, but the following case was diagnosticated by the speaker, and seen by Dr. Robb before rupture, and operated upon with removal of the unruptured sac:

Mrs. B., aged twenty-two, had been married three years, had had one child and one premature still-birth.

¹ Fifteenth Annual Meeting, Buffalo, N. Y., September 16-18, 1890. Continued from page 353 of the Journal.

Came under observation early in December, 1885. Had menstruated regularly up to July previous, but from that time to middle of November she had not menstruated. Menstruation began again in the middle of November with the discharge of "a piece of flesh," as she termed it, and with the re-establishment of menstruation she was relieved of severe pain arising from a lump low down on the right side, from which she had suffered constantly since early in October. First examination showed a very smooth, tense, elongated tumor, anterior to the cervix, lying far back in the sacral hollow; it could be easily felt over the whole extent of the anterior vaginal wall, extending above half way to the umbilicus, presenting a peculiar tense fluctuating feeling; uterus small and retroverted, reclining in the hollow of the sacrum. At her next visit she thought herself pregnant. The uterus could not be felt so clearly, and the case presented the appearance of extreme anteflexion of a pregnant uterus. After this she had several bloody discharges up to March 8th, when she had regular flow for five days. At this time a tense ovoid cyst could be felt through the anterior vaginal wall on the right side, its axis in the plane of superior strait, anterior extremity at symphysis pubis to the right, posterior extremity at right cornu uteri; connected by short pedicle to the uterus; sensitive, smooth, and had remarkable rubber-ball elastic feeling, much tenderness low down on left side, where there is an indistinct worm feeling about the retrosposed cornu uteri. The tumor had diminished remarkably in size while under observation. Diagnosis of extra uterine pregnancy positively made, and operation performed in presence of five other gentlemen.

In these cases it is always best to assume that the worst condition is present until by proof it is excluded.

The most recent case in which diagnosis was correctly made before operation was in the practice of the speaker, at the Johns Hopkins Hospital, before thirty-two witnesses, confirmed by operation, removing well developed fetus from the abdominal cavity, where it had escaped from a ruptured tube. Diagnosis can be positively made if the following symptoms are present: (1) Cessation of menstruation followed by irregular recurrence. (2) Pain in the lower part of the abdomen. (3) Fluctuating tumor. (4) Enlarged uterus (not always present). (5) Discharge of membrane, which is very characteristic. (6) Milk in the breasts. (7) Tumor diminishing in size under observation, a pathognomonic sign rarely present, unless electricity be used, which, of course, implies death of the fetus.

There is another class of doubtful cases where some of the symptoms are present, and still another class of uncertain cases where there are no signs, and which are generally discovered accidentally. If he finds a freely movable tumor in the abdomen, he would perform laparotomy; but if the tumor has ruptured into the broad ligament, he would use electricity, and wait for results up to the end of the third month. He would not consider the life of the fetus to the detriment of the life of the mother, but consider the fetus simply as a malignant foreign body. If he had a living fetus at term, he would open the abdomen; and if it proved to be an unruptured tube, with the placenta enucleated in the sac, the latter could be removed, and the life of the fetus saved. If the placenta were attached to the intestines, he would remove the fetus, and drop the fusi back into the abdominal cavity, and later perform laparotomy if necessary.

DR. HUNTER ROBB, of Philadelphia, believed that the tubes were the most frequent site of fecundation, that ovarian pregnancies do take place, and agreed with Dr. Jaggard that microscopical examination is alone reliable in determining this condition. He believed the diagnosis as easy as that of fibroid or parovarian cyst. He corroborated Dr. Kelly's cases.

DR. JOSEPH TABER JOHNSON, of Washington, remarked that the paper of Dr. Hanks, read before the Society in 1888, gives the history of eleven cases, with the statement that diagnosis ought to be possible in ninety or ninety-five per cent. of all cases; that he believes in electricity in the beginning, and operation afterwards if necessary. He thinks electricity will kill the fetus, and that in all cases of rupture the operation should be done at once.

DR. A. H. BUCKMASTER, of Brooklyn, thought it would be a fatal blow to the use of electricity in these cases if it should be proved that it could not accomplish the destruction of the fetus. In reply to Dr. Baldy's accusation that he had, with twenty milliamperes, failed to kill the fetus, he said that there was a large fibroid tumor present, through which the current was passed, and that very little could reach the fetus *in utero*; that it is unfair to assume that, because the current applied at a point outside the fetus in the uterus failed to kill, that it would not destroy the fetus in the tube, and that it was not a case to be quoted against the use of electricity.

DR. J. A. TEMPLE, of Toronto, related a case of extra uterine gestation on which he operated, and removed the tumor and tube without rupture. Patient made good recovery, and stitches were taken out on sixth day. On the eighth day she had a severe attack of mania, and talked incessantly day and night for three days, resisting all methods of treatment. On the twelfth day she became semi-comatose, did not recover consciousness, and died on the twenty-third day perfectly insensible. Passed abundance of urine during convalescence, which showed no traces of albumen, no symptoms of paralysis present. Fed with stomach tube for eleven days. He was confident the patient did not die from septicemia or other similar affection as the result of the operation, which, he believed, was a case which had every indication for such a procedure, but that she died from some unknown cause. No post-mortem could be obtained.

DR. MATTHEW D. MANN, of Buffalo, reiterated the views expressed in his paper in regard to the specimen which he presented two years ago, and notwithstanding Dr. Johnston's doubts of its genuineness, he still held it to be a true ovarian pregnancy. His opinion in regard to the use of electricity in properly elected cases was also unchanged.

DR. A. W. JOHNSTONE, of Cincinnati, doubts the existence of ovarian pregnancy, and believes he has never seen a true case. He believes the electrical treatment subjects the patients to all the recurrent evils of pelvic disease, and the only safe method is to cut in and clear everything away without delay.

AFTERNOON SESSION.

A paper by Dr. Andrew F. Currier, of New York, on

UNDER WHAT CONDITIONS CAN ELECTRICITY BE OF
POSITIVE SERVICE TO THE GYNECOLOGIST?
was read by title.

DR. E. C. DUDLEY, of Chicago, read

IN MEMORIAM — DR. WILLIAM H. BYFORD.

DR. W. C. FORD, of Utica, read a paper on the
QUESTION OF AMPÉRAGE IN THE TREATMENT OF
FIBROID TUMORS BY ELECTRICITY.

Myomatous growths are easily managed by galvanism. They are of comparatively low resistance, a very large and hard one offering but 300 ohms. The question has been asked, "What happens when the current passes through fibroid mass?" Simply the separation of the fluids in this mass and their reformation into different chemical combinations which interfere with the intra-uterine existence of the growth. This is merely a process of electrolysis. The current necessary to produce this electrolysis is not one of tension, but of volume or quantity, and this depends entirely on the cell which is used. The small bichromate of potash battery with a single plate of zinc and carbon which we find so much in use, unless a very large number of cells are employed does not give sufficient volume, has not sufficient ampérage to effect the necessary electrolysis, but by using a larger cell having a zinc plate between two good sized carbon plates, say (7×2), we get a greater surface exposed for chemical action and hence a greater volume, or ampérage of current, which affords sufficient electrolytic action to decompose the fluids of the fibroid tumor and arrest its growth, but with high tension and low ampérage as in the small cell battery, this result cannot be accomplished without employing a great number of cells. The latter has an electro-chemical action or cauterizing action, while the former produces simple electrolysis.

He uses the negative or active electrode in the uterus and positive electrode externally over the abdominal wall. His uterine electrode consists of a pure platinum needle with a blunt end like Apostoli's needle. He has also used the gas carbon electrode. For an abdominal electrode a plate of copper, covered with punk is substituted for Apostoli's clay electrode. The plates are of all sizes. The fluids of the tumor decompose at the internal negation electrode and bubble up and run out over the electrode in sufficient quantity to be caught in a spoon speculum, after a few minutes application, if the current have the proper ampérage. The author has accomplished this with a battery of fifteen of the large bichromate of potash cells referred to. The fluid of the tumor has an intense chlorine smell, and is strongly alkaline. The current is well distributed by the abdominal electrode, and there is no risk of blistering the abdomen as there is absolutely no cauterization produced.

The author was convinced that the cure of these fibroids by electricity could be brought about in no other way than by having a sufficient volume of electricity carried by the electrode to produce perfect electrolysis.

(To be continued.)

— Women who practise medicine suffer from inconveniences at times, as for instance: A man rang a door bell of a female physician at night, crying: "Quick! Tell the doctor to hurry, as my wife is about to be confined." Then the husband of the female physician, who had opened the door, responded: "It is impossible for the doctor to go at this moment. She is about to be confined herself."

THE PATHOLOGY OF INFLAMMATION.

INFLAMMATION PRIMARILY DUE TO A MORBID ALTERATION OF THE BLOOD-VESSELS.

EARLY in this century, Broussais, Andral and Brown taught the irritability theory of inflammation. The natural irritability of the tissues is manifested in all the physiological processes, in fact, life is itself but the incessant reaction of the anatomical elements against irritant agents, external and internal; inflammation is nothing but the product of an irritation more intense than is compatible with the normal state.

The most distinguished advocate of this doctrine is Virchow. According to the view enunciated in his cellular pathology, inflammation consists essentially in a hyper-activity of nutrition. An abnormal stimulus acts upon the living elements of a part, either directly or through the medium of the blood, in such a way as to cause them to attract to themselves and absorb a larger quantity of nutritive matter than usual. As result, changes in the composition of the part take place, which render it less capable of performing its functions.

Burdon-Sanderson, in his Lumleian lectures, 1882, emphasizes these textural alterations, while rejecting the hyper-nutrition theory. The essential nature of inflammation is expressed in the words injury and damage; the tissue changes cannot be regarded simply as a modification of normal processes. We have not merely disorder of function, but arrest. Inflammation is a phenomenon of diminished or destroyed vitality. Stasis is the mechanism by which inflammation kills. As regards stasis, the first stage is retardation, and this is due to widening of the blood-vessels. They dilate because they have lost their tone, that is, are damaged in their vital properties. Slowing of the stream is the essential condition of exudation and emigration.

Sanderson describes the part which bacteria have in the changes attending inflammation. The damaged tissue becomes a fit breeding place for micro-organisms, and they are the mischief spreaders. They have generally a secondary rôle, though in the infective inflam-

mations their rôle is that of direct causation, here they are the phlogogenous agents. Sanderson had made many careful observations of the inflamed cornea, chloride of zinc being the caustic irritant employed. The results were thus recorded: "No reaction, no perverted nutrition, nothing but damage, which might be compared to that which a corrosive liquid would do to a watch." The truly inflammatory phenomena are due to the participation in the injury of the adjoining marginal blood-vessels.

A careful study of these Lumleian lectures shows that the leading idea is substantially the same as that taught for many years by the late Julius Cohnheim, and formulated in his lectures on "General Pathology," a translation of which has been published this year by the Sydenham Society.

Cohnheim considers the numerous theories which have been adopted to explain inflammation. The neuro-humoral theory has had many illustrious advocates; it presents itself in two modified forms, an ischaemic and a paralytic. According to the former, it is to the contraction of the afferent arteries of a part, reflexly called forth by the excitation of sensory nerves, that the slowing of the capillary stream is due. According to the second, it is a reflex relaxation and dilatation of the arteries that occasions the inflammatory hyperemia. Now, narrowing of the arteries, Cohnheim says, can only produce anaemia, or, when extreme, necrosis. With respect to active hyperemia, it can only exceptionally give rise to exudation. Moreover, it has been proved that parts unconnected with the remainder of the body, except by means of their principal vessels, may undergo inflammation. In the frog, the tongue may become inflamed, even when the brain and medulla oblongata are completely destroyed. An eye whose trigeminus is paralyzed, or an extremity with complete paralysis of sensation and motion, is not for this reason inflamed, nor is it by any means protected against inflammation.

The cellular theory of inflammation presupposes an attraction of the tissues or tissue-cells on the vessels and their contents; the tissue-cells swell and enlarge, and give birth to new cells, the pus corpuscles. Such an attractive influence, says Cohnheim, could at most relate only to fluids, in the case of which we are acquainted with certain analogies in the phenomena of diffusion. But how the tissue-cells have the ability to entice colorless or red corpuscles out of the vessels is not readily comprehended. Add to this, that it can be shown with absolute certainty that in many instances, not only is marked hyperemia present, but also very considerable transudation, before the slightest change has occurred in the tissue-cells. These cells are indeed in many cases deeply affected by the causes of inflammation, and such as have survived the actual onslaught of the exciter of the inflammation must very often subsequently succumb to disintegration — necrosis. These cells, however, according to Cohnheim, do not form pus cells, which are, in all instances, extravasated leucocytes which have become dead.

If, then, inflammation begins neither in the nervous system nor in the anatomical elements of the part, the process must start in the blood-vessels. Here we come to the fundamental conception of inflammation (a conception for which we are indebted to Cohnheim) as the expression and consequence of a molecular alteration in the vessel walls. By this alteration, adhesion between the vessel wall and the blood, and in consequence, friction is increased; the result is the retardation of the blood stream within the inflamed district. On the other hand, the permeability, the porosity of the walls is augmented by the molecular change; the result is an increase of transudation and of the albuminous contents, as well as the admixture of colorless and red corpuscles with the transuded fluid. The inflammatory product is a true genuine filtrate, that is, a fluid which has passed through the actual pores of the filter, and not through new stomata in the intercellular cement; only the chemical alteration in the vessel wall has made the natural pores a little coarser, so as to let through more colloid substance along with leucocytes and red corpuscles. The exit of leucocytes does not depend on spontaneous movements (as some have taught), but is a mere process of mechanical filtration.

As for the causes of inflammation, it may be affirmed that every agency by which the chemical constitution of the vessel walls is at all altered, and which, on the other hand, is not so powerful as to bring about the death of the vessels, is capable of producing an inflammation of the part of the body concerned. Causes may be classed under three principal heads, as traumatic, toxic and infective. The agencies capable of injuriously affecting the vessel wall are multiple.

But little that is new has been added with reference to the cardinal symptoms and signs of inflammation which have been recognized in all ages. That which especially distinguishes inflammation from active or passive hyperemia is certainly the exudation; on this point all are agreed. What we owe especially to Cohnheim is the demonstration that it is only the vessel wall which is responsible for the entire series of events in inflammation. That we are not dealing with an action on the blood, says this writer, is evident *a priori*, for the blood is continually in motion, and can never be more than momentarily exposed to the local action. The vaso-motor nerves may with equal certainty be excluded. The fact that the vessels are wont, under the influence of the agents employed by us, to dilate very much more than is ever the case in paralysis of the vaso-constrictors or stimulation of the vaso-dilators, seems to weigh against this participation. Thus, the dilatation and injection of the rabbit's ear, following division of the corresponding sympathetic, increases considerably on painting it with croton oil or on introducing it into hot water. Moreover, all the effects that have been described set in, in precisely the same way and with equal promptitude, in parts deprived of all connection with the central nervous system. Lastly, we have not to do with an action or re-

action of the tissues surrounding the vessels. For no alterations are observed in the latter except, at most, such as are of a deleterious character, as, for example, coagulation or rupture of the muscle-fibres, stoppage of the whipping motion in the ciliated epithelium of the tongue, and the like; "we are, therefore, compelled by exclusion, to come back to the vessel walls as the essential originating focus. According to this view, then, we have here to deal with a molecular change of the vessel walls, whose highest degree involves the death of the latter, but whose slighter degrees, on the other hand, call forth a certain typical series of abnormal events in connection with the motion of the blood and the transudation. The sum total of these events, together with their consequences, have been for ages comprised under the notion and name of inflammation."

A PLEA FOR CONSERVATISM IN MINOR GYNECOLOGY.

THAT there is too much minor gynecology at the present day is a very common opinion, especially among those who see much serious pelvic disease. A plea for greater conservatism was lately made by Dr. Joseph Price before the Philadelphia County Medical Society, and was sympathetically received by the gentlemen taking part in the discussion.

Many cases of major pelvic trouble are due to minor operations, which have become the fashion to such an extent that they are often looked upon as routine treatment by a large class of practitioners of more or less limited gynecological training. But diagnosis in the pelvis is difficult, dormant or unrecognized pelvic inflammation is not infrequently lighted up by an apparently trivial procedure and the foundation laid for a future laparotomy.

Emmet himself has called attention to the dangers of his cervical operation except in carefully selected cases. Many patients are left in a worse condition after the repair of the cervix than they were in before. It should not be undertaken except in case of absolute necessity until the absence of any pre-existing pelvic disease has been ascertained.

Another favorite operation which is much abused is the forcible dilatation of the cervix. Dysmenorrhoea is not relieved by this process unless it be due to actual stenosis of the os or cervix, but many women with what might be considered a stenosis of the os have no dysmenorrhoea. A very small opening is all that is required for menstrual drainage. It is therefore necessary to make a careful study of all symptoms before concluding that the trouble is due to obstruction to the flow. Although relief is often obtained, it should be borne in mind that forcible dilatation is a distinct traumatism, and as such is never entirely free from danger.

The uterine sound is responsible for much inflammatory pelvic trouble, especially since it has become a common instrument for diagnosis and is a particular favorite of the less skilful examiner, although nearly discarded by many men of larger experience.

A strong objection to the use of electricity by the tyro is the mechanical disturbance due to the frequent and careless introduction of the sound and electrode. The curette also, although a valuable instrument, has been the indirect as well as direct source of a long list of victims. And finally the routine treatment by caustic intra-uterine injections has often hastened, if not caused, pelvic inflammatory trouble leading at last to abdominal section.

MEDICAL NOTES.

— According to official returns from Spain, 1,814 fresh cases of cholera and 959 deaths occurred during the month of September, thus bringing the totals since the beginning of the epidemic up to 4,870 attacks with 2,516 deaths.

— The Belgian Parliament has recently passed the following law restricting the practice of hypnotism:

SECTION 1. Any one who exhibits in public a hypnotized person shall be punished by imprisonment for not less than fourteen days, nor more than three months, and a fine of from twenty six to one thousand francs.

SECT. 2. Any one not licensed to practise medicine who hypnotizes a person under eighteen years of age, or a person of unsound mind, even if such person is not in any way exhibited in public, shall be punished by imprisonment of not less than fourteen days nor more than a year, and a fine of from twenty-six to one thousand francs.

SECT. 3. Any one, who with fraudulent or malicious intent, allows a hypnotized person to write or sign a document of any nature shall be punishable by imprisonment with hard labor. The same punishment applies to any person who makes use of such a document."

— A warning comes from New Zealand which it may be well to bear in mind in this country also. Dr. Trevor (Ashburton) writes to the Christchurch editor of the *New Zealand Medical Journal*:

"I have been intending to ask you for some time past to warn the profession, through the *New Zealand Medical Journal*, of the danger they run in using hypodermic syringes made in France or Germany. They are not marked for English measurement, although it looks exactly the same, but on measurement 5 m. is exactly 10 m. English measurement. I found this in one I obtained for the hospital, and on examination of the stock kept by the chemist, they were nearly all the same. The wholesale firm from whom they were obtained, stated they had sold a great number of the same kind. There is nothing to distinguish them from others with English measurement, consequently I fear serious mistakes must happen."

— Dr. Cheeves Bevill, of Winfield, Ark., reports (*Medical Record*, September 27, 1890) the case of a woman, about twenty-five years of age, who was in the fifth month of pregnancy, and was suffering from prolapse of the uterus. A physician had ordered an in-

jection of lead-water or alum, and this was given by the husband of the woman. After about two ounces of the wash had been thrown into the vagina, the patient raised herself up, exclaiming, "I feel so funny," and sank back and died.

— In New Orleans the women of the "Unsectarian Aid Society" have for the past three years carried on a training-school for nurses. They have decided to open, in connection with the school, a hospital for women and children, which shall be available for poor as well as for paying patients. Any physician will be permitted to send a patient there, and can continue in charge of the case. The nursing will be done by the nurses of the training-school. The Society will devote all its efforts to furthering the interests of the new establishment, but will also appoint an advisory board of business men to assist in the management, and work will be begun at once. It is expected that the place will be ready by November 1st. In the meantime subscriptions, even of small amounts, are sought. For the present, two large houses are hired, and the necessary changes in them will be made, but it is expected that in the near future suitable buildings will be erected.

NEW ENGLAND.

— The Boston daily papers warn the physicians of the city to look out for a man who calls at doctor's offices and says that he will wait. He does not wait, but leaves with anything which happens to take his fancy. He has lately been at work at the South End.

— A citizen will bring suit against the city of Salem to recover damages for a case of typhoid fever alleged to have been caused by the offensive contents of a barn cellar on the adjoining estate. The plaintiff's wife was taken with the fever and is now seriously ill. The attention of the Board of Health has been repeatedly called to this cellar, but the nuisance was not permanently abated until after the outbreak of the disease, when, by order of the Board of Health, the cellar was filled up.

— The Connecticut Medical Society is making preparations to observe its centennial anniversary in 1892. Dr. Gordon W. Russell of Hartford, has been invited to prepare a medical history of the Colony and State previous to 1792, and Dr. Francis Bacon of New Haven, is to write the history subsequent to that date.

NEW YORK.

— Chief Engineer Fteley of the Croton Aqueduct, has presented a communication to the Aqueduct Commissioners in which he describes a new plan for providing an increased storage of Croton water, and brings forward strong arguments in its support. In view of the fact that the project for a great dam near Quaker Bridge was postponed until the completion of the aqueduct, and in the meantime a system of subsidiary reservoirs has been put under way, he recommends the abandonment of the Quaker Bridge scheme, as at first proposed, and the construction instead of an earth and masonry dam about one mile below the

present reservoir. The necessity of largely increasing the capacity of that reservoir is recognized by all, but the plan proposed by Mr. Fteley could be carried out in about one-half the time, and at less than one-half the cost required for the original project. He calculates that it would impound the flow of a watershed only six per cent. less in extent, and would afford sufficient storage to supply the aqueduct with a continuous flow of 250,000,000 gallons a day through the most protracted dry seasons. This, with the other provisions for storage farther up the valley, would be amply sufficient for the next twenty years, at the end of which time it seems probable that some other source of water-supply than the Croton watershed would have to be sought in any case.

— The new system of State care of the indigent insane went into effect October 1st, so far as the present accommodations of the State hospitals will permit, but additional appropriations of considerable amount are required from the Legislature before the reform can be carried fully out. It will be remembered that New York County is one of those exempt from the provisions of the new law; but from a recent presentation of the Grand Jury, it is evident that there is room for improvement in the city lunatic asylums. It points out that in the one on Blackwell's Island, with a maximum of 1,200, there are now 1,684 patients under care. While the main buildings are solidly built of stone, the additions called the pavilions are of frame, resting on the surface, with no air currents underneath to prevent dampness, and some of them are so old as to actually require propping to avoid a collapse.

Miscellany.

PERICARDITIS IN CHILDHOOD.

KNOFF (*Rev. mens. des Mal. de l'Enf.*, April, 1890, and *American Journal of Medical Sciences*, August, 1890), reports ten cases of pericarditis in children. Of these ten there were three under one year of age, three between one and two, and four between six and ten. Pericarditis in the newborn is usually due to a septicemic process, which starts from the maternal organism, or else from the umbilicus of the child. Of the chronic diseases which predispose to pericarditis, tuberculosis is a good illustration, as are also all the inflammatory processes of the pleura, lungs, sternum, vertebral column, bronchial and mediastinal glands, thymus, and esophagus. Pericarditis may also follow inflammation of the abdominal organs and peritoneum. In six of the author's cases the disease followed inflammation of the pleura and lungs, in one it followed chorea, in two scarlatina, and in one the cause was not ascertained. In very young patients there is often an absence of the ordinary physical signs which reveal the disease in the adult, including weakening of the heart-sounds and increase in the area of cardiac dulness. In fact the disease may develop without any appreciable symptom. Autopsies made by the author showed that the exudation was usually not abundant, and hence it could not influence the position of the

heart, the area of dulness, or the relative position of contiguous organs. The exudation was also fluid in character, without fibrinous deposit, and hence the absence of friction murmurs. In older children the diagnosis is also a matter of difficulty, and when pericarditis is suspected an examination should be made every day, to observe the slightest modifications which may occur in the physical signs. The earlier in the case a diagnosis is made the more favorable will it be as to treatment. Among the unfavorable complications may be mentioned adhesion between the two layers of the pericardium, for paralysis of the cardiac muscle will result with extensive dropsy. Symptoms of this form of cardiac paralysis are small and frequent pulse, subnormal temperature, œdema of the cheeks, lids, and lower extremities, and albumin in the urine.

A CASE OF TUBERCLE INOCULATION.

DENCKE, in the *Deutsche Med. Wochenschrift*, 1890, No. 13, puts on record what seems to be a remarkably good case of tubercle inoculation.

A strong and apparently very healthy child, of four months of age, fell head first into a chamber vessel, breaking it, and making an extensive skin wound of the forehead and nose. This vessel was filled with the mother's sputa, which was known to contain tubercle bacilli. The open wound on the child's head was bathed in the sputa for some time, but was finally washed out with corrosive sublimate solution, and dressed with iodoform collodion. The wound healed by first intention, but six weeks later the line of cicatrix had become livid and swollen, and an abscess had formed in the left parotid region, the contents of which contained a large number of tubercle bacilli. Later the lymph glands of the same side of the neck became swollen, and the child finally died of tuberculosis.

The criticism that the disease may have been inherited, the author answers by quoting Carnet's conclusions that congenital tuberculosis is extremely rare, and by pointing to the remarkably healthy appearance of the child previous to the local infection.

Correspondence.

[From our Special Correspondent.]

PARIS LETTER.

SKETCHES OF WELL-KNOWN MEDICAL MEN IN PARIS.

PARIS, June 6, 1890.

PROFESSOR POTAIN.

DR. POTAIN is Professor of Clinical Medicine at the Hôpital La Charité. He is quite a figure both physically and intellectually. He cannot be said to be good-looking, but his face is very expressive of great intelligence and goodness. He is much liked by all who know him and his pupils are much attached to him, so much so that they have given him the name of Father Potain. He is incontestably one of the leading physicians of France, which position he has acquired from the remarkable powers of diagnosis he possesses. In a purely scientific point of view, others may have gained a wider reputation, — Professor Charcot, for example, to whom we are indebted for so much of what we know about the nervous system — but as a general practitioner, Dr. Potain certainly takes the lead. It was his

work on "Diseases of the Chest" published more than twenty years ago, which first brought him to notice and still forms the standard work on diseases of the lungs and of the heart. His consummate skill in diagnosis of diseases of the heart has become proverbial, and he has considerably enlarged the domain of our knowledge in this point of view. But the dread of publishing a hazardous opinion renders him infinitely timid and circumspect. He pushes his scientific loyalty to its extreme limits, and it is on this account only that his works are rare, and that he is less known in foreign countries. But, it is acknowledged by all, that he is none the less the master type of a clinical teacher, celebrated as he is for the certainty of his doctrines and the impeccable professional dignity of his representations. As observed above, his pupils esteem him much, and although he speaks in a low voice his lectures are always largely attended. He is perhaps the most occupied medical man in Paris, and the demand on his time is so great that he is obliged to have a list of applicants for consultations and patients must think themselves fortunate if they can obtain an interview at the end of eight or ten days. Although his whole time is taken up between the hospital and his private practice he does not hurry his patients through but examines each with scrupulous patience, and never leaves them until he has formed as precise a diagnosis as modern science will permit. Besides these qualities he practises his profession with great disinterestedness; so much so, that his colleagues have several times been obliged to ask him to raise his charges so as not to injure the other members of the profession.

DR. EMPIST.

Although not a very old man, the name of Dr. Empist has been so familiarly known to two or three generations of medical students that when his name is mentioned astonishment is expressed at his being still alive, which may be accounted for by the following reason: In the year 1864, Dr. Empist published a memorable work on "la granulie," which, at the time, created a great sensation. With great talent Dr. Empist studied the phenomena, till then imperfectly known, of tuberculosis of rapid course; before this, writers had but vague ideas on the acute manifestations of this disease, and the names of cerebral fever, galloping consumption were given rather at random. Dr. Empist regulated this state of things, classed the symptoms, precisioned the pathological anatomy in a most able manner, so much so that in a hot controversy with the celebrated Virchow he gained the day. From that time the author soon became renowned, his work was placed in the first rank among the classical works, and the young doctors, accustomed since twenty-five years to read the name of Empist in all the manuals and in all the treatises of internal pathology were led to the inference that this celebrated physician had at least one foot in the grave. But such is far from being the case, as every morning Dr. Empist may still be seen at his service in the Hôtel Dieu, and those who follow him in his daily visits can bear testimony that he is not so old as he is thought to be. His inaugural thesis, which treats of paralysis consecutive to luxations, dates only from 1850, he is therefore scarcely more than sixty-five or sixty-six years of age. He now scarcely occupies himself with scientific works; hospital and private practice taking up the whole of his time. Of a very modest nature, and satisfied with his notoriety, Dr. Empist has published little that is noteworthy since his work on granulie. He is much esteemed by his pupils as well as by his confrères.

DR. TILLAUX.

Dr. Tillaux is considered to be one of the most upright men in the profession. He is an excellent surgeon and amply merits the sympathetic admiration of his confrères, his pupils and his patients. As a practitioner he is very successful, he is not only one of the most busy surgeons of Paris but he is summoned to all parts of Europe in consultation. He is surgeon to the Hôtel Dieu and he is much esteemed by his pupils. He excels in the art of diagnosis, and puts himself to great pains to impart his knowledge to

others about him. He is an admirable operator, operates with scrupulous care, according to the rules of the most severe antiseptics. His statistics are most favorable and the numerous successes therein related reflect the highest credit on him. Dr. Tillaux is still only an agrégé of the Faculty, although it was supposed that when he had published his treatise on topographical anatomy some years ago he would have been appointed professor. In this, however, he and his friends were disappointed and the reason alleged was that Dr. Tillaux, although an excellent surgeon, is not sufficiently scientific to occupy the position of Professor. His work was considered defective in some respects, it was too simplified, and was illustrated with plates of a correctness rather too approximative. The work, however, is looked upon as a classical one, and each student possesses a copy.

DR. VIDAL.

Dr. Vidal is celebrated as a specialist for skin diseases, and it was at the Hôpital Saint Louis that he acquired the well-earned reputation. He is a conscientious practitioner and although there is a great tax on his time, he never delegates his hospital work to others but attends to the patients as if he had nothing else to do. He is little over sixty years of age, but since arriving at that age, he has abstained from publishing much as he thinks that this must be left to the younger generation. The works he has published must not be forgotten, among them may be cited his inaugural thesis on chronic rheumatism, on exfoliative dermatitis and lepra nostras, without counting excellent articles in the "Dictionnaire Encyclopédique" of Dr. Décambre, and other important communications made to the different societies to which he belongs.

ELECTRICITY FOR RHEUMATISM.

BOSTON, October 9, 1890.

MR. EDITOR: — In Dr. Prince's instructive article on "The Practical Uses of Electricity," in your issue of October 2, 1890, some skepticism was expressed regarding the reduction of rheumatic swelling under this agent, patients' statements on this point seeming to him to result largely from imagination. I should like to take this opportunity of stating that I have verified this phenomenon by personal observation in several cases where I have made local electrical applications for monarticular rheumatism of long standing.

The most marked case coming under my observation I have already published in the JOURNAL of August 2, 1888 ("Katalytic Action of Electricity: Its Practical Value in Rheumatic Affections"). In this case, treated in conjunction with Dr. W. J. Otis, the wrist had remained stiff, swollen, red and painful on motion for two months after an attack of rheumatic fever. There was wasting of the extensor muscles of the forearm, the grasp was nil. The effect of the daily application of a mild galvanic current (combined with faradism of the affected muscles) was perceptible from the first. The swelling lessened and flexibility increased after each application. At the end of the third week the wrist measured one-quarter of an inch less, and the forearm three-eighths of an inch more, while the grasp with the dynamometer measured fifteen. At the end of the fifth week no swelling was perceptible, all movements of the wrist and fingers were free, excepting a very slight restriction in extension. The grasp was good.

In a case of swelling of the ankles reported in the same paper, the swelling could be seen to lessen, both by the patient and myself, and the movements of the feet, too, became more free during each application. The swelling between the treatments became gradually less marked until the normal condition was restored in about ten weeks.

Since this publication I have seen other similar cases, and have become convinced that properly selected cases of subacute rheumatism offer a most favorable field for definite therapeutic results from this much abused but still useful agent.

Yours truly,
GEORGE L. WALTON.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 11, 1890.

W. M. BRAISTED, Detroit, Mich., appointed an assistant surgeon in the United States Navy.

P. S. WALKE, medical director, detached from temporary duty as commanding Medical Examining Board.

H. E. AMES, passed assistant surgeon, detached from temporary duty as member of Medical Examining Board.

C. G. HERRON, surgeon, ordered to Naval Hospital, New York.

R. C. PERSONS, surgeon, detached from Naval Hospital, New York, and wait orders.

H. B. SCOTT, passed assistant surgeon, ordered before the Retiring Board.

A. F. PRICE, surgeon, detached from Naval Dispensary, Washington, D. C.

FRAZER ANDERSON, passed assistant surgeon, ordered to Naval Dispensary, Washington, D. C.

C. H. HARRIS, medical director, ordered to hold himself in readiness for duty to U. S. S. "San Francisco."

W. C. BRAISTED, assistant surgeon, ordered to Army and Naval Hospital, Hot Springs.

L. W. SPEARLING, assistant surgeon, ordered to hold himself in readiness for orders to the U. S. S. "San Francisco."

C. A. SIEGFRIED, surgeon, ordered to the U. S. Training Ship "New Hampshire."

N. P. BLACKWOOD, assistant surgeon, detached from duty in Bureau of Medicine and Surgery, and granted leave of absence.

L. H. STONE, assistant surgeon, detached from the U. S. S. "New Hampshire," and wait orders.

JNO. C. EDELMAN, passed assistant surgeon, ordered to hold himself in readiness for duty to the U. S. S. "San Francisco."

J. E. GARDNER, passed assistant surgeon, detached from the "Albatross," and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FROM SEPTEMBER 8, 1890, TO OCTOBER 4, 1890.

HUTTON, W. H. H., surgeon. Detailed as chairman Board of Examiners. October 2, 1890.

LONG, W. H., surgeon. Detailed as member Board of Examiners. October 2, 1890.

PURVANCE, GEO., surgeon. Granted leave of absence for thirty days. September 10, 1890.

GODFREY, JOHN, surgeon. Detailed as recorder Board of Examiners. October 2, 1890.

WHEELER, W. A., passed assistant surgeon. To proceed to New Orleans, La., for temporary duty. October 3, 1890.

BANKS, C. E., passed assistant surgeon. Granted leave of absence for twenty days. October 3, 1890.

AMES, H. P. M., passed assistant surgeon. To proceed to New Orleans, La., for duty. September 13, 1890.

PETTUS, W. J., passed assistant surgeon. To proceed to Vineyard Haven, Mass., for temporary duty. October 1, 1890.

HUSSEY, S. H., assistant surgeon. To proceed to New Orleans, La., for temporary duty. September 19, 1890. To proceed to Norfolk, Va., for temporary duty. October 3, 1890.

WERTENBAKER, C. F., assistant surgeon. Granted leave of absence for twenty days. September 12, 1890.

PERRY, J. C., assistant surgeon. Upon expiration of leave to rejoin station at Mobile, Ala. September 29, 1890.

YOUNG, G. B., assistant surgeon. To proceed to Memphis, Tenn., for temporary duty. September 13, 1890. To rejoin station, St. Louis, Mo., when relieved at Memphis, Tenn. October 3, 1890.

SOCIETY NOTICES.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION will hold its annual meeting in Atlanta, Ga., November 11, 12 and 13, 1890. George J. Engelmann, M.D., St. Louis, President; W. E. B. Davis, M.D., Birmingham, Ala., Secretary; Virgil O. Hardon, M.D., Atlanta, Ga., Chairman of the Committee of Arrangements.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, October 22, 1890, at 7.45 o'clock.

Business: Election of chairman for the ensuing year.

Dr. Douglas Graham will present a paper upon "Personal Experiences with Masseurs Abroad." Drs. G. L. Walton, C. P. Putnam and G. C. Garber are expected to take part in the discussion. Dr. Irving Fisher will make a preliminary report, on behalf of the committee appointed at the last meeting, upon "The Need of Hospital Accommodation for Patients with Syphilis." ALBERT N. BLODGETT, M.D., Sec'y, 138 Boylston St.

Deaths reported 2,167; under five years of age 833: principal infections diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 369, consumption 274, acute lung diseases 182, diarrhoeal diseases 173, diphtheria and croup 61, typhoid fever 59, whooping-cough 24, marshy fever 17, cerebro-spinal meningitis 10, scarlet fever 7, miasmes 4, erysipelas 4.

From whooping-cough, Brooklyn 9, New York 7, Baltimore 5, Boston 2, Worcester 1 and Washington 1 each. From malarial fever, Brooklyn 5, New York 4, New Orleans 3, Nashville and Charleston 2 each, Baltimore 1. From cerebro-spinal meningitis, New York 4, Brooklyn and Washington 2 each, Worcester 1. From scarlet fever, St. Louis 3, Brooklyn 2, New York and Baltimore 1 each. From measles, New York 3, Brooklyn 1. From erysipelas, New York and Brooklyn 2 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,359, for the week ending September 27th, the death-rate was 20.0. Deaths reported 3,738: acute diseases of the respiratory organs (London) 222, diarrhoea 386, scarlet fever 68, whooping-cough 63, measles 62, diphtheria 58, fever 58, small-pox (London) 1.

The death-rates ranged from 11.4 in Derby to 32.6 in Manchester, Birmingham 17.2, Bradford 20.8, Huddersfield 17.7, Hull 20.7, Leeds 21.9, Leicester 16.6, Liverpool 23.8, London 17.2, Newcastle-on-Tyne 25.6, Nottingham 14.3, Portsmouth 21.3, Sheffield 20.8, Sunderland 25.2.

In Edinburgh 16.7, Glasgow 22.2, Dublin 20.8.

The meteorological record for the week ending Oct. 4, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending	Barom- eter.	Thermometer.		Relative Humidity.		Direction of Wind.		Velocity of Wind.		State of Weather.*		Rainfall. Hrs. & Min. Amount in inches.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 3, 1890, TO OCTOBER 10, 1890.

By direction of the Secretary of War, Captain JAS. A. FINLEY, assistant surgeon, is relieved from duty at Fort Totten, N. Dak., and will report in person to the commanding officer, Jefferson Barracks, Mo., for duty at that station, relieving Captain Wm. D. CROSBY, assistant surgeon. Captain Crosby, on being relieved by Captain Finley, will report in person to the commanding officer, Fort Pembina, N. Dak., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

Lieutenant-Colonel CHAS. C. BYRNE, surgeon, is relieved from duty as attending surgeon at the Soldiers' Home, near this city, and will report in person to the commanding officer, Fort Sam Houston, Tex., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

Leave of absence for one month is granted Lieutenant-Colonel JOSEPH C. BAILY, assistant medical purveyor, medical director of the department. S. O. 86, Par. 3, Department of Texas, October 3, 1890.

By direction of the Secretary of War, the leave of absence granted First Lieutenant LEONARD WOOD, assistant surgeon, in Special Orders No. 74, August 30, 1890, Department of California, is extended one month. S. O. 232, Par. 7, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, Major HENRY M. CRONKHITE, surgeon, is relieved from duty at Fort Lewis, Col., and will report in person to the commanding officer, Fort Trumbull, Conn., for duty at that station, relieving Captain ROBERT J. GIBSON, assistant surgeon. Captain Gibson, on being relieved from duty by Major Cronkhite, will report in person to the commanding officer, Fort Sam Houston, Tex., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, Major WILLIAM H. GARDNER, surgeon, is relieved from duty at Washington Barracks, D. C., to take effect on the arrival of Major JOSEPH K. CORSON, surgeon, and will report in person to the commanding officer, Angel Island, Cal., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, Captain WM. C. BODDEN, assistant surgeon, is relieved from duty at Fort Sam Houston, Tex., upon the arrival of Lieutenant-Colonel C. C. BYRNE, surgeon, and will report in person to the commanding officer, Fort Davis, Tex., for duty at that station, relieving Captain PETER R. EGAN, assistant surgeon. Captain Egan, on being relieved by Captain Bodden, will report in person to the commanding officer, Fort Warren, Mass., for duty at that station, relieving Captain GEO. McCREERY, assistant surgeon. Captain McCreeery, on being relieved by Captain Egan, will report in person to the commanding officer, Fort Clark, Tex., for duty at that station, relieving Captain CHAS. M. GANDY, assistant surgeon. Captain Gandy, on being relieved by Captain McCreeery, will report in person to the commanding officer, Fort Shaw, Mont., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, Major CURTIS E. MUNN, surgeon, is relieved from duty at Angel Island, Cal., and will report in person to the commanding officer, Fort Monroe, Va., for duty at that station, relieving Major JOHN BROOKE, surgeon. Major Brooke, on being relieved by Major Munn, will report in person to the commanding officer, Fort Leavenworth, Kan., for duty at that station, relieving Major ALFRED A. WOODHULL, surgeon. Major Woodhull, on being relieved by Major Brooke, will report in person to the commanding officer, Fort Sherman, Idaho, for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, the following changes in the stations and duties of officers of the medical department are ordered: Major GEO. M. STERNBERG, surgeon, is relieved from duty as attending surgeon and examiner of recruits at Baltimore, Md., and as a member of the Army Medical Board, appointed to meet in New York City, N. Y., and will repair to San Francisco, Cal., and take charge of the Medical Surveying Depot at that place, as acting assistant medical purveyor, relieving Colonel B. J. D. IRWIN, surgeon. Colonel Irwin, on being thus relieved, will report in person to the commanding general, Department of the Columbia, and assignment to duty as medical director of that department and assistant surgeon, Vancouver Barracks, Washington, relieving Major WILLIAM E. WATERS, surgeon, now post surgeon, and temporarily in charge of the medical director's office. Major Waters, on being thus relieved, will report in person to the commanding officer, Fort Custer, Mont., for duty at that station. S. O. 232, Par. 8, A. G. O., October 3, 1890.

By direction of the Secretary of War, Major VAN BUREN HUBBARD, surgeon, is relieved from duty at Columbus Barracks, O., and will report in person to the commanding officer, Fort Spokane, Wash., for duty at that station, relieving Captain

HENRY S. TURRILL, assistant surgeon. Captain Turrill, on being relieved by Major Hubbard, will report in person to the commanding officer, Madison Barracks, N. Y., for duty at that station, relieving Major JOHN D. HALL, surgeon. Major Hall, on being relieved by Captain Turrill, will report in person to the commanding officer, Fort Canby, Wash., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, First Lieutenant ALLEN M. SMITH, assistant surgeon, is relieved from duty at Fort Snelling, Minn., and will report in person to the commanding officer, Fort Verde, Ariz., for duty at that station, relieving Assistant Surgeon PAUL SHILLOCK. Lieutenant Shillock, upon being relieved, will report in person to the commanding officer, Fort Custer, Mont., for duty at that station, relieving Captain WM. R. HALL, assistant surgeon. Captain Hall, upon being relieved by Lieutenant Shillock, will report in person to the commanding officer, Fort Schuyler, N. Y., for duty at that station, relieving Captain NORTON STRONG, assistant surgeon. Captain Strong, on being relieved by Captain Hall, will report in person to the commanding officer at Fort Meade, S. Dak., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, Captain C. N. BERKELEY MACAULEY, assistant surgeon, is relieved from duty at Fort Supply, I. T., and will report in person to the commanding officer, Fort Lewis, Col., for duty at that station. S. O. 233, Par. 2, A. G. O., Washington, D. C., October 4, 1890.

By direction of the Secretary of War, Captain RUDOLPH G. ENERT, assistant surgeon, is relieved from duty at Angel Island, Cal., to take effect upon the arrival, at that post, of Major WM. GARDNER, surgeon, and will then proceed to Vancouver Barracks, Wash., and report for duty to the commanding officer of that post for duty. S. O. 232, Par. 15, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, Captain ROBERT B. BROWN, assistant surgeon, will proceed from Fort Hamilton, N. Y., to Mount Vernon Barracks, Ala., and report in person to the commanding officer of that post for temporary duty, relieving Captain JOHN J. COCHMAN, assistant surgeon, who will return to his proper station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, leave of absence for three months is granted Captain ROBERT J. GIBSON, assistant surgeon, to take effect on being relieved from duty at Fort Trumbull, Conn., by Major HENRY M. CRONKHITE, surgeon. S. O. 232, Par. 12, A. G. O., Washington, D. C., October 3, 1890.

By direction of the Secretary of War, Captain WALTER REED, assistant surgeon, is relieved from duty at Mount Vernon Barracks, Ala., and assigned to duty as attending surgeon and examiner of recruits at Baltimore, Md. S. O. 233, Par. 7, A. G. O., Washington, D. C., October 4, 1890.

By direction of the Secretary of War, Captain ARTHUR W. TAYLOR, assistant surgeon, is relieved from duty at Fort Winnebago, New Mex., to take effect on the expiration of his present sick leave of absence, and will report in person to the commanding officer, Fort Adams, R. I., for duty at that station, relieving Captain J. J. COCHMAN, assistant surgeon. Captain Cochran, on being relieved by Captain Taylor, will report in person to the commanding officer, Camp Eagle Pass, Tex., for duty at that station, relieving First Lieutenant PAUL CLENDENEN, assistant surgeon. Lieutenant Clendenen, on being relieved by Captain Cochran, will report in person to the commanding officer, Fort Brady, Mich., for duty at that station. S. O. 232, Par. 8, A. G. O., Washington, D. C., October 3, 1890.

PROMOTIONS.

Assistant Surgeon EDWARD R. MORRIS, September 17, 1890, to be assistant surgeon, United States army, with the rank of captain, in accordance with the act of June 23, 1874.

Lieutenant-Colonel BERNARD J. D. IRWIN, assistant medical purveyor, to be surgeon, with the rank of colonel, August 28, 1890.

Major BLENCOWE E. FRYER, surgeon, to be assistant medical purveyor, with the rank of lieutenant-colonel, August 28, 1890.

Captain STEPHEN G. COWDRY, assistant surgeon, to be surgeon, with the rank of major, August 28, 1890.

APPOINTMENT.

Colonel EDWARD P. VOLLMER, surgeon, to be chief medical purveyor, with the rank of colonel, August 28, 1890.

MALIGNANT STRICTURE OF THE OESOPHAGUS. ITS TREATMENT BY SYMONDS'S METHOD OF PERMANENT TUBAGE. WITH CASES.¹

BY S. J. MIXTER, M.D.,

Surgeon to Out-Patients, Massachusetts General Hospital; Demonstrator of Anatomy, Harvard Medical School.

AMONG the recent triumphs of surgery, the operations for the relief of stenosis of the alimentary canal, occupy a prominent position. Excision and intestinal anastomosis have been added to colotomy or other forms of operation for the formation of an artificial anus, and excision of the rectum is a well-recognized operation.

The stomach and intestine can now be reached by the operator, and by one of several different methods its contents can be given passage downwards and outwards. The oesophagus, however, in the greater part of its course, is beyond the reach of the knife. It is true that by means of the electric light and suitable apparatus, we may view its interior as easily as that of the urethra, but here there is no chance for anastomosis, and the most that we can expect is to keep the narrowing canal from becoming totally closed, in which case a gastrostomy is the only means of averting starvation. This has generally been accomplished by the frequent passage of the probang or oesophageal bougie.

This method of procedure is sufficient in many cases to prevent a closure, and the patient dies of the progress of the disease but not from starvation. In other cases after this method of treatment has been followed for a considerable time, it is found impossible to prevent further contraction, the passage of the probang gives the patient great pain, and is often followed by profuse haemorrhage, due to the laceration of the malignant granulations. Not infrequently, also, the probang finds its way, not along the canal, but into the new growth and a false passage or pocket results. In such a case the subsequent passage of the instrument becomes almost, if not quite, an impossibility.

The division or cutting of a malignant stricture of the oesophagus, does not seem a rational procedure. In a few cases a patient presents himself with total obstruction, and in that case, of course, gastrostomy with its dangers and discomforts and many complications in its after-treatment, the only resource of the surgeon. A permanent opening in the stomach is, as a rule, more difficult to manage than an opening into the intestine (artificial anus).

If now the patient is seen presenting the difficulties above spoken of in the introduction of the probang, but whose stricture allows the passage of a flexible instrument, is there a way by which the oesophagus can be kept open, and the patient relieved from the frequent use of the probang with its dangers and pain?

It is in this class of cases that intubation of the oesophagus is of the greatest use. The instrument used is like a flexible woven catheter, about six inches in length, the top expanding like a funnel, to a diameter of about half an inch, and the tube itself ranging from No. 6 to No. 20 English. At the top of the funnel is fastened a strong silk cord. A tube of a suitable size having been selected, it is dipped in warm

water to make it more flexible, lubricated with glycerine or vaseline, and by means of a flexible stilette or a probang, passed into the oesophagus and through the stricture until its further passage is stopped by the expansion in the tube. The stilette is then withdrawn, and the patient finds, to his surprise, that he can swallow liquids with perfect ease.

Permanent tubage of the oesophagus has been used by different surgeons for the relief of stricture, but the tube used, being a long one, was passed through the nose or mouth, and being left in place was most uncomfortable and caused ulceration at different points where there was pressure, as behind the cricoid. To Symonds is due the credit of inventing the short tube described above, which entirely changes the whole process of treatment, and it will, I feel sure, be considered as the greatest advance in oesophageal surgery, and will do more to relieve suffering in a great number of cases than any operation yet performed on this part of the alimentary canal.

Having had several patients with malignant stricture under my care, and finding the treatment by probang or daily introduction of the stomach tube unsatisfactory, I was influenced by Symonds's articles in the *British Medical Journal*, for 1889, to send to England for tubes, as they could not be procured in this country. Soon after they arrived Dr. Warren kindly placed under my charge a patient at the Massachusetts General Hospital, with advanced malignant disease of the oesophagus, and a history of having swallowed not even liquids for days. A No. 20 F. bougie was with difficulty passed, and on its withdrawal a No. 9 E. tube was passed through the stricture which was situated near the lower end of the oesophagus. The patient was then enabled to swallow liquids with ease. Before food was taken into the stomach he said that he had no sensation of hunger although almost no food had been taken for over a week and emaciation and exhaustion were extreme. As soon, however, as the milk and brandy had revived him, his appetite returned and for the next few days he assured me that he was constantly hungry, though milk, eggs and all kinds of liquid food were constantly supplied him. For two weeks he gained a pound a day. When he left the Hospital after wearing the tube a month, he could swallow liquids and soft solids with ease. This patient was lost sight of.

CASE II was also a patient placed under my care by Dr. Warren. A woman with a cicatrical contraction from swallowing caustic potash. The passage of any instrument was very difficult and painful. A tube was passed through the stricture giving great relief for a time, but one morning it was discovered that the string which was tied behind the ear was very taut, and on trying to withdraw the tube, it was evident that it had passed beyond the stricture and it was impossible to withdraw it. For the next few days various methods were tried for recovering the tube and finally, as all attempts proved futile, the cord was cut as low as possible, and the further progress of the tube left to nature. The patient left the hospital in three weeks, the stricture having been dilated to a considerable extent. The tube was passed by the rectum eleven weeks later without having caused the slightest disturbance.

CASE III. A patient kindly referred to me by Dr. Homans at the Massachusetts General Hospital, was an old man with probable malignant stricture of six

¹ Read before the Boston Society for Medical Improvement, May 26, 1890.

months' standing. He had been unable to swallow even liquids for several days. The smallest probang was passed with great difficulty. A small tube was introduced, and in two days a larger one was passed. This was worn for about a week. The patient gained flesh and strength rapidly, and soon left the Hospital. Since that time he has been under my care, coming from his home about thirty miles away, once every ten or fourteen days, as a rule, but sometimes wearing a tube three weeks without changing. About three months after the first intubation, while he was wearing the largest-sized tube, he complained one day of some "sore throat" which I thought might be due to the irritation of the string in the pharynx, and I removed it, intending to leave it out for a few days. Two days after he appeared at my office saying that he had been unable to swallow even liquids for twenty-four hours. A very small tube was with difficulty introduced and this has been replaced at the usual intervals by larger tubes, and now he is quite comfortable, though beginning to show the usual signs of malignant disease.

CASE IV. An old man with probable malignant disease with the usual symptoms, and complete obstruction for some days. A tube was introduced and worn for some days, when a piece of food plugged it and the patient took it out, and for some days swallowed easily. Then the stricture closed again and the tube was replaced. This patient has now been under my care for five months, wearing the tube almost constantly without discomfort.

CASE V. An old man who had been in Dr. Beach's wards in the Massachusetts General Hospital for treatment of almost impassable stricture of oesophagus. A tube was introduced and the patient returned to his home six hundred miles distant. In about three months he appeared at the Out-Patient Department, bringing the tube which had been taken out and cleaned several times but which had finally become worn out and unfit for use. A fresh tube was introduced and in a few days changed for a larger one (No. 15 E.). He was given two fresh ones and returned to his home. He assured me that he considered that a journey of twelve hundred miles was not a high price to pay for the immense relief given by the intubation.

The tube can be left in place for a considerable time, though about once in ten days it is well to clean and replace it. In several instances I have left it three weeks. Of the accidents that may happen, one, the passage of the tube into the stomach has been mentioned. In Symonds's articles this accident is mentioned and no ill effects are observed.

In one case the string was worn through by the patient's teeth, the thread being swallowed. The tube was easily recovered by means of a flexible oesophageal forceps.

In one case (IV) it was almost impossible to pass a probang or bougie of the size of the tube first removed, or to replace the tube itself, perhaps owing to a pocket beside the stricture. A small urethral bougie could, however, always be passed. An instrument to serve as a guide was accordingly made of a small bougie-tip (about two inches long), joined smoothly to whalebone of the same size, and this having been introduced through the stricture, a tube open at the end could be passed down over it and when in place the guide was withdrawn. I find that in the majority of cases the tube can best be passed in this manner.

The thread can be most satisfactorily and securely fastened by tying it to a lock of the patient's hair in front of the ear, and securing the knot with collodion.

From the few cases I have had, I feel thoroughly convinced that this method of treatment is of the greatest value in suitable cases. Even in cases where it is not necessary to continue its use for a great length of time, as in cases of traumatic stricture, where the passage is small and tortuous, the introduction of the tube for a few days dilates the stricture and renders the subsequent passage of the necessary instruments much easier.

OBSTETRICAL WORK IN A COTTAGE HOSPITAL.¹

BY HENRY COLT, M.D., PITTSFIELD, MASS.

IT is hardly necessary at this day, to dwell long upon the advantage a cottage hospital is to a community, for in England where the idea had its inception thirty years ago, the good work which such institutions accomplish, is fully appreciated, and the results published, and in this country medical men have been quick to praise the usefulness of small well-managed hospitals.

A brief review of the advantages which English and American writers have brought out as belonging especially to the cottage hospital, may be of interest. First, that in them the mortality is less than in larger ones; second, that they are better adapted for the treatment of acute diseases; third, that diseases can be classified more easily; fourth, that they are homelike; and fifth, they are not costly.

It would be foreign to the subject of this paper to enter into detail as to the reasons that have led various writers to draw these conclusions, but that such conclusions are true, can hardly be disputed.

The management of the cottage hospital with which I am most familiar, is the House of Mercy in Pittsfield. It claims the distinction of being the first of this class to be established in New England, having been incorporated in 1874, and from my connection with it, a period of nine years, I can safely say that the results seem to bear out all that has been claimed for institutions of a similar character. An accurate description of the building was published in the "Ninth Annual Report of the State Board of Health," by Dr. J. F. A. Adams, of Pittsfield. As the house is practically the same now as in 1878, when the article referred to was written, I will quote Dr. Adams's description of the building. It stands upon "a triangular lot of land at the intersection of three streets, at the northern limit of the village. . . . The lot measures three-quarters of an acre, and the soil is a coarse, dry gravel. Upon this they have erected a hospital for thirteen beds, capable of holding more if necessary. It is a two-story frame building; or more correctly two separate buildings connected by a short corridor. . . . There are no general wards, it having been decided to have single-bedded rooms only. . . . Every room in this building has an open fireplace connected with a large flue in one of the four massive chimneys." The rooms for patients vary in size from 9×12 to 14×16. As I have said, the building is practically the same now as in 1878, but in 1888 the Bishop Memorial Training-school for Nurses, was

¹ Read at the annual meeting of the Massachusetts Medical Society, June, 1890.

built, connected with the House of Mercy by a corridor, and the transference to the new building of more conveniently arranged doctors', matrons' and managers' rooms, the nurses' quarters being on the third floor, left in the old building several new rooms for patients. There are also eight rooms in the new building for patients, making the total capacity twenty-six or thirty-eight beds. The heating of the rooms is by steam, direct radiation, and no special system of ventilation other than open fireplaces.

The school for nurses was established in 1885, and has been an unqualified success, the demand for nurses far exceeding the supply.

The character of cases does not differ materially from those treated at any hospital. Persons suffering from contagious diseases are, however, not admitted. In medical cases we see both the acute and chronic forms of pulmonary, cardiac and renal troubles, the different forms of continued fevers, from severe typhoid to a mild febricula. In surgical work there have been minor and major operations, from amputation of the thigh to an amputation of a toe, several laparotomies and work that is distinctively gynecological. I have briefly given a description of the Pittsfield Cottage Hospital, thinking that in so doing, the work in obstetrics can be better understood.

In looking through some of the literature upon cottage hospitals I was struck by the fact that no mention was made of the advantages of such institutions for the carrying out of obstetrical work. There is much space given to the success in treating both medical and surgical cases, and the diseases incident to childhood, but as to obstetrical cases I have found no record. In answer to a letter of inquiry sent to the superintendents of hospitals situated in twelve of the larger towns and cities of this State, excluding Boston, I found that, except in three instances, obstetrical cases either were not received, or that owing to a lack of proper room arrangement, they could not be taken care of. In two instances they received such cases, but they were placed in buildings separate from the hospital. In Pittsfield we receive such cases, but have no separate ward for their treatment. Possibly the arrangement of having a single room for each patient makes this course an easy one for us to carry out, and it is of course probable in the other small hospitals throughout the State, that the plan of the buildings necessarily prohibits the admittance of an obstetrical case, but the work with us has been carried on so easily that I learned with some surprise that such cases were not more generally received.

While the number of this class of patients has not been large, yet the fact that we are among the few who take them in, may tend to emphasize the results that we have attained. From 1877 to 1890 there have been thirty-four cases admitted. Of these nineteen were multiparae and fifteen primiparae. In two instances only was it necessary to use forceps; the patients were both primiparae, and in both cases the children were still born. Out of this number (thirty-four) there was but one abnormal presentation, that being a face, and there has been but one case of twins. This rather meagre presentation of statistics, cannot, of course, excite much interest or comment, but I will in addition make the statement that in this number we have not seen a case of puerperal septicemia or had a patient die after her confinement. There has been an occasional rise of temperature, but in no

instance could such a condition be called septicemic.

Dr. W. L. Richardson in an article in the *Boston Medical and Surgical Journal*, for 1887 on "The Use of Antiseptics in Obstetrical Practice," says, "with very few exceptions all cases in which the temperature did not exceed 100° are classified as normal; while those whose temperature rose between 100° and 102° are considered as doubtful; all others being classed as dangerous. The few exceptions made in this classification are in those cases where the temperature may have exceeded these arbitrarily selected limits, but where such rise was only transitory and due, as shown by the clinical record, to some clearly defined cause such, for example, as mental emotion, indiscretion in diet, etc."

Such a statement holds true in the cases with us, and it is quite rare to have a temperature stay at or reach 100°. Taking into consideration the fact that there are often in the hospital a variety of surgical and medical cases in all stages of convalescence, or the reverse, it is with pardonable pride we can point to such a record. The means adopted to secure this result have been to make the environment of the patient as aseptic as possible, especially has this been the case in the last few years, following out the generally accepted antiseptic treatment. I will however state that *every* precaution is not used to secure asepsis, inasmuch as certain steps are not taken, which are insisted upon, with good reason too, by the physicians in charge of a strictly lying-in hospital, but at all it seems to us, every reasonable precaution is taken. If a confinement case is to occupy a room in which there has been a medical or surgical case with a rise of temperature, the room is fumigated, the walls washed with carbolic solution, the pillows and mattress mads over, and clean fresh bedding provided. During the progress of the labor, a carbolic spray is often used about the room. The nurse in attendance is not allowed to go into any other room where there is a rise of temperature. If there has been in the room a case with no rise of temperature, no special precautions are taken other than making the room perfectly clean. The physicians in attendance have not, I believe, ordered a bath for the patient before the commencement of labor, and in only one or two instances has an antiseptic vaginal douche been given either before or after labor. The careful cleansing of the hands is, however, strictly adhered to, together with the use of a disinfecting fluid, either a bichloride or carbolic solution, before making any examination. If any instruments are used, they are first thoroughly carbonized.

Since the article of Dr. Richardson's appeared, which before was referred to, the antiseptic pad which he recommended, has been constantly used. The nurse in attendance is carefully instructed to use every precaution to insure asepsis, and such instructions have been most faithfully carried out. While realizing the dangerous element a case of puerperal septicemia would be, both as to carrying on successful obstetrical and surgical work, yet we believe that in using the care we do, the good results in the past can be secured for the future.

The class of patients we receive is not by any means limited to those, who from lack of money, are forced to depend upon charitable institutions. Many women well able to pay a physician at their homes,

voluntarily choose to come to the House of Mercy for their confinement, realizing that skilful and intelligent nurses will be in attendance, and that they run less risk from septic disturbances than in their own homes. While the managers of the House of Mercy do not propose that it shall be considered in any way a lying-in hospital, yet they are ready and willing to receive a certain number of cases every year, and the results thus far secured bear out the idea of its being a safe, wise, and above all, a charitable thing to do.

I would, therefore, wish to impress upon those of the profession who may be connected with these smaller institutions that obstetrical work in a cottage hospital can be well carried on, and I trust that the results which I have placed before you, may induce you to make an attempt to secure to not only poor and friendless women a desirable place for their confinement, but to those well able to pay, a temporary home, which, in the majority of cases, is better adapted to their needs than their own.

A HYDROPHOBIA SCARE.

BY CLARENCE W. SPRING, M.D., FITCHBURG, MASS.

SINCE the time when the case of the Newark children was so extensively discussed in the American press, and proved so rich a prize for enterprising journalists, imaginative reporters, and dime museum managers, the subject of hydrophobia has been more than usually prominent before the public mind, and by the press has received a varied treatment. But since the opening of the Pasteur Institute in New York in February of the present year, the discussion has received a new impetus somewhat similar to what it received in France immediately following the opening of the Pasteur Institute in Paris, and the interest in the disease as it occurs in our midst may be fairly said to be on the increase.

During the last few months scarcely a day has passed without the chronicle in the daily press of one or more cases of hydrophobia to man and animals; and a large number of communities have had what may be called a "hydrophobic scare," with or without serious results.

It is the object of the writer to briefly state the sequence of events which occurred in Fitchburg during the past summer as a contribution to the study of this dread disease, and to offer a few remarks on the attitude of the profession towards its treatment.

On May 26th a lad, aged twelve, presented himself for treatment, stating that he had just been bitten by a dog which jumped upon him as he was on the street. On examination a small wound through the true skin was found on the left shoulder, and in the arm-pit and neighboring region of the scapula were several abrasions of the skin of a more or less superficial nature. The parts were well protected by clothing, though the wounds were deep enough to bleed freely. They were promptly cauterized and in about ten days were healed.

The reason for taking an unusual interest in the case arose from the fact that the dog was presumed, by his actions, and the fact that he had bitten several other dogs, to be mad. The dog was accordingly caught and tied up; but, as usually happens in such cases, the subsequent history of the animal was cut

short by his being promptly killed. His history previous to his death was, in brief, that, some two weeks before these events happened, he was bitten by a stray hound which ran about in the city for a time, and which, after biting a number of other dogs, disappeared. It was not a dog which was licensed, or which could be farther traced. Since that time little reason had existed to suspect any trouble till he began to show a changed disposition, a cross nature, and a tendency to bite people and dogs; and the culmination was reached in his attack upon the boy.

An effort was made to determine whether rabies could be diagnosed more definitely than was possible by the clinical history, which, in itself, lacked much of being complete. An autopsy was accordingly made, but with the result of little save negative evidence, though the brain and medulla and parts of the cord were carefully examined. A further attempt was made to prove the diagnosis by a few inoculation experiments, which were carried out with kittens. Two young kittens, six weeks old, were inoculated with a fresh solution of the medulla under the skin in the region of the abdomen. They were kept under close observation for some seventy days, but the results were entirely negative, and they were killed at the end of that time and nothing abnormal found on examination. The experiments were made as carefully as possible, though of necessity lacking in the technique deemed essential by the best laboratory methods.

While these investigations were going on, the boy was watched with a good deal of interest, not to say anxiety, and the dogs which had been bitten by this same animal, were kept under restraint and closely watched, particularly a brown spaniel which was bitten on the nose immediately after the boy received his wound.

Some seventeen days elapsed without any signs of trouble, when this spaniel began to develop symptoms of an interesting nature. He began to grow sulky, and showed a marked change in disposition, refused food, snapped at whatever was near him, refused his master's caresses, and showed an increasing restlessness, though not at first of a violent nature. A peculiar dragging of the hind legs when he walked soon came on, and after two days developed into a more general paralysis. The jaw dropped, could not be kept closed; abundant saliva ran from the mouth; he refused food and drink; and soon died of paralysis and exhaustion, some three days after showing the first symptoms.

These facts, of course, opened a new chapter in the history of the case, and one which gave a chance for further study.

An autopsy was made by the writer, with the assistance of a veterinary surgeon, immediately after death, and the positive points found at that examination were, in brief, as follows: The conjunctiva were injected, the right pupil fully dilated, the left normal; the membranes of lips, nose and mouth were covered with a thick sanguineous frothy fluid. The tongue was protruded and caught between the teeth. The whole membrane of the posterior fauces was covered with a brownish fluid, was deeply injected, and almost purple in color. The larynx and trachea were likewise covered with the same kind of fluid, which, under the microscope, showed an abundance of pus cells. These parts were, like the neighboring ones, deeply injected. The brain in the posterior region showed an increased

amount of blood, was, in portions of the pons and medulla, deeply injected, and small hemorrhagic spots were seen here and there. The brain, as a whole, was not edematous. The other parts of the body, all of which were carefully examined, did not show anything especially abnormal. The examination in this respect proved important, as it showed the absence of those diseases, which are said to cause symptoms similar to those of rabies — such as parasitic enteritis, gastro enteritis from poison, and other conditions peculiar to animals.

In view of these facts, namely, the history of the case, the symptoms observed during life, the rapidly fatal result from an intensely acute nervous disease, and the conditions found after death, the probable diagnosis of rabies was made. Attempts were made with the fresh solution of the medulla to carry out some inoculation experiments, but, as in the first instance, they resulted negatively.

On the basis of this diagnosis, and after a careful discussion of the matter with the father of the boy who had been bitten, the treatment by preventive inoculation, according to the method of M. Pasteur, was deemed advisable and readily assented to. Accordingly, the boy was sent to the Pasteur Institute at New York, and placed under the care of Dr. Gibier. At the same time the writer sent the full particulars of the case, and a portion of the medulla of the dog for examination. Unfortunately a solution of chloral and glycerine was used to preserve the specimen, and it was not thought possible to make any inoculation experiments with it. The case was considered by Dr. Gibier as one eminently proper for treatment, and the inoculations were at once begun. The record of the treatment I take from notes kindly sent me by Dr. Gibier. On June 16th three inoculations were made, one at 10 A. M., one at 2 P. M., and one at 6 P. M. Two injections were made each time, consisting of twelve cubic centimetres of virus. On June 17th two inoculations were given in the same way, at 2 and 6 P. M. On the 18th the same treatment was used; and on the 19th, the fourth day, a virulent liquid was used, which was increased in intensity up to the seventh day, when a very virulent liquid was used. On the eighth day no injections were used, but they were continued on the subsequent days, one each day, till the sixteenth day, when the patient was considered as sufficiently protected.

The boy stood the treatment well, and, save a slight inflammation about one of the puncture points, no accident happened during the inoculations. The boy remains to-day (109 days after his treatment ceased) sound and well.

Of course, in a comparatively small community, a case like this could not happen without attracting a great deal of attention, and naturally causing a good deal of anxiety among all classes of people. Every effort was made to give the public a true and unexaggerated account of what had happened, and to cause the city authorities to take proper measures for the further protection of animals and men; which they did only with great reluctance, and but poorly carried out during the rest of the summer. No further trouble occurred, and the "scare" was over. The importance of correctly dealing with such cases, as they happen occasionally in a community, was most strongly impressed upon the writer's mind, and led him to consider the subject anew, with reference to some of its most

practical points; particularly with reference to the new method of treatment, an interest in which was most strongly excited by a recent visit to Pasteur's laboratory in Paris, where the matter was studied at some length.

If we are to accept the treatment of M. Pasteur as one of the rational procedures of therapeutics, a faith in its efficiency must be inculcated in the minds of the profession, as upon this faith the unfortunate sufferers, to whom the fear of hydrophobia has come, rely for their advice and counsel. It is not the purpose of the writer to discuss this method of treatment, as to its scientific correctness, or to question the accuracy of the methods by which final working results have been reached. The object of preventive medicine and curative medicine is, in the main, the same; but the methods of reaching this end are widely different in their adaptation.

The uncertainty of the occurrence of a disease, is an element which necessarily enters into a discussion of the methods of preventive treatment for that disease. But, excepting the method employed as scientifically correct, the possibility of never having the disease at all, provided no treatment is used to prevent it, if that possibility is reduced to a minimum, should not detract from the presumed efficiency of the method as shown by comparative results.

This is particularly true regarding the new method of treating hydrophobia by preventive inoculations. The element of uncertainty attaches to most cases from the very start, and it is to point out the necessity of removing as much as possible of this uncertainty that I report this case with its appended remarks. A large amount of the distrust which the public has in the treatment of this disease, and even in the existence of the disease itself, lies at the door of the medical profession. The new method of treatment is, as it were, on trial; and we owe it to ourselves to do all that can be done in making tests which will prove or disprove its value as a therapeutic agent. The first step in reaching this result would be the careful selection of cases, to determine on what basis of fact they rest in order to reduce the uncertainty of diagnosis to a minimum, if not to entirely remove it. It is by the careful selection of cases as practised by Dr. Gibier, and not the haphazard subjection of every case to this treatment, that the comparative results are made of some value. A diagnosis by clinical signs alone is not trustworthy, if possible at all, and the importance of a post-mortem on every suspicious case as it occurs, together with subsequent experimentation by inoculations by those competent to make them, cannot be too strongly insisted upon. The writer believes at the present day the medical profession owes it to itself to adopt these more careful methods of studying this disease, in order that its duty to the community at large, which it is bound to protect, may be more closely defined. If cases assume a similar phase to that of the case reported, the matter of treatment becomes a highly important one. No one can for a moment doubt the attitude of those unfortunates who have been bitten by angry or rabid animals, who has once visited the clinique of M. Pasteur, and seen the throng of all nationalities and conditions of men, some hundred or more daily, pass in one by one to receive the inoculations which they hope and expect will cure them of the disease, if the poison has entered their blood, or relieve them of the fear of it if it has not. Pasteur's record for his first four years of

treatment of 53 deaths out of 7,393 persons treated, or 0.71%, as compared with the lowest estimate of the same kind of cases not treated at all (8% according to Bollinger), means something, and is at least significant, if we only limit the efficiency of the method to curing cases of so-called nervous hydrophobia or lyssophobia and not the true disease.

If we are not to support the earnest, and I believe honest endeavors of such men as Pasteur, Gibier and others, who are using this method, and if their method is to be disproved, let it be by reason of the severe tests of clinical experience, careful observations and selection of cases, and accurate experimentation by inoculation to which all may in a way contribute their share. As such a contribution the foregoing is respectfully submitted.

COLORADO AS A HEALTH RESORT.

BY E. C. ATKINS, M.D., COLORADO SPRINGS.

SINCE the subject of the climatic treatment of tubercular disease of the lungs is occupying so large a place in the mind of the profession at present, perhaps the observations and conclusions of a physician made during a year spent in Colorado for tubercular lung disease may be of interest to some of your readers; and the more so because I am led to think, from what I have seen during my stay here, that the Eastern physicians are not sufficiently well posted on the results to be obtained here in incipient cases, and that a personal observation would lead them to be more hopeful in their prognosis of such cases.

One, who is considered an authority here, says that ninety-five per cent. of all cases that come in the early stages are either cured or greatly benefited. While that statement may partake somewhat of the largeness of things in general in the West, it is safe to say that more than half, and perhaps three-fourths, of such cases do recover. This is the fact which I think the average Eastern physician does not appreciate.

The results obtained depend very largely upon the nature and extent of the lesions, and the general condition of the patient. While it is true that now and then a case, which, to all external appearances, is in the latter stages of disease, does recover, and regain a fair degree of health, it is also true that most of such cases with extensive disease are not expected to recover, but will live much longer here than in the East.

To obtain the best results patients must come in the earlier stages, and the earlier the better; before the digestion and other general functions are seriously impaired. In a case where nothing can be found by physical examination, but where a slight cough and a very scanty expectoration exist, I believe the simple presence of tubercle bacilli in the sputum should decide in favor of Colorado.

The typical case, however, for treatment here is that where sufficient hemorrhage has occurred to convince the patient that radical measures are necessary, and when the physical examination does not show extensive disease. Such cases are usually willing to come, and almost invariably do well. Haemorrhagic cases are more amenable to cure than catarrhal cases pure and simple, but next in line comes catarrhal phthisis with cough and expectoration, containing tubercle bacilli; or more correctly speaking tubercular bronchitis. Physical examination in such cases may

reveal almost nothing, no rales, perhaps slight elevation of pitch at one apex. Such a case should come out at once, and a hopeful prognosis be given, for his chances are good. Next, cases in the second stage of disease with consolidation of one or both apices, with or without hemorrhage. Such cases should be sent out, and a fair or doubtful prognosis given according as the general condition of the patient is good or poor. A patient in this condition, accompanied by night sweats, loss of flesh and strength, may improve rapidly on coming here. It is well worth trying. It is all he can do, and many such recover.

What shall be done with cases well advanced, where the prognosis is bad, is difficult to decide. Perhaps it is as well for them to stay at home. It is a question of prolonging life a few months or a year or two, with just a possible hope of improvement. The intelligent physician must decide for there are no rules to cover such cases. I would say, however, "If in doubt, come!"

Simple prostration or weakness from loss of blood by copious or repeated hemorrhage is no indication that the patient should not come, provided the disease is not extensive. Many such are brought on stretchers and do well.

The prevailing impression that coming to a high altitude is productive of fatal hemorrhage is only a "bugbear" that has grown out of a few rare instances. Now and then such a case does occur and a patient dies of severe hemorrhage induced by the change of altitude, but among the thousands that come here, such accidents are rare and usually in cases well advanced in the third stage of disease.

The whole question turns upon the physical signs more than on the present condition or strength of the patient. It must be a very sick person who cannot be brought here with the present excellent facilities for travelling.

Such being the facts, how are we to account for them? What are the essential elements at work here for the cure of tubercular disease. I believe them to be about as follows:

- (1) Dryness of air.
- (2) Elevation of from four thousand to six thousand feet.
- (3) Purity of air.

It is difficult to know which of these to place first, for all are absolutely essential. The first and second are not sufficient alone, nor are the second and third. The first and third *might* be, as is seen in cases cured in Southern California. Add to these three conditions a climate that admits of the patient being out of doors much of the time, at all seasons of the year, and you have the conditions complete for the cure of tubercular lung disease. This state of things exists in Colorado.

One who has ever lived at an elevation of eight thousand to nine thousand feet, realizes fully the effect of altitude upon the lungs; for it seems as if the air-cells were distended to their utmost, and it is fair to suppose that this is the case and that air-cells infiltrated by disease or collapsed by disuse, are forcibly distended, giving the dry and pure air a chance to do its work upon them. That this is so is shown by the casts of cells and tubules frequently coughed up while in high altitude, which is not so common in lower.

And just here lies the advantage of Colorado over Southern California. California lacks one of the ele-

ments necessary for the cure of a majority of cases, namely, elevation. Moreover, while the air of California is pure and comparatively dry, it does not compare in dryness with that of Colorado; for the reason that California is on the coast while Colorado is one thousand miles from any body of water, and between us and the ocean is a mountain range which condenses the moisture and holds it all on the other side, while on the east, north and south are the hot arid lands of Kansas, Nebraska and Indian Territory. Thus the moisture shut out on the west, and sucked up by hundreds of miles of parched plains on the east, leaves the air of Colorado so dry that one's mucous surfaces become parched and cracked until they become accustomed to the dryness. Moreover, there is, in these elevated regions, a tonic, something in the air, which though indescribable, has a most marked effect upon all who come here. Call it super-electrification or what you will, it is here, and under its influence the digestive functions are stimulated to their utmost, the appetite improves and becomes vigorous, the nervous system takes on new life, there is an exhilaration of the whole system and a general improvement of all the vital functions results. The importance of this element in cases of phthisis will be readily understood.

Nearly all of the towns of Colorado east of the range are favorable to phthisis, and it remains to select a place congenial to the tastes and habits of the patient. While there is much to be said in favor of Denver, it is generally accepted that the smaller places which are freer from smoke and dust and the impure air, which is a common objection to all large cities, are to be preferred. Colorado Springs, Manitou, Idaho Springs, and Cañon City are among the more favored resorts.

One should be under the care of a physician here as well as elsewhere to obtain the best results. Most of them have "been through the mill" themselves and their experience will be of great value. Personal experience is often too dearly bought.

RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

THE CEREBRAL CONVOLUTIONS.

THE morphology of the cerebral convolutions, their significance, and the cause of their appearance are some of the burning questions of the day. They were discussed at the recent Congress at Berlin, but it will be long before we get the complete record. Professor Cunningham delivered an address before the Section of Anatomy and Physiology of the British Medical Association¹ which states very well some of the questions now under discussion and which shows the present standing of the case. In the first place the morphology and the embryology of the convolutions and fissures is not in a very satisfactory state. Futile attempts have been made to reduce to a common plan the cerebral folds of carnivora and primates. Professor Cunningham thinks the failure not to be wondered at as he believes that both came from a common smooth-brained ancestor. He considers the chief differences between the hemispheres of the human and lower forms of the primate brain (apart from the great development of the lower part of the frontal lobe) to consist first in greater richness of

secondary furrows and convolutions in man, and second, in the greater tendency of the chief fissures in the human brain to be bridged over, or interrupted by small gyri. He finds moreover, and this is an important apparent failure of the alleged law, that the development of the individual represents that of the race, that the human fetal brain is less like that of the ape than is the full-grown organ.

The chief purpose of the address was to discuss the influences by which the furrows and convolutions are produced. He rejects uncompromisingly, and beyond question, justly, the theory that the furrows are formed by blood-vessels. He alludes to Schwalbe having pointed out that the cerebellum is the strongest argument against this theory, for the cerebellar arteries though at times in the lips of the fissures, at other times, run across them. A new and very different vascular theory has been suggested by Dr. Richter, which the lecturer condensed as follows: "On the cerebral surface there are different degrees of growth energy. Along the lines of interference or breakage of the pulsatory molecular concussions there is a check to surface growth, and by reason of this, furrows are induced. In the areas between these furrows there is an exuberance of growth which leads to the formation of the convolutions." This theory also is worthless. On the one hand anomalies of the arteries would affect the type of the brain, on the other hand, in normal cases the furrows should make their appearance in more regular sequence than they do, and always in the same manner. This naturally brings up the question of the effect of the shape of the head on the character of the convolutions. "Is the brachycephalic brain moulded into shape by the brachycephalic skull? or are both the result of the same hereditary influence, and, therefore, in perfect harmony with each other as to their growth?" I am inclined to adopt the latter view; and, such being the case, I do not believe that, in normal conditions, the direction of the furrows and convolutions is affected by a restraint placed upon the growth of the cerebrum by the skull capsule. Rüdinger insists strongly that the anatomical peculiarities of brachycephalic and dolichocephalic heads are determined prior to birth."

Having rejected various theories, Professor Cunningham seems inclined to think that Yelgersma's² new views (which he shows, however, not to be so very new after all) are very satisfactory.

The gist of his statement of the law is found in the following passage: "The geometrical law involved is simply this, that in the growth of a body the surface increases with the second, but the interior with the third power of the radius. From this it is evident, seeing that the proportion of internal white matter and external gray matter is in all cases a uniform one, that in the evolution of a large animal out of a small animal a disproportion between the gray capsule and the white core of the cerebrum must result. This is compensated for by the extended cortex placing itself in folds or puckles, and thereby reducing the capacity of the capsule to a degree which brings it into correspondence with the white contents; consequently the formation of the convolutions and furrows is simply the result of the tendency on the part of the superficial layer to increase by surface extension, and of a mutual space accommodation of the gray substance and of the white conducting paths."

¹ British Medical Journal, August 2, 1880.

² Morphologisches Jahrbuch, 1880.

The same theory is made to explain the folds of the cerebellum. It is made to account also for the fact that in large animals the convolutions are likely to be especially rich, as in the whale for instance, while such mammals as have smooth brains are generally small. Yelgersma admits that his theory fails to account for the similarity of plan in brains of the same animal group. Cunningham suggests that if the theory of cerebral localization be true the different parts of the cortex must grow according to their functional activity.

Yelgersma's theory strikes us as very far from sufficient. It may show the advantages which result from the folding of the gray matter into convolutions, but, it does not in the least, explain what produces them.

THE MINUTE STRUCTURE OF THE SPINAL CORD.

Professor Golgi² of Pavia, calls attention to former observations of his which, appearing at different times in Italian publications, have not received the general attention they deserve. The central point of his researches is the morphological difference between motor and sensory nerve-cells, and the arrangement of their processes. In the first place he holds that all the nerve-cells of the cord may, in a certain sense, be called unipolar, as but a single one of their processes ever joins nerve fibres. The course of this process is entirely different in two classes of cells and serves as the real distinction between them. In one set this process breaks up into minute fibrils which take part in the formation of a general nervous network; in the other, though it may send off small offshoots, it preserves its individuality and ultimately becomes the axis cylinder of a nerve. The places in which these cells are found make it probable that the former are sensory and the latter motor. Certain analogies also favor this view. As for the other processes of the ganglion cells, the so-called proplasma processes, they never directly nor indirectly serve for the origin of nerve fibres. They are in close relations with connective tissue-cells and with blood-vessels, and presumably have something to do with the nutrition of the nervous tissue.

There is a nervous network extending throughout the gray matter of the cord, formed (a) by the breaking up of the nerve processes of the cells of the former class, (b) by fibres of the posterior roots which break up in the same way, (c) by offshoots from the nerve processes of cells of the second class, and (d) by fibres given off by the axis cylinders of the different tracts of the white substance. We omit further details as too complicated, but would point out that this wonderfully complicated and minute nervous network suggests an explanation of some of the discrepancies of observations as to the course of motor or sensory impulses. It can hardly be doubted, if these statements be admitted, that in many cases, at least, more than one pathway may be open.

THE BURSA PHARYNGEA.

This old question has come up again, but may be quickly disposed of. Dr. Poelchen³ has made further researches and finds that, though the bursa that Luschka figured had probably no existence, yet there is a pocket in the adenoid tissue of the mucous membrane at the top of the pharynx which is a region particularly exposed to pathological changes.

² Anatomisches Ansiger, Nos. 13, 14 and 15, 1890.
³ Virchow's Archiv., Bd. 119, 1890.

Dr. Potiquet⁴ in a somewhat earlier paper states similar conclusions and suggests a name for this pocket. He rejects calling it after Luschka as that would be indorsing an anatomical error and proposes one of the names by which Robin called it — *foramen cæcum*. This, he says, is sufficiently vague; which he argues is fitting for the name of a fossa of which the existence, the shape, the size and the origin are all uncertain. So far it is all very well, but it seems to us that this miserable little fossa has already names enough, and that it is generally recognized as the *bursa pharyngea*.

THE EFFECT OF HANGING POSTURES ON THE VERTEBRAL COLUMN.

Dr. James Cagney⁵ has written a paper on this subject which deserves study, for the question is an important one. We must confess, however, that parts of the paper are not clear to us, nor can we always agree with the author. He states that it has been assumed, so far as he knows, without evidence, that the vertebral column may be stretched by suspension of the body, and, that what is true of the whole, is true of each of its parts. He proposed to test this assumption in the case of each of the curves separately. The purpose of his inquiries being, apparently, to ascertain the effect of suspension on the spinal cord.

He begins with the dorsal curve which is both the most important and the most simple. If we pull on the two ends of this curve the anterior surface is lengthened and the hind border, that is, the line of the spines, shortened. "From these facts, it appears that the hinder surface of the column contracts while the bodies open out anteriorly, and that, therefore, there is a point of rotation round a transverse horizontal axis between each pair of contiguous vertebrae. This point of rotation must be at the posterior edges of the upper and lower surfaces of the bodies of the vertebrae. It is well known that the bodies of the dorsal vertebrae are thicker behind than in front, whilst the intervertebral disks are of the same thickness throughout. In an expansion or straightening of the curve, the points where the bones are thickest will be approximated, and the intervertebral substance will undergo the utmost compression there; and thus a series of fulcra is provided in a line just in front of the spinal canal. The segments behind the fulcra approach each other, and therefore the spinal canal is shortened; but, shortening of the spinal canal in any part implies a relaxation of that portion of the spinal cord which is within it." All this seems to us simple and beyond question. It may be very easily verified on a bisected ligamentous preparation of the spine.

Dr. Cagney endeavors to show that a shortening and a relaxation take place in all the three curves when the body hangs freely, and that this occurs by a different mechanism for each curve. We are not quite convinced concerning the cervical and lumbar. Apart from the mechanics, Dr. Cagney's argument is, that the curves lengthen out in suspension; that is, become arcs of larger circles and as the subtending cords remain unchanged are consequently shortened, for if the cords are equal it is evident that the arc of the larger circle approaches more nearly to a straight line. What we have failed to see is the proof that the line of the combined cords is not lengthened. The question is both interesting and important from a practical point of view.

THE RELATION BETWEEN THE LENGTH OF THE STERNUM AND THE HEIGHT OF THE BODY.

The writer of this report read a paper at the meeting at Philadelphia last December of the Association of American Anatomists entitled "Medico-Legal Studies on the Human Skeleton," of which the portion devoted to the sternum was published in the July number of the *Journal of Anatomy and Physiology*. It treated of the sternum as an index of sex, age and height. The last point is the only one to be considered here. It is mentioned because little has been done and it seems desirable that others should add to the number of observations. Measurements (bearing on this question) were made on seventy men and thirty-nine women, all white. The length of the sternum, that is of the manubrium and body, the rib-bearing portions—was found in the seventy men to be 9.65% of the height. The men were divided into two groups of the thirty-five shortest and the thirty-five tallest. The sterna of the former averaged 9.75% of the height and the latter 9.61%. The men were divided into still other groups without materially changing the percentage, which varied, for the groups, from 9.57 to 9.98. The average percentage of the thirty-nine women was 9.22, of the nineteen shortest 9.17, and of the twenty tallest 9.26. The variation between all the groups, male and female, was surprisingly small, the difference between the extreme groups being only eighty-one of one per cent. Of course, when individuals are dealt with, considerable discrepancies occur, but it is remarkable that comparatively few would have to be eliminated to bring all very near to the means of a few groups.

In this paper the writer referred to an inaugural dissertation on the sternum (1881) by Strauch, which he knew only by abstracts. He has very recently received it through the kindness of Professor Stiede of Königsberg. Strauch gives the proportion of the sternum to the height of one hundred men and one hundred women, but, as we think, unfortunately includes the ensiform. He, however, gives his results counting only the manubrium and body, which, when we change the notation into percentage of the height, agree pretty well with ours. His percentage for the male averages very nearly 9.60,¹ the writer's being 9.65. For the female his percentage is 9.00+ and the writer's 9.22. Strauch mentions the observations of Professor Körber who measured 1,400 living men, apparently Russian recruits, not including the ensiform and found the sternum to be 10.75% of the height, the only exceptions being those of 164 and 166 cm. We cannot suppose that this means that all the others corresponded exactly. There are two or three possible explanations for the discrepancy of Körber's results. It is possible that recruits are hardly average specimens of the male population. It is very difficult, if not impossible, to measure the sternum accurately in the flesh; and finally it is probable that dead bodies measured lying, are longer than when they were living and measured upright.

There can be no question that a good deal of individual variation must occur and that it would never be safe to decide on a man's height from his sternum alone. It might be useful as confirmatory evidence together with other measurements, and it is not at all

unlikely that it may prove a better guide than the length of the bones of the limbs. It is to be hoped that further observations will be made.

Hospital Practice.

BOSTON CITY HOSPITAL.

SUPRA-PUBIC LITHOTOMY IN A BOY OF TWELVE.

SERVICE OF ARNER POST, M.D., Visiting Surgeon.
REPORTED BY JOEL E. GOLDTHWAIT, M.D., House Surgeon.

W. D., twelve years of age, entered the hospital the latter part of June (1890), with the following history:

Since he was quite small the patient has had irregular attacks of pain, preceding micturition, and referred to the end of the penis. The attacks vary greatly in duration, usually lasting for a few days or weeks; with intervals, usually of longer duration, of entire freedom from any symptoms. For the past few months these attacks have been growing more severe, while during the last two weeks the pain has been much more acute than formerly and has been present almost constantly. The pain is relieved by micturition.

For quite a long time there has been difficulty in starting the stream of urine, necessitating violent straining, but when once started very little effort is required. The presence of blood in the urine has not been noticed.

On examining the child, the first things that attracted attention were the conditions which had evidently been produced by the straining that precedes micturition. There was quite extensive sub-conjunctival hemorrhage on both sides; the abdominal muscles, particularly the recti, were abnormally developed and there was also a moderate prolapse of the rectum.

On exploring the bladder, a large-sized calculus could be felt, both with a sound and with a flexible catheter. This same mass was felt by digital examination through the rectum. It was freely movable, and on pushing it upwards the urine was passed without difficulty.

The prepuce was fully twice the normal length, with a mere pin-hole opening. Retraction over the glans was impossible.

In the interval between the admission to the hospital and the operation, the patient was kept in bed, with the pelvis elevated. There was quite constant pain preceding micturition, which was relieved occasionally by inverting the child, head downwards; while at other times, when apparently due to the spasmoid contraction of the bladder-wall upon the calculus, it was only controlled by morphia or complete etherization.

July 10th, the operation was performed by Dr. Post. Owing to the unusually small size of the urethra, the smallest evacuating tubes could not be passed into the bladder; hence all idea of crushing the stone had to be abandoned.

Operation. — The bladder was distended by injecting about four ounces of a two per cent. solution of boracic acid. The rectal bag was not used. A median incision two inches long was made, the lower end being just over the pubes. This was carried down to the bladder. All hemorrhage controlled by pressure-forceps. The

¹ From some source of error which escapes us we make it by changing the notation of certain results 9.61 and of others 9.59.

peritoneum was thought to be exposed, but without any attempt to positively identify it, it was drawn towards the upper angle of the wound, where it was held and protected during the operation by the finger of an assistant. A longitudinal incision about an inch long was made in the bladder-wall. Through this incision a stone weighing 585 grains was removed with some difficulty. The bladder was washed out with a two per cent. boracic-acid solution, and the two extremities of the wound closed with silk sutures, the middle portion being left open for drainage. No drainage-tubes were used. A large absorbent-gauze pad was applied, the inner layers being moistened in corrosive sublimate solution (1-3,000). While the boy was under ether the prepuce was cut and the phimosis relieved.

The convalescence was uneventful. The urine drained freely through the wound, very little, if any, coming through the urethra until the seventh day after operation, when a urethral bougie was passed, after which the urine was passed voluntarily by the urethra in varying quantities until, on the twenty-seventh day, the abdominal wound entirely closed, it having been merely a slight sinus for a week or two previous to this, through which the urine escaped only by drops.

On the fourth day after operation, the child was out of doors in a wheel-chair.

On the eighteenth day, he was playing about the ward with the other children.

August 11th, one month from the time of operation, the patient was discharged from the hospital in excellent general condition. The abdominal wound had been closed for several days, and the urine was passed by the urethra without difficulty.

Reports of Societies.

RHODE ISLAND MEDICAL SOCIETY.

GEORGE D. HERSEY, M.D., SECRETARY.

QUARTERLY MEETING, September 11, 1890.

DR. J. F. HALLER read a paper on

MODERN PHYSICAL DETERIORATION, AND SOME REMEDIAL SUGGESTIONS.

At the recent medical congress in Berlin, Professor Paul Gibier, in a paper on "Temperaments," proposed a new classification—the acid, the alkaline and the neutral or normal temperament. Professor Gibier holds that persons with the alkaline temperament are free from ailments of the heart and blood-vessels, eczema, and the various forms of cancer. The secretions are but slightly acid, and acidity of the stomach is unknown in early life. Women with this temperament bear children easily, and seldom have rheumatism or gout, but when living under unfavorable circumstances, are prone to consumption. The acid temperament does not favor the development of tuberculous and scrofulous diseases; but its possessors are exposed to neuralgia, migraine, rheumatism, gout, aneurism, asthma, diseases of the nervous system, cancer and malignant tumors. The neutral is the normal temperament, and insures health and long life. It is to be cultivated by attention to exercise and diet. Professor Gibier holds that in modern life there is an

increasing number of people with the acid or alkaline temperament, and hence an increasing frequency of tuberculous, nervous and skin diseases.

Whether this theory is right or wrong, it is a step towards concentration, and calls attention to the steady physical deterioration of the race. This progressive degeneracy is largely due to hereditary influences, but is also caused in great measure by acquired or self-induced, and hence preventable, causes. While so much is being done for the mental improvement of the rising generation of Americans, their physical culture is left very much to inclination or chance. Prior to 1860, the leading American colleges had no gymnasiums, and to this day but very few of our prominent schools give methodical attention to the physical development of the students, while special courses of instruction on public and private hygiene and State preventive medicine are almost unknown. All of our schools should have a uniform regular system of gymnastic exercises, as in Germany, France, Belgium and Sweden, where physical education is an essential part of the school curriculum.

The modern European systems of gymnastics are mostly founded on the principles of physical training laid down by the Swedish gymnast, P. H. Ling; and we find this system adapted for general instruction in Baron Nils Posse's recently published "Swedish System of Educational Gymnastics." The same system as adapted to massage and medical gymnastics will be found in Hartvig Nissen's "Swedish Movement and Massage Treatment." The latter is of special value to physicians, as there is no period of life when a man or woman may not profit by systematized exercise judiciously pursued.

DR. E. P. KING: I would like to ask the essayist if he has any statistics to show that the race has deteriorated in physical stature. I am told it would be impossible to get a regiment of modern soldiers inside the armor of old times—a regiment like those New Hampshire men that were parading the city yesterday, for example. I am told, too, that the early Italian artists, when they took their fellow-citizens as models, painted a rather scrawny-looking lot; that it was not until they had discovered the remains of the old Greek art that they painted their subjects rounder and fuller and more muscular. The Amoskeag Veterans would, I think, compare very favorably with the figures of the pre-Raphael panels and frescos.

Dr. King said he would not like the reader to think him out of sympathy with the recommendations of the paper, and called attention to the prizes for physical culture lately awarded at Harvard, as evidence of an accomplished step in the direction desired.

DR. L. F. C. GARVIN: There is certainly an increase of longevity in modern times. I think that the New Englander of to-day would suffer somewhat in physical comparison with his ancestors of colonial times, just as he does in contrast with the inhabitants of the less cultured parts of America. The average height of regiments from Kentucky and the backwoods of Maine exceeded that of recruits from the cities of New England and the Middle States. Then, the defective sight is much more common here than in portions of the country where books are less studied and out-door life is the pastime of youth. Max O'Rell in "Jonathan and His Continent," however, makes special mention of good physical condition of Americans, saying that not one in ten thousand of the

persons one meets upon the streets of New York, is deformed.

In Rhode Island factory villages it is not uncommon to see operatives who show signs of a rickety childhood, but these people are of foreign birth, and their ancestors have been mill-hands for generations. It is said that deformities are much more frequent in some counties of England than in others where a different manufacture is carried on. These defects are doubtless due largely to mothers going into mills to work, and leaving their infants to be brought up on artificial diet. Frequently these immigrant women who have borne large families have but two or three living children, the rest having died in infancy. In comparison with these mothers of foreign birth, I have observed that native American women are deficient in muscular vigor, their labors being oftener protracted by lack of pains.

Dr. W. H. PALMER: I believe that the American people are deteriorating physically. The fact is observed not so much in the physique of the people as in their loss of physical vigor. Stature has been preserved better than resistance to disease or endurance of the same. There is proof of this deterioration in the fact that notwithstanding the advance of medical science there is an increase of mental and nervous diseases; also in the fact that the proper depleting treatment of disease during the last century has changed to the necessary supportive treatment of the day. One cause of this deterioration is race intermarriage; another cause is fast living. I am glad the reader has emphasized the hereditary factor of deterioration, for it can hardly be overrated. His remedial measures against race deterioration are excellent, but to my mind begin in *medias res*. The best remedy is undoubtedly the prevention of the source, to wit, the birth of beings physically imperfect. Gymnastic exercise will increase physical vigor, but just about as the twig is bent the tree will incline.

It was not so much the martial exercise, the athletic sports, the dining at common tables and education in physical and moral courage that gave to the Lacedemonians, in their best estate, their remarkable physiques and physical endurance as the law of Lycurgus which forbade the rearing of children not born strong and well-proportioned. When legislation shall prevent the marriage of persons of deformed bodies and weak, diseased constitutions; when medical science shall no longer exhaust its skill in preserving those weakling births which nature can best care for by those beneficent laws governing the struggle for existence, and the survival of the fittest, then shall we look for race invigoration. Evolution means progress only under the law of selection.

Dr. E. C. SEGUIN: I must say that I cannot endorse the pessimistic views which have been advanced relative to the health of the human race, by the author of the very interesting paper and by several gentlemen who have spoken. On the contrary, I believe that historical and statistical evidence goes to prove that the health and strength of civilized races have improved in the last ninety or a hundred years. Here and there, in certain areas, among certain nations degeneracy may have occurred, but the general tendency has been, in accordance with the law of evolution, toward improvement. I cannot imagine that man should be free from the operation of that great law which means progression as well as variation for all living beings, especially

the higher mammalia. True, we often interfere with the operation of the law of natural selection and often prevent the decay and death of the unfit, but in spite of this, progress is evident. Proofs lie in these facts: that longevity has increased in civilized countries, and at the same time the population of nearly all civilized nations has increased greatly in this century. Then again, it is an admitted fact, that civilized men, the most civilized men, are larger and stronger than savages. In the wilds of Africa and in the uncivilized regions of Asia, we meet with the smallest men. Comparisons have been referred to as between Ancient or Middle Age soldiers and our own; but such comparisons are dangerous, inasmuch as statistics did not really begin to be created until after 1840. Some figures of height and chest measurements were given out after the late Civil War, which would show that, instead of having a regiment or two of men over six feet high, as Frederick the Great had (referred to by the author of the paper), we had tens of thousands of such large men in our army.

I am more interested, however, in the closing and practical part of Dr. Haller's paper, wherein he advocates the cultivation of gymnastics in schools. I especially agree with him in the distinction he draws between hygienic or physiological gymnastics and athletic gymnastics. In referring to the good work begun in this direction by many of our colleges, he has, I think, hardly done justice to Professor Sargent of the gymnasium at Harvard University, whose aim has pre-eminently been physiological development by gymnastics. Allow me to suggest, however, that though these collegiate gymnastic courses are excellent, and doubtless will bring forth fruit, it looks to me like beginning at the wrong end. The time when hygienic or physiological gymnastics should be begun is in early childhood, before deformities have begun to appear, and when the bones and muscles are yet plastic. When our young man and young women reach the college gymnasium, their osseous and muscular systems are almost complete in development—not fully so, however, so that improvement does ensue. But from the sixth year, at least, the children in our schools should be taught by competent teachers to breathe properly, to use both hands equally, to drill their muscles, and deficient or weak parts should be carefully exercised and improved. As Dr. Haller says, by all means we must use our professional and personal influence to induce the authorities to introduce hygienic gymnastics in the primary, public and private schools. The foundations of health and strength should be laid then and there. Besides, it should be borne in mind, as stated by another speaker, that the vast majority of our public-school children never reach the colleges, and hence never have opportunities for scientific instruction in gymnastics.

It has seemed a strange thing to me that we Americans should complacently sit with folded hands and imagine our primary schools to be the best. In many parts of Europe, even in small States like Belgium and Switzerland, the schools are ahead of ours in scope, in attention to height and shape of seats and desks, and in lighting arrangements. Besides, in Europe much more attention is given to manual or industrial education for the poor; and in some schools ethics is taught; a science which with us is practically ignored and relegated to the Sunday-school and church, where thousands of young people will not or cannot go to get it.

These may be far-away improvements; but what deserves immediate attention, and what it is perfectly reasonable for us physicians to demand, is that the children of our primary schools, public and private, should have scientific instruction in physiological gymnastics and personal hygiene.

THE NEW YORK ACADEMY OF MEDICINE.
NEUROLOGICAL SECTION.*

DISCUSSION ON RABIES OR HYDROPHOBIA.

THE president of the Section, DR. L. C. GRAY, in discussing the clinical aspects of the disease, said that the extreme variability in the period of incubation had given ground for the belief held by many competent observers that if there really existed such a disease as hydrophobia at all, death might also occur, as the result of fear, with symptoms closely resembling the true disease; and the speaker thought himself justified in assuming that frequent mistakes were made in the diagnosis of rabies, the so-called dumb rabies being merely a symptom of simple purulent meningitis and meningo-encephalitis, and that very few cases of either rabies or hydrophobia, the latter term being used to signify the disease in man, had been observed in New York City, or in the country at large. He believed that there was a disease running a fatal epizootic course in the dog and other lower animals capable of being communicated to the human being and causing death, though the evidence of this would rest mainly upon pathological and experimental findings.

DR. C. L. DANA said that there was no constant change to be found in this disease. The nervous centres, which were the parts chiefly involved, were congested, and occasionally showed hemorrhagic and softened spots, with subsequent evidences of increased vascular activity. Exudation of leucocytes into the perivascular spaces, and possibly the beginning of a multiple focal myelo-encephalitis or of focal necrosis. The symptoms were evidently not the result of any organic changes in nerve tissue, but of a distinct poison, the product, undoubtedly, of microbial activity. In the light of Pasteur's scientific work, this question of specific origin was proven.

The speaker did not believe that there were authentic clinical records of a single case in which the fear of hydrophobia had caused a disease measurably similar to rabies, nor was there a case of death from this hypothetical phantasm. There had possibly been some tetanus following bites or acute mania, in those predisposed, from fright. He thought Pasteur had demonstrated the fact that, as a reliable prophylactic measure, aurorable inoculations could be successfully employed.

DR. H. M. BIGGS then gave an elaborate description of the respective methods of inoculation and of the various emulsions used in the work of both Pasteur and Ferran.

DR. H. C. ERNST, of Boston, who has done considerable experimental work in this field of inquiry, said that he regarded the results of Pasteur as among the greatest achievements of modern medicine. The speaker had been entirely converted to a thorough acceptance of the theory, after conducting a series of inoculation experiments. If there was one thing certain in medicine it was the unerring precision in the

results obtained by the inoculation with these cord emulsions under the dura mater of the healthy rabbit. There was nothing like it in the whole range of scientific experimentation. As to the existence of a constant lesion, pathognomonic of rabies, he did not know that this could at present be defined with scientific accuracy, but careful observation had demonstrated the very uniform presence of infiltration of the minute vessel walls in the medulla with white cells, engorgement of the veins, and occasionally peri-vascular hemorrhages. What appeared like small miliary abscesses were also present. The condition had been aptly covered by the term miliary bulbitis.

The speaker then gave the clinical histories of three cases of true rabies in man, which had come under his own personal observation and which, taken with the fact that a large number of dogs were affected at or about the same period, pointed to the recent existence of an epidemic of rabies in Boston. One of the cases cited in detail, was of special interest, because the patient between the paroxysms was able to describe his condition. He had been especially questioned as to whether there existed any repugnance to water and had positively stated that this was not so, but that any mental process connected with the act of deglutition, causes an uncontrollable spasm of the muscles of the throat, and this patient had also described himself as perfectly conscious of his acts during the violent paroxysms, but as being utterly unable to control himself. Even while thus quietly describing his sensations, the fit would come on and the next moment he would be on the floor, struggling with four or five men, and then as to the value of the preventive method the speaker instanced the case of a boy who was bitten in August by a dog which within fifteen minutes had also bitten several dogs. Of these, two had died of rabies and the father of the boy becoming alarmed, had consulted the speaker. Inoculation was advised and submitted to twice a day. No bad symptoms had resulted. Before the boy's return home a third dog had succumbed to unquestionable rabies.

Whether there was anything in Pasteur's claims or not, one thing was certain, he had got hold of a specific virus which could be transferred from one animal to another indefinitely, always producing a sequence of practically identical symptoms. The experiments made by Dr. Spitzka had not been carried far enough, they had produced something similar to the appearance of rabies in the rabbits, but had offered no sort of ground for comparison with Pasteur's experiments. While hardly wishing to stand up as a champion of the Pasteur method, if the statistics of the Institute were not reliable, he was still bound to believe in the honesty in purpose of Pasteur and his assistants. It was a significant fact that after the careful elimination of all cases in which an element of uncertainty existed, the mortality rate for those treated by inoculation under the method, was only ninety-eight one-hundredths of one per cent. He expressed surprise at the statement that there could be no such condition as pseudo-lyso-phobia.

DR. R. W. BIRDSALL said he had seen a number of cases of pseudo-rabies resulting from fright after a bite or scratch of a dog. These cases had not resulted in death, though he was not prepared to go so far as to say that death from fright was not possible. The nervous shock sustained might set up a series of changes such as motor paresis, edema of the brain and coma,

* October Meeting, 1890.

resulting in death. He did not believe they were yet in a position to be able to refer the phenomena of true rabies to the existence of one kind of specific germ. The effects might be due to the presence of distinct varieties.

DR. H. P. LOOMIS had only considered the subject from a pathological standpoint. The findings tallied very much with those described by Dr. Ernst. Sections of the lower portion of the medulla had showed congestion of the capillary vessels and giant-cell infiltration of the adventitia, but no capillary hemorrhages or thrombi.

DR. BYRON, who has made extensive experiments both at the Carnegie and Loomis laboratories, had arrived at the conclusions that (1) inoculations of the specific virus of rabies under the skin were completely useless; (2) that the results desired could never be produced by any process except subdural inoculation, and that even then the result was doubtful. The question was a serious one, and the subject still in need of further experimental research before any definite scientific conclusions could be formulated.

DR. E. C. SPITZKA said he had made no experiments on rabbits as intimated by Dr. Ernst, who had evidently not followed the points of the speaker's work. In the experiments made by him on dogs he had made no claim that these animals had represented true cases of hydrophobia; but by the introduction of various irritating substances into the brains of these dogs, he had produced a condition of bogus hydrophobia. He was now associated with the conduct of a series of elaborate experiments on rabies, the results of which, could not, as yet, be formulated.

DR. L. C. GRAY thought the discussion had proved (1) that there existed undoubtedly in the lower animals a disease, known as rabies, possibly made up of several diseases, due to different micro-organisms; (2) that this disease was more frequent in the lower animals than a similar disease in man known as hydrophobia; (3) that while this so-called rabies in animals occurred very often in this country, it occurs less frequently in the human being; (4) that very few medical men have seen genuine cases of hydrophobia; (5) that cases of pseudo-hydrophobia were by no means uncommon and that death could result from the condition; (6) that there still existed considerable diversity of opinion as to the value of Pasteur's method which would furnish material for discussion and incite to further experiment.

AMERICAN GYNECOLOGICAL SOCIETY.¹

DISCUSSION ON THE QUESTION OF AMPÈRAGE IN THE TREATMENT OF FIBROID TUMORS BY ELECTRICITY.

DR. TREMAINE, of Buffalo, was not able to obviate intra-uterine cauterization even with a very mild current and after an experience of sixteen cases he was rather disappointed with the electrical treatment. He believed the actual value of Apostoli's treatment of fibroids was still *sub judice*, and raised the question as to what became of the abdominal walls and other thin tissues if the electrolytic action, which passed through them to get at the tumor, was sufficient to completely decompose and dissipate the tumor—why these tissues were not also decomposed.

¹ Fifteenth Annual Meeting, Buffalo, N. Y., September 16-18, 1890. Continued from page 377 of the Journal.

DR. A. J. C. SKENE, of Brooklyn, believed there was a certain amount of electrolysis going on in the abdominal walls and in the intervening tissues between them and the fibroid tumor, but that they remained intact while the tumor was dissipated for the reason that it was of lower vitality and could not resist the decomposing action of the current. Even if the normal tissues do sustain a certain electrolytic action, their great vitality enables them to soon regain their original condition, while the fibroid does not. He did not believe that cauterization was ever necessary to stop the growth of the tumor, and that in avoiding it all the dangers of electrolysis would be obviated. He would never carry electrolysis to the point of cauterization. He believed that electrolysis with the positive pole in the cavity of the uterus produced stenosis, and that it could be avoided by the use of the negative pole. Very few cases can ever be said to be cured, that is to say that the tumor has entirely disappeared, but if we limit the word "cure" to mean an arrest of the growth, in that sense many have been cured. In many cases the tumor has been very much diminished in size and the symptoms have been cured, which might be called "symptomatic cure." He thought that Apostoli meant to be honest, but, like all other enthusiasts, he was inclined to over-estimate his work, but that in the main he is correct.

DR. H. P. C. WILSON, of Baltimore, believed that for violent bleeding myoma, the carbon uterine electrode was the proper one and he much preferred it to the platinum electrode; that electricity was not applicable for intra-uterine pediculated myoma, or sub-peritoneal pediculated myoma, or soft edematous myoma; but that the intra-mural form could be cured in the sense referred to by Dr. Skene. He believed that much of the dissatisfaction with the use of the electrical treatment was due to the fact that operators were too sanguine and used electricity for all kinds of tumors when it should only be used in selected cases.

DR. MYNTER, of Buffalo, called attention to the statement of Dr. Ford in regard to the difference between electrolytic action and electro-chemical action, the former produced by a moderate number of cells with a large surface and low intensity, while the latter was caused by the application of a battery of very small cells, having a very high tension, and thought that perhaps the diversity of opinion in regard to electricity was due to the fact that many who administered it did not have the proper battery. He was also convinced that the electro-chemical action frequently caused sloughing.

DR. ROSEBRUGH, of Hamilton, Ontario, asked whether in cases claimed to be cured there was any other form of medication, such as ergot, given coexistent with electricity?

DR. H. P. C. WILSON, of Baltimore, used no medication except enough to regulate the bowels and nervous system with bromide of potash, etc. He considered ergot as absolutely worthless in fibroids.

DR. W. C. FORD, of Utica, never found that the soft edematous fibroids would not yield to electricity, but that in the very hard ones he had found it necessary to cauterize in order to make any impression on them.

DR. GEHRUNG, of St. Louis, believed that better results could be obtained by puncture, where it was admissible, then by treating the tumor through the walls of the uterus, and that in the large exudation

tumors filling the pelvic cavity and firmly adherent to all the pelvic organs — where any operation was impossible — could be successfully treated by puncture and electrolysis. He uses the trocar electrode and double canula, with two tubes attached, through which, by the use of the aspirator, he can wash out the cavities of the tumor if it be a cystic one.

DR. A. J. SKENE, of Brooklyn, thought that ergot was only useful in sub-mucous uterine tumors with a tendency to become pedunculated, or those that were undergoing a natural process of elimination — cases which did not call for electrolysis. In cases of bleeding fibroids he would remove a portion of the hypertrophied mucous membrane of the uterus to control hemorrhage; then apply iodine to the mucous membrane which acts as a disinfectant, and then electricity. In cases where the hemorrhage was not severe he would use ordinary disinfectants, but in obstinate cases he believed that *hydrastis canadensis* was valuable and that it had a beneficial effect on the mucous membrane of the uterus. He frequently used it in connection with cureting, iodine and electricity.

SECOND DAY.—MORNING SESSION.

VAGINAL FIXATION OF THE STUMP IN ABDOMINAL HYSTERECTOMY.

by DR. HENRY T. BYFORD, of Chicago.

Dr. Byford presented this paper as a supplement to one read by him a year ago. Extended experience had taught him the advisability of modifying the method which he had recommended, and he cited eight cases in which he had deviated from his former operative procedure. The method which he had advised consisted of making a stump of the Schroeder-Martin intra-peritoneal variety, and then, instead of dropping it into the abdominal cavity, of separating the bladder from the cervix, cutting and tearing down through the anterior vaginal wall, anteverting the stump into the vagina, and holding it there by tenaculum forceps. The peritoneal cavity was closed over the stump by suturing the reflected edge of the bladder peritoneum to the posterior surface of the stump with catgut.

The characteristic steps of the operation as now performed by Dr. Byford, are as follows:

Ligate the broad ligament; separate the bladder from the cervix; put on a temporary elastic ligature below the tumor; transfix and cut off the mass above; ligate the stump in several parts with silk; remove the elastic ligature; perforate the anterior vaginal wall in front of the cervix; turn the stump forwards into the vagina, and clamp it firmly there; sew the peritoneal edge, that was separated along with the bladder from the anterior surface of the uterus, to the posterior surface of the stump, so as to close off the peritoneal cavity from the vagina; close the ventral incision, with or without drainage. A small strip of iodiform gauze, stuffed from below into the rent in the anterior vaginal wall, and left for twenty-four or thirty-six hours, may be used to prevent any accumulation of discharge at that point. The time occupied in separating the bladder and anterior vaginal wall from the cervix and putting on the clamp-forceps should be no longer than for the adjustment of the stump in ventral fixation. The other steps are practically the same. Bladder wounds can be treated extra-peritoneally, without displacement of the viscera.

In each case of those reported by Dr. Byford, the shortened upper end worked its way back into the

connective tissue behind the bladder, so that, in a few weeks, the os and cervical canal were normal as to position and mobility. One case resulted fatally at the end of the fourth day, death occurring from general septic peritonitis, which was not, however, in any way connected with the treatment of the stump.

DR. HOWARD KELLY, of Baltimore, would divide fibroids into four classes:

(1) Those which are pedunculated and intra-uterine which can be removed from the cervix. (2) Those which can be removed through the abdominal incision by myomectomy, without removing any substantial portion of the uterus. (3) Those with a distinct pedicle which can be removed by supra-vaginal hysterectomy; also those in which the pedicle can be formed, but where it is necessary to cut under the tubes and ovaries and through the broad ligament to get at it. (4) Atypical cases, where the tumor is spread out laterally in the broad ligament, almost filling the pelvis, and where it is impossible to get a pedicle, the patient usually dying from hemorrhage and shock. These latter cases cannot be treated by section, which is limited to cases with a distinct pedicle; and there is no well defined method of treatment for them.

In treating these fibroids we must consider first that we have a very large fleshy pedicle, the ligating of which controls the hemorrhage at the time of operation, but which may be profuse after it is dropped back into the abdominal cavity and thus prove a source of contamination. He compared the methods of treatment of Hegar, the extra-peritoneal, and its modifications by Zwiefel, and of Schroeder, the intra-peritoneal; his own, a modification of the two, and also Dr. Byford's. The first he claimed to have had such a death-rate that it was abandoned, but subsequently rendered legitimate by Zwiefel, who performed it with more care. Hegar's method of allowing the stump to slough off, he considered an unsurgical procedure as to tie a string to the finger and allow it to slough off. It is also very difficult where the stump is short, which contracting up into the abdominal wound has often caused sloughing into the tissues below, followed by death or a very protracted convalescence. To overcome this difficulty, he adopted the plan of suturing the stump with buried and superficial sutures, and suspending it in the lower angle of the abdominal incision. A square pad of iodiform gauze is placed over the external end of the stump through a hole in the middle of which the sutures which have been left with long ends are drawn, and can be grasped with the forceps at any time, in case of accident, thus giving complete control of the stump. This has stood the test of nine cases with but one death, which was due to vascular lesions. Dr. Byford's method is good for the smaller tumors, but it would be very difficult to deal with a broad pedicle by this method. It has the advantage of avoiding the risk of hernia which follows from suspension of the tumor in the angle of the abdominal wound, and also affords excellent drainage, being in a dependent position. It is probably as good an alternative in these cases as any other that we have, but must be tested in a wider field before its real value can be determined.

DR. WILLIAM POLK, of New York, referred to the fourth class of tumors mentioned by Dr. Kelly, which he treated by a plan which was a modification of the one suggested by Dr. Minor, of Buffalo, in the treatment of non-pedunculated ovarian tumors — a process

of complete enucleation. He would ligate the uterine artery, and in some cases, where there was a good deal of hemorrhage from the posterior wall of the tumor, he thought it advisable to cut down and ligate the utero-sacral ligaments on either side, in order to control the hemorrhage. He burns a hole with the cautery right through the cervical canal, burning the tissues well around the hole, after which the cavity is packed with a long strip of iodoform gauze which is brought out of the opening, and the abdominal incision is closed in the ordinary manner adopted in the treatment of ovarian tumors that are enucleated in a like manner, thus affording complete disinfection of the cervix.

DR. E. C. DUDLEY, of Chicago, had performed Byford's operation in two cases with perfect success, with a simple modification in the packing of iodoform gauze.

DR. A. J. C. SKENE, of Brooklyn, thought that Byford's method was only adapted to the cases where the stump is small, and that it would be difficult for him to handle a large stump. He believed that complete removal of the cervix might be substituted for Byford's operation, also in dilatation of the cervix and complete inversion of the same. Before adopting Byford's method, the relative value of these other two methods should be ascertained.

DR. JOSEPH TABER JOHNSON, of Washington, had successfully performed five cases by the Bantock method. He thought it was better to have a long convalescence caused by the sloughing off of the stump in this operation, than to try some other operation and have no recovery at all. He believed the method referred to by Dr. Skene of the complete removal of the infected stump, and providing proper drainage, would be the ideal method.

DR. E. C. DUDLEY, of Chicago, had tried inversion of the stump, and found it an exceedingly difficult operation to perform and almost impossible to accomplish, no matter how much dilatation was used. He had also attempted the removal of the entire stump by placing on the lock forceps through the vagina to secure hemostasis, but believed it a very difficult and not very practical operation. Dr. Byford's method should be adopted in all cases of large fibromata which completely filled the uterus and spread out into the broad ligament, especially if the size of the cervix be reduced by the cautery as spoken of by Dr. Polk. The vagina is quite capacious and will hold a pretty large stump.

DR. GEORGE KEITH, of Edinburgh, corrected the statement of Dr. Johnson that his father had given up hysterectomy. He gives his patients electricity first, and if that treatment is not successful, he resorts to operation — that is his practice at the present time.

DR. WILLIAM M. POLK, of New York, was glad to know that the elder Keith had not given up hysterectomy, which was encouraging to those who wished to maintain the same position. He agreed with Dr. Dudley that the operation for the complete removal of the uterus and cervix by applying clamps through the vagina to control hemorrhage, was a very difficult and unsatisfactory operation; and was inferior to the complete extirpation of the uterus by the use of the ligature, notwithstanding the fact that in some cases where the cervix is deep down, that operation was prolonged by a good deal of bleeding. Dr. Byford's method has the advantage of simplifying and shorten-

ing the operation. Another method suggested about the same time, or since Dr. Byford's, which accomplishes about the same end, is that after the stump was cut off and the bladder dissected away instead of making an opening into the vagina, with one blade of the scissors in the cervix, and the other outside, the cervix can be cut right down into the vagina, and the mass turned inside out, on the same principle as in the Porro operation in Cesarean section.

DR. HOWARD KELLY, of Baltimore, believed there was still another class of cases in which hemorrhage could not be controlled by the methods described by Dr. Polk and others, and for those cases he had devised a corrugated uterine sound by which he could discover the relative position of the uterine arteries when they were displaced, and in that way control the hemorrhage. These tumors, no matter how large, seldom reach to the ovarian arteries and veins at the points of emergence from the abdominal aorta, and he would in cases of excessive hemorrhage tie these arteries and veins up into the abdominal cavity and in desperate cases where it was impossible to get the tumor out, he would adopt the heroic treatment of temporarily compressing the abdominal aorta, and he is convinced that there is a certain class of cases that cannot be treated in any other way. In his own operation if there is any oozing after the stump is sutured he ligates the uterine arteries and has always succeeded in checking any hemorrhage that might have occurred. Bantock's operation is exclusively and only fitted for cases of pediculated fibroids, and if applied strictly to such cases, the mortality should be nil.

DR. J. C. TEMPLE, of Toronto, agreed with Dr. Skene that the total extirpation of the entire mass was the most rational procedure. He did not believe in the inversion of the mass through the dilated cervix as he had found it a most difficult method. Dr. Byford's plan is a good one in selected cases where it is not desired to remove the whole of the tumor.

The President, DR. JOHN P. REYNOLDS, of Boston, delivered the

ANNUAL ADDRESS,

in which he dealt with the subject of the sacredness of the family, and of the matrimonial state, in a masterly way.

INJURIES TO THE URETERS DURING LABOR.

DR. ALEXANDER J. C. SKENE, read a paper with the above title. He stated that, while engaged in private and hospital obstetric practice, he had attended many cases which differed materially from any recorded in obstetrical literature. In consultation, he had seen many of similar character. From clinical phenomena observed, he was led to believe that injuries to the ureters, during labor, were the cause of the phenomena witnessed. The patients are usually primiparae, or those who have had many tedious labors, instrumental or manual, and the progress after delivery, satisfactory, or fairly so. The lochial discharge and the secretion of milk is usually normal; the bowels and the kidneys act normally; sometimes there is retention of urine, or frequent and painful urination. Pelvic pain and tenderness in the lower part of the abdomen are present, but are not always severe at first. The symptoms become more acute after a time, the pain and tenderness increase rather abruptly, and a chill or rigor may occur at this time; distension

of the bowels takes place, and the temperature and pulse run up. Pressure shows increased tenderness, and bimanual manipulation of the kidney, upon the affected side, usually causes a sense of distress rather than acute pain.

The increase in the severity of the symptoms supervenes in from three to five days, and soon thereafter a quantity of pus, and sometimes blood, appears in the urine. When the discharge of pus begins the patient is generally relieved to some extent. The pain is less, and both temperature and pulse are reduced a little. In connection with pus and blood, renal casts may be found, but this is not invariably the case. The pus, in diminished quantity, continues to be discharged for a week or more. The bleeding generally subsides in a day or two days, and most of the cases gradually recover. In other cases, acute disease of the kidneys appears, about the time that pus begins to be discharged from the bladder, and uremia, and sometimes uremic coma, follows. Such cases end fatally, as a rule, but there are a few records of recovery. In uncomplicated cases, a vaginal examination is negative, excepting that tenderness is detected high up on the affected side. If there is evidence of kidney disease, the thought naturally occurs that it must have begun during pregnancy, and that the acute symptoms which follow labor are due to a sudden increase of a pre-existing nephritis. The existence of renal disease cannot be held to be a rule, as, in many cases, there is nothing which would even suggest it.

The diagnosis of injuries to the ureters must be made by the exclusion of the more common puerperal affections, such as peritonitis, cellulitis or general septicemia. Metritis is excluded on the ground that the lochia are normal, that there is absence of tenderness, and that involution progresses as it should. The symptomatic fever is too mild in character to indicate general peritonitis, and the physical signs of that affection are wanting. The tenderness on pressure on the affected side and the constitutional disturbances not otherwise accounted for are suggestive of cellulitis, but the evidence, in the way of physical signs, is insufficient. The sudden appearance of blood and pus in the urine leads one to suspect that an abscess has formed in the cellular tissue, and discharged into the bladder. This is, however, excluded on the ground that physical signs of cellulitis are lacking, and that, furthermore, an abscess never discharges into the bladder in so short a time after the inception of pelvic cellulitis.

In the cases which are complicated with traumatic cystitis, it might be presumed that an abscess had formed in the wall of the bladder; but this is excluded for the reason that the violent symptoms and physical signs found in traumatic interstitial cystitis are absent. The history of injury to the ureters does, in fact, differ from that of any of the puerperal diseases found in medical literature.

Dr. Skene stated that he believed that the evidence of acute nephritis, which was found in several post-mortem examinations, had little significance, and that the lesion was simply secondary to an injury to the ureters. If the ureter is not completely blocked, recovery may take place; but if the stricture in the ureter be complete, acute uremia may supervene, and cause death.

If the cervix uteri and the pelvic floor be injured

and metro-cellulitis follows, the ureters may be secondarily affected. In such cases the development of the pathological lesions is reversed.

Dr. Skene cited several cases in which he had made post-mortem examinations, where it was evident that traumatism of the ureter was the initial lesion, and led to extensive and fatal disease. It would appear that laceration of the ureter had been produced by the head of the child, the hand of the obstetrician, or, more frequently, by injudicious use of the forceps.

The following, Dr. Skene says, is a convenient classification of diseases and injuries of the ureters: (1) Injuries of the ureters during labor. (2) Obstructions of the ureters, secondary to other pelvic inflammations. (3) Obstructions due to neoplasms and uterine displacements. The second and third are taken from Englemann.

The conditions which predispose to injury to the ureters are: The bladder and terminal ends of the ureters resting low in the pelvis towards the end of gestation. Defective nutrition of the ureters, with a consequent loss of elasticity and resisting power. Preexisting lesion or functional derangement of the ureters.

Among the direct causes are: The increased pressure and traction to which the ureters are exposed, in cases in which the cervix uteri and bladder are carried down into the pelvis before the advancing head; When the membranes rupture before dilatation is complete; The presence of fecal matter in the rectum; Faulty methods of operating, especially the giving of undue lateral motion to the forceps.

The treatment following injury to the ureters is, in great measure, expectant. Free catharsis, washing out the bladder, catheterization, remedies to relieve pain, will be found indicated, severally or collectively. The surgical treatment of these affections is not in a highly developed state.

(To be continued.)

Recent Literature.

International Atlas of Rare Skin Diseases. Editors: MALCOLM MORRIS, London; P. G. UNNA, Hamburg; L. A. DUHRING, Philadelphia; H. LELOIR, Lille. Hamburg and Leipzig: Leopold Voss.

The object of this work is to present for the study and enlightenment of those especially interested in dermatology, accurate pictorial representations of unusual affections of the skin, together with a description of the case, and, as far as possible, the result of histological, bacteriological and experimental pathological investigations. It is the intention of the editors, who represent the German, French, English and American schools, to publish from two or three numbers yearly, and the first two portions, containing each three subjects with accompanying text, have been received. The design of the work is to be heartily applauded, and especially its international character, as recent congresses have abundantly proved that many of the rarer cutaneous affections are classed under widely varying heads by dermatologists of different nationalities, and any attempt at a mutual understanding must be heralded as true progress.

The illustrations are carefully and probably accurately elaborated, and the printing is very good.

The criticism that suggests itself at once is as to the object in producing the text in three different languages—German, French and English, thereby adding materially to the expense of an already costly work. As the subscribers will be composed almost entirely of specialists in dermatology, whose reading of necessity embraces works in the three foremost languages, it is difficult to understand the need of such a repetition of the subject-matter. A wiser plan would have been to confine the text of each article to one of the three languages at the option of the contributor, by which means the danger of misunderstanding would be rendered much less, and the cost of publication decreased—a plan that has already been successfully carried out by several scientific periodicals.

Ointments and Oleates, Especially in Skin Diseases.
By JOHN V. SHOEMAKER, A.M., M.D. Second Edition. Philadelphia and London: F. A. Davis. 1890.

In this book, which forms No. 6 in the "Physician's and Student's Ready-reference Series," the author has added to his previous work on the oleates, a consideration of ointments, which occupies the first 207 of the 273 pages of reading-matter. After a short prelude on the general subject of ointments, the writer enters upon a detailed description of those officinal in the United States, French, German and Austrian pharmacopoeias, as well as those used extemporaneously, and, in addition, of those most used in Italy, Spain and in the Spanish colonies. Numerous formularies have been added, with most generous indications for their use in the various skin affections. In the latter part of the book the writer's well-known views with regard to the oleates and their applicability are repeated in this second edition, together with some suggestions as to improved methods of preparation.

A System of Oral Surgery: Being a Treatise on the Diseases and Surgery of the Mouth, Jaws, Face, Teeth, and Associate Parts. By JAMES E. GARRETTSON, A.M., M.D., D.D.S., President of the Medico-Chirurgical Hospital and Emeritus Professor of Oral and General Clinical Surgery in the Medico-Chirurgical College, etc. Illustrated with numerous wood-cuts and steel plates. Fifth edition, thoroughly revised, with additions. Large octavo, pp. 1,364. Philadelphia: J. B. Lippincott Company. 1890.

This work has been the standard dental surgery for nearly a generation. The fifth edition has been improved by condensing the older material and by the addition of much new matter. The chapter on diagnosis is particularly worthy of careful and repeated reading. Every subject relating to dentistry is so accurately and fully treated that reading the work with a critical intent one finds nothing which could be improved.

W. H. E.

—A celebrated actress was married, and accouched six months after the wedding. Her husband, all indignant, went to consult a physician in regard to the affair, demanding a reason for this precocity. "Be assured," said the doctor, "that this affair is all right. The first children of actresses are often precocious, but the children that follow are not. Let that console you, old fellow."—*Cincinnati Lancet-Clinic.*

THE SIGNIFICANCE OF FEVER.—II.¹

THE UTILITY OF ANTIPYRETICS.

FEVER is a complex morbid state characterized by derangement of all the important functions of the body. Besides the hyperthermia, due to increased heat-production and disorder of the mechanism of heat-regulation and removal, which is the most obvious and noteworthy phenomenon, there are the well-known respiratory and cardiac symptoms, the loss of appetite and failure of digestion, the muscular prostration, the nervous (sensory, motor and vaso-motor) disturbances, the urinary derangements, the general impairment of nutrition, etc.

The word *antipyretic* is used as a synonym of the older word *febrifuge*, and denotes any agency, medicinal or otherwise, which lowers or suppresses the febrile heat with its attendant pathological phenomena. This is the ancient and lexicographical use of the word; it must, however, be recognized that this word is often used at the present day in a much more limited sense to signify an agent which abates the hyperthermia without to the same degree, if at all, modifying the other elements of the febrile syndrome.

It is obvious that the more completely a remedial agent meets all these elements, the better the antipyretic which it constitutes; and the most effective antipyretic is that which strikes at the cause of the fever, annihilating it, or rendering it inert. Thus, quinine in intermittent fever is the ideal antipyretic, for all the symptoms of the fever are made better under its influence, and it is a curative means; there can be little doubt that it is a poison to the specific microbe. Salicylate of soda is believed by some to have a similar action in rheumatic fever, though the effects are by no means so marked or so constant. Quinine has no such direct and specific action in septicæmia or in any of the other infectious fevers, falling to the level of antipyrin, acetanilid, kairin, thallin, and other antipyretics which combat morbid heat principally.

Antipyrin has been regarded as the typical antipy-

¹ Continued from page 331 of the Journal.

retic,² but its range of operation is limited. It lowers febrile heat chiefly by restraining thermogenesis, it also promotes heat-elimination, but does not restore heat-regulation (thermotaxis). It alleviates the nervous asthenic symptoms, is both analgesic and hypnotic; it brings down the pulse and steadies it; is not, however, toxic to the infectious agent, and does not shorten by a day the duration of the fever. In pneumonia, typhoid and other specific fevers, it keeps down the fever till the crisis appears, but does not hasten the crisis. Abundant testimonies to this effect have been adduced by the hospital internes of all lands; in many hospitals antipyrin is now only prescribed to allay nervous symptoms and to combat febrile heat when this seems attaining a dangerous height. Although it has been of late rendered probable that much of the old terror respecting the disorganized effect of hyperthermia on the organism was illusory, yet no one doubts that the long continuance of a high febrile heat amounting to hyperpyrexia is deleterious to the blood and tissues, and especially to the heart and blood-vessels, hence there is every interest in keeping the temperature of fever-patients within safe limits, though not absolutely at the normal figure.

What has been said of antipyrin is applicable to acetanilid, phenacetin, kairin and thallin. There is a general consent at the present day in the abandonment of the two last mentioned drugs. And there are certain drawbacks attending the use of antipyrin and acetanilid which make it necessary to use some caution in their administration. We believe that it has been shown that acetanilid (antifebrine) is quite as good and safe an antipyretic as antipyrin, though not, perhaps, quite as good an analgesic.

It is, of course, desirable to find antipyretics that favorably modify all the elements of the febrile syndrome, and especially such as remove the cause. Unfortunately, for most of the specific fevers, such antipyretics are yet to be discovered.

One great objection to the use of the "antipyretic agents of the aromatic series," as they have been called, is that they retard the exchanges and diminish both the liquids and the solids of the urine. What is affirmed of antipyrin is affirmed also of acetanilid, thallin, etc., that they diminish the excitability of the nervous centres which regulate the exchanges; they also lessen the respiratory power of the blood, destroying the oxyhaemoglobin (according to Brouardel and Loyer); they diminish the quantity of urine from twenty to forty per cent, also the quantity of solids in the urine (urea, urates, phosphates, chlorides, etc.) fully sixteen per cent. (A. Robin), so that their rôle as febrifuge medicines is very much compromised.

Another class of antipyretics facilitates heat-elimination. Alcohol and sweet spirits of nitre are supposed to act by dilating the cutaneous vessels and increasing radiation; others are powerful sudorifics (Dover's powder, antimonials, the warm bath). Statistical data are abundant to show the remedial virtues of hydrotherapy

² Vide MacAlister, *Lancet*, 1888.

in at least one of the specific fevers, typhoid fever,³ and they suggest the affirmation of Ziemssen, that of all the therapeutic methods which have been adopted for typhoid, hydrotherapy deserves to be put foremost. Ziemssen has described the action of the cold and lukewarm baths as follows: "The bath cools the blood of the feverish patient, at first at the periphery, and next, by the circulation of the cooled blood from the skin to the interior of the body, the internal organs are affected. The cooled blood has an immediate stimulant action on the depressed nerve centres, and this is regarded as the most valuable effect of the bath. The lowered vitality of the brain is raised, and from the refreshed centre extends a fresher stimulation of the nerves which preside over the circulation, the respiration, the digestive process, the locomotor apparatus, etc. The result is a quiet sleep, a clear sensorium, a refreshed look, easier movements, and a desire for food."

It is not known whether cold bathing has any restraining effect on thermogenesis. The opponents of the cold bath affirm that heat-production goes on unchecked and they point out the danger of internal congestions and hemorrhages from this forcing of the circulating blood from the periphery to the central parts.⁴ The advocates of hydrotherapy are not altogether oblivious of this danger, and counsel baths of moderate rather than of very low temperature. Almost all recognize the utility of lukewarm baths and of frequent cold sponging.

More elements of the febrile syndrome are favorably affected by refrigerant methods than by any other kind of treatment. The digestive functions are improved; there is increased desire for food and what is taken is better digested than before. Increased tone is given to the heart-muscle and to the blood-vessels, and the circulation becomes more normal. Deeper and more prolonged inspirations are taken; haematosis is better performed, and broncho-pulmonary congestions combated. The secretions are augmented; urine, saliva, perspiration; the tongue becomes moist, the eye clear, the surface soft.⁵

On the Continent, Brand and Liebermeister have been among the most earnest partisans of the cold-bath treatment of continued fevers. This method does not lay claim to effecting complete disappearance of the fever, or bringing back the temperature constantly to the normal. Such result, as Liebermeister says, would be impracticable, and certainly impossible in grave cases. What this method of treatment does aim to do "is to transform a grave continuous fever into a much less dangerous remittent or intermittent. We are to endeavor less to combat the exacerbations than to render the remissions more marked and of longer duration."

Doubtless, in the treatment of continuous fevers, the whole matter of the utility of cold baths (which are inconvenient, if not absolute impracticable, in private practice) is still *sub judice*. Senator, in summing up

³ Memoirs of Küchenmeister, Naunyn, Sidney Copland, and others.

⁴ Soc. Méd. des Hôp., 1885, 1886.

⁵ Antipyresis and Antipyretics, Von Ziemssen, 1889.

the results of the cold-water treatment in those hospitals of Berlin where the method has been rigorously carried out, and comparing from the point of view of mortality these results with those obtained by himself in the hospital Augusta, where no exclusive treatment is enforced, has shown that the mortality has been greater under the cold-water treatment. At the meeting of the Society of Internal Medicine held in Berlin, January 18, 1886, Leyden affirmed that the advantages claimed for the rigid antipyretic treatment of typhoid fever were largely illusory. Frantz also stated that the results of hospital trials which had come under his observation were against the free use of cold baths in continued fevers.

Of course, the error of relying exclusively on statistics has been shown again and again, and if this were the only or the principal criterion, therapeutics could never advance. It would be foolish to gainsay all the facts alleged by the German hydrotherapists and by Glenard of Lyons, and it must be remembered that epidemics are of varying severity.

In medio tutissimum ibis — there is a mean which can be followed with safety. No one questions the usefulness, in certain cases, of warm baths (91° F. to 95° F.) and these may, as Liebermeister suggests, be gradually cooled down twenty degrees or more by the addition of cold water; with careful watching of the patient, no harm and certainly much advantage will result from the occasional use of these baths. In private practice the wet-pack is of more easy application, and it is certainly less fatiguing to the patient, though its effects are much less marked and less lasting than those of the cold bath, and the same may be said of cold sponging.

Hospital statistics are now being gradually accumulated in New York in regard to the cold-bath treatment of typhoid, and there is a prospect that we may some time have some home figures which may enable us to arrive at an approximate estimate of the positive practical value of such statistics.

OXALURIA AND NERVOUS STATES.

GOLDING BIRD was one of the first to insist on a definite train of nervous phenomena associated with the excretion of oxalic acid in the urine. He did not, however, attribute these symptoms to any special constitutional state; the word oxaluria was used by him to connote the congeries of symptoms commonly occurring with appreciable deposits of oxalic acid in the urine, due, as he believes, often to alimentary indiscretions and chronic dyspepsia; in some of his writings, he speaks of an *oxalic diathesis* comparable to the uric diathesis. Persons affected with this form of disease are, he says, generally remarkably depressed in spirits; they are emaciated, extremely nervous and painfully susceptible to external impressions, have tremblings of the limbs, with insomnia, often are hypochondriacal to an extreme degree; they are, in fact, types of neurasthenia, well-pronounced dyspeptic

symptoms are always complained of, and gastralgia is generally present. The urine is of a high specific gravity, and deposits abundance of oxalate of lime-crystals with triple phosphates. Among the occasional exciting causes, he enumerated child-bearing and over-lactation, venereal excesses and intemperance, injury to the constitution by syphilis and mercury. The affection is, however, especially an accompaniment of nervous dyspepsia.

Garrod, Furhbrengir and Ralfe also hold to the doctrine of an oxalic diathesis, while Lecorché and Esbach regard oxaluria as only a symptomatic and unimportant accompaniment of the nervous states with which it is found associated. The last named authorities affirm that oxalic acid always exists in the urine in minute quantities; and when it is present in relative excess, this is the result of the ingestion of food or medicine containing this salt, free or in combination.

Neidert¹ has offered a new contribution to the vexed question of oxaluria and nervous states connected therewith. It is still, he says, a matter of dispute whether oxaluria shall be regarded as a pathological entity, or whether it be simply a symptom of a pathological state. Neidert inclines to the view that it is a constitutional affection belonging to the same category as diabetes. According to several observations which he has made, diabetes in the parent sometimes entails oxaluria in the child.

The conclusions at which the writer has arrived are as follows:

An assemblage of nervous manifestations, of decidedly abnormal character, lasting for several years, may, under the influence of certain causes, undergo transformation more or less suddenly into a pathological state which is characterized by the appearance in the blood of oxalate of lime, and by the excretion of this salt in the urine. In these cases, we have to do, not with an accumulation, the result of diet, but with an abnormal and continuous production of oxalic acid at the expense of the tissues of the organism. We have here a quite particular individual predisposition, an alteration of the nervous system and very likely of the cerebrum; the result of this affection of innervation is a retardation of nutrition, or, it may be, a qualitative abnormality in the transformation of the sugar circulating in the economy (Cantani).

The abuse of gaseous waters and particularly of Seltzer waters, according to Cantani, has a great importance on the etiology of oxaluria. Heredit has also a considerable part, and Cantani's observations agree with those of Neidert, that diabetes may alternate with oxaluria, or coexist with it.

Oxaluria is a disease *sui generis*, which, by itself and the accidents which it occasions, has a character of sufficient gravity to cause death.

Considering our ignorance of the pathogeny of this affection, it is difficult to institute any rational therapeutics; but as the nervous and gastric troubles are the initial and essential symptoms, we should first combat these. The ingestion of easily digestible azotized

¹ Münch. Medizin. Woch., August 26, 1890.

aliments will enable one to guard against the evils of abnormal oxidation processes, and spare the nitrogenized tissues. Warm baths with frictions and cold effusions during the bath, have rendered incontestable service against the nervous manifestations, and especially the trembling of the extremities and the insomnia; Faradization has also given good results.

Medicines of every kind have always failed; Cantani, nevertheless, recommends hydrochloric acid, peptin, the carbonated alkalies, and especially, bicarbonate of soda and lithia. Neidert affirms that he has obtained the best results from a rigorous nitrogenous regimen similar to the diabetic regimen.

MEDICAL NOTES.

— After July 1, 1893, the Colorado State Board of Health will accept the diplomas of no school which does not have an obligatory three years' course of instruction of five months each in three different years.

— *Deaths in the Profession Abroad.* — Professor Wenzel Gruber died of apoplexy at Vienna, aged seventy-six. He was an Austrian by birth, but had been Professor of Anatomy at St. Petersburg for nearly forty years, during which time he published some five hundred papers, chiefly on anatomical subjects. Some years ago he was named an Imperial Councillor of State by the Czar. Among other eminent foreign members of the profession who have recently died are Dr. G. C. H. Lehmann, Professor of Ophthalmology in the University of Copenhagen, at the age of seventy-five; and Dr. Ernest Hardy, head of the chemical laboratory of the Paris Academy of Medicine, well-known for his researches in physiological and pathological chemistry. He was sixty-three years of age.

— A firm of chemists in Birmingham, England, place upon all poisons sold by them, directions as to the antidote which should be applied in cases where the poisons are taken accidentally or with suicidal intent. An English chemical journal gives an instance where this precaution was the means of saving life. A correspondent of the *Medical Record* suggests that the simplest and nearest-at-hand antidotes should be given on the label, and these might be used by the family or friends while waiting for a doctor. "Scraping the ceiling with the fire-shovel," or swallowing the "white of egg," may save a valuable life in an emergency if thought of in time.

BOSTON.

— The managers of the Children's Hospital, yesterday, invited the friends of the institution to inspect the new wing, which has just been completed. Heretofore the west wing has been used for both medical and surgical cases. The addition will make it possible to use the old building for surgical cases only.

— The addition to the Carney Hospital, which is now nearly finished, will cost about \$140,000, of

which amount \$50,000 has already been paid. In order to decrease this debt and help to place the hospital on a sure and solid foundation on opening its new wing, a grand festival will be held in Music Hall on Wednesday, October 29th. One of the greatest needs of the hospital at present is the endowment of free beds, which are such a source of revenue to the other large hospitals of the city. At present the Carney has but five which are endowed, although it admits a large number of free patients. The management will give the proprietorship of a free bed to any corporation or association for \$250 a year, or to an individual subscriber for \$100 a year. As this is the only general hospital in the city which will take certain chronic forms of disease, its appeal for help should meet with a ready response.

— In answer to a letter in the *Boston Post*, the president of the Boston Young Men's Christian Union says that in 1875 there was organized a charity in Boston then and since known as the "Country Week." This charity provides vacation visits in the country, on farms and at other homes, for the poor and worthy children (including some of the mothers) of this city. We believe the Boston "Country Week" to be the first organization of the kind established in this country, New York and other prominent cities having since adopted similar plans for their poor children during the summer months. The "Country Week," which has for so many years been in charge of the Boston Young Men's Christian Union, has always received the hearty support of a generous public. The work has increased year by year, and the sixteenth season, which has just closed, has provided these country vacations to a larger number than in any previous year, the number thus favored this season being 3,253.

NEW YORK.

— The complete returns of the census of the city made by the police, show the population to be 1,710,715, as against 1,513,501 the number arrived at in the Federal Census in June.

— Dr. Henry G. McGonegal, an abortionist, who was in trouble before, has been sentenced to fourteen years hard labor in State Prison, for causing the death of a young woman upon whom he operated. In pronouncing sentence the judge stated that but for the age of the culprit, which is seventy years, he would have imposed the full penalty of the law, twenty years.

— The Monmouth Memorial Association has bought and taken possession of a hotel building at Long Branch which provides that place with a much-needed and very well-appointed hospital. A large proportion of the purchase money was raised through the earnest efforts of Dr. S. H. Hunt, President of the Association.

— In consequence of the prevalence of diphtheria in a certain district of Paterson, N. J., the Board of Health of that place has recommended the closing of the public school in that quarter and advised the residents to refrain from attending church, Sunday-school

or other public places for the next month. During September there were 83 cases of diphtheria and 14 deaths, and up to the 15th of October, 34 cases and nine deaths in Paterson. Seventy-one per cent. of all the cases have been in the district referred to, where the sewerage is said to be very poor.

— Dr. C. F. MacDonald has made an official report to the Governor of the execution by electricity of Wm. Kemmler in, August, in the course of which he says: "Notwithstanding the wide publication of the execution of Kemmler, and the efforts which have been made to proclaim it a failure, and to invest it with an air of repulsion, brutality and horror, it is confidently believed that, when all the facts in the case are rightly understood, the first execution by electricity will be regarded as a successful experiment, and that in time, due credit will be accorded to those whose duty required them to act as principals in carrying out the law, the establishment of which is destined, in the not distant future, to be regarded as a step in the direction of a higher civilization."

"As might have been expected, at the first execution by this method, there were certain defects of a minor character in the arrangement and operation of the apparatus which those in charge of the next execution, guided by present experience, will be able to avoid or overcome. But, in spite of these defects, the important fact remains that unconsciousness was instantly effected, and death was painless. When this is understood, together with the additional fact that less than four minutes elapsed from the time the first contact of the current was made to the time the last one was discontinued, and Kemmler was absolutely dead, it will be conceded by all fair-minded persons that the object to be attained, as far as relates to the individual, in the execution of a criminal, namely, sudden and painless death, was fully realized in Kemmler's case; and had the first contact of the current been maintained for full twenty seconds, as first suggested, in all probability there would have been no reflex muscular movement after it was broken, and no unfavorable criticism of the result could then have truthfully been made. The reflex movements referred to were similar to those which have occasionally been observed, for a short time, in animals experimentally killed by electricity, after the current was too quickly interrupted; the animal, however, not recovering consciousness or life. Hence they may properly be regarded as involuntary muscular movements of a reflex character, following the interruption of the current, and in no sense a resumption of normal respiration, however much they may appear to be so to a superficial observer, or to one not familiar with the phenomena in animals above referred to. These movements are as nothing compared with those usually exhibited by animals suddenly decapitated and which usually continue for some seconds, or even minutes, etc."

In conclusion, Dr. MacDonald makes a number of suggestions for the future better regulation of execution by electricity.

Miscellany.

NEW YORK PASTEUR INSTITUTE.

THE Director of the New York Pasteur Institute, Dr. Paul Gibier, informs us that since the opening of this Institute, February 18, 1890, 610 persons, having been bitten by dogs or cats, have come to be treated. These patients may be divided into two categories:

(1) For 480 of these persons it was demonstrated that the animals which attacked them were not mad. Consequently the patients were sent back after having had their wounds attended, during the proper length of time, when it was necessary. Of this series 400 patients were consulted or treated gratis.

(2) In 130 cases the anti-hydrophobic treatment was applied, hydrophobia having been demonstrated by veterinary examination of the animals which inflicted bites or by the inoculation in the laboratory, and in many cases by the death of some other persons or animals bitten by the same dogs. All these persons are, to day enjoying good health. In 80 cases the patients received the treatment free of charge.

Correspondence.

THE MEDICAL DEPARTMENT OF THE UNION PACIFIC RAILWAY.

DENVER, COLO., September 22, 1890.

MR. EDITOR: — In your letter of August 29th, you spoke of the aid rendered to the injured in railroad disasters in the East, as shown at the two wrecks near Boston, namely, at the Bussey Bridge and at Quincy, Mass., and ask how these matters are handled in the West. In reply I have to state the following:

All the large railway corporations of the West have medical departments organized to a greater or less degree of completeness according to their necessities. It is the policy of some railway systems to care only for their injured employees and passengers at their own expense; while others, on account of the barren and unpopulated country through which their lines extend, assess their employees a small sum, generally forty or fifty cents a month, and, with an organized medical department, take care of their employees in sickness as well as when injured. In case of accident along such systems as the latter, the same organized corps of physicians care for the injured passengers in a wreck, the expense of doing this being borne entirely by the railway company.

The medical department of the Union Pacific Railway may be taken as a type of the medical department of a western railway system. This system extends from the Missouri River and a point near the Gulf of Mexico in a northwesterly direction to the Pacific Ocean.

It is thus called upon to care for the sick and injured employees and passengers in thickly settled regions, supplied with hospitals and doctors, and also upon the barren plains.

Though the scope of the medical department is much larger in caring for the sick and injured employees of the Company, I will only describe that portion of it which pertains to caring for the injured in a wreck.

The head of the medical department is the chief surgeon. His authority extends over the entire system. He selects and appoints his own assistants in the large towns and cities. They are called division surgeons, and their authority extends over a certain number of miles of the road adjacent to their cities, which is called a division. In the small towns and villages in each division are appointed other surgeons, who are called assistant or local surgeons. Thus the railroad company has an organized corps of surgeons, in which the assistant surgeons report to the division surgeons, and the division surgeons report to the chief surgeon.

Circulars are issued notifying the railroad employees who the company surgeons are, and to enable the surgeons to be readily found by the employees of a wrecked train, and to have the information close at hand. The time card of each railroad division contains the names of all the company surgeons of that division, with the towns in which they live, and the street and number of their offices and residences, and the telephone numbers if they have one.

In case of an accident to an employee, the nearest company surgeon attends the case alone. In case of a large wreck with many injured persons, the nearest company surgeon calls upon all good surgeons that he can find in his town and neighborhood, and wires his division surgeon for assistance. The division surgeon orders the neighboring company surgeons to the scene of the wreck, and with a sufficiently large staff of surgeons from his own city, and with surgical supplies goes to the wreck himself. Of course the various assistant superintendents and superintendents co-operate with the nearest local surgeon and with the division surgeon in securing aid. The chief surgeon acts as division surgeon in his own city and in cases where a railroad disaster occurs on other divisions, he also is sent for by the division surgeon.

The authority of the company is thus vested in one of its representatives. The assistant surgeon being in charge of everything until the arrival of the division surgeon, who, in turn, yields to the chief surgeon in cases where this official is sent for.

STRETCHERS.

In all the suitable small towns along the lines of the system are kept railroad stretchers of the style invented by the writer, and of which sketches are appended. This stretcher consists of three parts, A, B and C.

Central part (B), with handles extended.

Stretcher complete, ready for use.

Stretcher packed.

These enable the injured employee to be carried with the least suffering to the nearest hospital. They are, of course, supplied with mattress and blankets, and, as it is often necessary to move an injured employee many miles to the nearest hospital, it will be readily seen that the spring carriage (C) is of the greatest advantage.

In the large towns or cities where trains would be fitted

out to go to a railroad disaster, there is in or near the depot a medical department supply-room in which are kept ready for immediate use mattresses, blankets, pillows, sheets, pillow slips and folding boards. These boards are of the following kind: Each folding board consists of two pine boards six feet six inches long and fifteen inches wide, these are hinged together with three large, strong strap hinges so they will open and shut like a backgammon board. When not in use they are folded up and stowed away. When in use they are opened out, laid on the backs of the seats in the passenger coaches, and by the means of the mattresses, blankets and pillows, with the sheets and pillow slips, comfortable beds for the injured can be made up in the passenger coaches while the train is running to the scene of the wreck.

WRECKING CAR SURGICAL SUPPLY BOX.

When a surgeon is hurriedly called to a wreck, it is impossible for him to gather up in a hurry all that he will need to care for the injured when he reaches them. To obviate these omissions the wants of our assistant surgeons have been anticipated, and all our division surgeons and most important assistant surgeons have been furnished with what we call a wrecking car surgical supply box, of which a ground floor plan and a list of contents is given. The box looks much like a small carpenter's tool chest, and the inside is economically divided up for what is here stated:

UNION PACIFIC MEDICAL DEPARTMENT. WRECKING CAR SURGICAL SUPPLY BOX.

Contents and Their Uses.

1. Splint wood. For broken bones and supporting injured joints.
2. Saw. For cutting splint wood into desired shape.
3. Shears. For cutting up the seam of a coat sleeve or pants leg to get at injured limb.
4. Cotton wadding and Lister gauze. To be used for padding, or when soaked in the phenyle solution, for dressing wounds.
5. Bandages. Narrow, for head and fingers; medium, for arm and leg; wide, for thigh and body.
6. Sponges. For washing wounds, or for tucking into cone made with a towel, for giving ether.
7. Cosmolene. For burns and scalds.
8. Cotton cloth. For applying cosmolene.
9. Towels. For ordinary use, but chiefly for rolling into cone for giving ether.
10. Nylle bone. For assorted sutures.
11. Brand. For stimulation.
12. Ether. For producing anesthesia as needed.
13. Rubber tubing. For controlling hemorrhage.
14. Hoffman's anodyne. As a stimulant for women; use as directed on bottle.
15. Morphine tablets. One-eighth of a grain for pain; give as directed on bottle.
16. Phenyle. Add a teaspoonful to a basin of very warm water, and use for washing wounds, or soaking dressing before applying.
17. Adhesive plaster. Use as a chest swathe for broken ribs, or wrap up as needed.
18. Extract of blades. To fasten into handle if blade breaks.
19. Perfected tubing. For draining wounds.
20. Wash basins.
21. Spoons.
22. Pins.

This box is to be kept in the station, in care of the agent, subject to the orders of the assistant surgeon, and its contents are not to be used by assistant surgeons for dressing ordinary wounds. It is to be considered what it is planned for: a surgical supply box in cases of wrecks.

When the box needs refilling, return to

O. J. PFEIFFER, Chief Surgeon.

Room "A," Union Depot, Denver, Col.

The wrecks upon a large western railway system may occur in thickly settled localities, or upon desert plains which are devoid of any towns, except those made necessary by the division terminals of the railroad as homes for the employees.

Trains which run through the barren districts are transcontinental, and are, therefore, supplied with Pullman sleeping cars, or second-class and excursion sleepers. These are available as hospital cars in case of a wreck. In case of a freight wreck a caboose can generally be used as a place in which to care for the injured train men.

When a railroad disaster occurs in settled localities the nearest company surgeon, with his neighboring assistants, his stretcher and surgical supply box, is soon on the ground, and very soon after, his division surgeon comes to his aid with a hospital car rapidly improvised by means of supplies that are immediately at hand.

It is, therefore, seen that the surgeon located in an isolated town has at hand the means for assisting the injured, and the division surgeon in the nearest large town is always equipped to go to the aid of the assistant surgeon at the shortest notice.

A railroad surgeon is always expected to be where he can be reached, and in case of his absence, he is required to have a suitable substitute in his place who can be found without fail.

In case of wreck near Denver, for example, information comes of its nature, and the number of severely injured persons, say twenty. The surgeon in charge of this division is called by telephone, he telephones for his assistants (of whom he has a certain number with whom it is arranged that they are to be subject to call at any time) to report at once to the station with their satchels and supplies and instruments. Meanwhile the wrecking train (a train which is always kept ready by railroad companies for clearing the track in case of wrecks) is backed into

the station. To this, by telephone instructions from the surgeon in charge, have been attached two or three passenger coaches. Into these are loaded from the supply-room seventeen folding boards, and a corresponding amount of bedding, two surgical supply boxes, and three of the portable railroad stretchers.

At the wreck a supply of cold water is found in the water coolers of the cars, and hot water is obtained from the engine. While proceeding to the wreck, the boards and bedding are made up into comfortable beds, and fires are built in the stoves; when the wreck is reached, the hospital cars are ready for the injured who are brought into the cars by means of the portable stretchers, which finally are used as beds for the three most seriously injured, the jar of moving the latter being lessened by the spring supports upon which the stretchers are made to rest. The hospital cars when loaded are then slowly pulled back to Denver. On the way back the names, addresses and injuries are noted upon prepared blanks; ambulances and carriages are wired for to meet the train at the station to take to their homes such as can be taken there, while the remainder are run in the hospital cars as near as possible to the railway hospital, from which they are transferred to the hospital beds.

Yours very truly,
O. J. PEIFFER, M.D., Chief Surgeon, Union Pac. System.

REPORTED MORTALITY FOR THE WEEK ENDING OCTOBER 11, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 11, 1890, TO OCTOBER 17, 1890.

By direction of the Acting Secretary of War, the retirement from active service on October 12, 1890, by operation of law, of Captain ANDREW V. CHERBOURNIER, medical storekeeper, under the provisions of the act of Congress, approved June 30, 1882, is announced. S. O. 240, Par. 11, A. G. O., Washington, D. C., October 13, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 18, 1890.

GEORGE A. BRIGHT, surgeon, detached from temporary duty at the Naval Academy and placed on waiting orders.

J. G. ATRIES, surgeon, detached from temporary duty at the Naval Academy and placed on waiting orders.

GEORGE P. LUMSDEN, passed assistant surgeon, detached from U. S. S. "Boston" and granted three months' leave.

E. W. ANZAL, past assistant surgeon, detached from the Naval Academy and ordered to U. S. S. "Boston."

HOWARD SMITH, surgeon, ordered to appear before the Retiring Board at Mare Island, Cal.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, October 27th, at the Medical Library, 19 Boylston Place, at 8 o'clock p. m.

Papers: Dr. A. T. Cabot, "The Non-operative Treatment of Enlarged Prostate." Dr. R. W. Lovett, "Acute Circumscribed Edema, with a Report of Three Cases Affecting the Hand." G. G. SEARS, M.D., *Secretary.*

SUFFOLK DISTRICT MEDICAL SOCIETY.—The stated meeting will be held at 19 Boylston Place on Saturday, October 25, 1890, at 8 p. m.

Papers: Dr. G. H. Monks, "An Operation for the Correction of the Deformity Due to Prominent Ears." Mr. Edward Atkinson, "The Application of Heat as a Factor in Nutrition" (commonly called cooking). Illustrated by examples.

Incidental Business: Choice of a committee of five to prepare a list of candidates for officers of the Society.

Supper after the meeting.

JAMES J. MINOT, *Secretary.*

DEATH.

Died in Amherst, Mass., October 16, 1890, Israel Houston Tayler, M.M.S.S., aged seventy-eight years.

BOOKS AND PAMPHLETS RECEIVED.

Preventive Inoculation. By Frank S. Billings, M.D. Reprint. 1890.

A. Davis. 1890.

Original Articles.**ACUTE CIRCUMSCRIBED ÖDEMA.¹**
WITH A REPORT OF THREE CASES AFFECTING THE
HAND.

BY ROBERT W. LOVETT, M.D.

THE three cases which I have the pleasure of presenting to you this evening appeared at the Surgical Out-Patient Department of the Carney Hospital within a short space of time last summer. They evidently all belonged to the same class, but they were unlike anything that I had ever seen, and I was led to look up the subject, to find that they were examples of a well-recognized affection which has received very scant attention in the text-books or in general medical literature.

These cases were characterized by an acute and rapid swelling of one hand and forearm which began without known cause and reached an enormous size without being accompanied by pain, local heat, or constitutional disturbance.

The occurrence of local edemas in various parts of the body, under such conditions, has been recognized and described as angio-neurotic edema, acute circumscribed edema, pseudo-phlegmonous edema and similar names. It is perhaps most commonly seen as a localized and transient swelling of the lip, face, or larynx.

CASE I. Miss M. D., twenty-three years old, single, telegraph operator.

The patient appeared at the hospital March 25, 1890, with the left hand and forearm enormously swollen. The swelling had begun without known cause four days previously, coming on in the night, and had increased up to the time of her visit to the hospital. The previous history was good, there was no account of any rheumatism or other trouble, and up to within a few days the patient had been in excellent health. Just then she felt rather poorly and had lost her appetite.

The temperature was normal, and there was little or no pain in the affected arm. The appearance was that of an excessively severe cellulitis of the hand and arm, but there was no local heat, and the skin was pale on account of the tension caused by the swelling. There was no evidence of any lymphangitis, no tenderness, and the swelling was elastic to the touch. It involved the hand and forearm with a slight enlargement above the forearm. Dr. Temple, who saw the case with me, was unable to make any diagnosis. On general principles a poultice was ordered and salicylate of soda in large doses, and the patient detecting the uncertainty regarding her case, did not return. I saw her October 13th, and obtained the history of the remainder of the attack. The swelling in the left hand subsided gradually without new symptoms, lasting about four weeks, but before that hand was well, the right hand and arm began to swell in a similar manner and the second attack proved more persistent than the first, lasting six or eight weeks. When it subsided it left a certain amount of stiffness of the fingers, and a tendency to the formation of subcutaneous ecchymoses which are still seen from time to time. The general health is now excellent.

This case is of particular interest in its very long

¹ Read at the Boston Society for Medical Improvement, October 27, 1890.

duration as compared with most of the reported cases. It bears, of course, a close resemblance to rheumatism, but pain, local heat, and elevation of temperature, were absent, there was no exposure or history of rheumatism, and the affection was not controlled or affected by salicylate of soda.

CASE II. Thomas B., thirty-five years old, tailor.

July 28th, 1890, the patient appeared at the hospital with extreme swelling of the right hand and wrist which had begun suddenly in the night, thirty-six hours previously, and had been progressively increasing. The patient's health was excellent, and the swelling began without known cause, being at first accompanied by intolerable itching. There was no pain, tenderness, or local heat, the temperature was normal and the appetite good.

The swelling involved the hand and lower half of the forearm and terminated by a transverse abrupt line; the swelling was elastic and gave a sense of fluctuation. Poultices and salicylate of soda were again prescribed. On the following day the edema had advanced two or three inches up the forearm and again terminated in an abrupt line. The condition of the hand was the same; on the third day the swelling had extended above the elbow, but had diminished somewhat in the hand.

From this time on the edema gradually diminished and in a week from its onset it had entirely disappeared although the hand did not return to its full usefulness until three or four days later. There has been no repetition of the attack, and the patient is now in excellent health.

CASE III. John S., twenty-three years old, teamster.

July 30, 1890, this patient appeared with the right hand and forearm very much swollen. The attack had begun twenty-four hours previously without known cause, and was not accompanied by pain, heat, or febrile disturbance. No cause was known for the attack. The characteristics of the swelling were in every way like those just described in Case II. Both these cases were also seen by Dr. Sears, who did not consider them in any way rheumatic.

An advance was made in the treatment of this case in the use of a dry compression dressing instead of a poultice. Sheet wadding was applied to the arm and about wet pasteboard was firmly bandaged which dried and furnished firm, even compression. This case progressed faster than either of the others, and in four days from the beginning of the attack the swelling had practically disappeared. Since then the patient has remained in perfect health.

Medical literature contains a few articles relating to this affection, and reported cases are not very many. This cannot be due to the rarity of them so much as to the manifold appearances which they present, thus preventing their recognition as examples of one affection, and to the fact of the benign and transient character of the swelling which makes the affection seem of little account. It is to German writers that we are chiefly indebted for a recognition of this affection.

Its characteristics are simple; local edema of a transient character occurs in various parts of the body, without known cause in most instances. In some cases it is accompanied by slight digestive disturbances while in others no constitutional symptoms are present. It is not accompanied by high temperature which may, however, be present as a result of the digestive disturbance. Local heat is absent as well as all evidences

of lymphangitis. Pain is not a frequent symptom, but it may be present and is generally of a burning character. Urticular eruptions not infrequently are present at the same time as the swelling and itching, and burning are often complained of at the site of the swelling without objective signs. Abdominal colic is mentioned by some writers as a common accompaniment of local oedema, and is attributed to a similar oedema of the intestinal walls.² In the same way watery vomiting is accorded a very prominent place in the symptomatology by Strübing, who considers it due to a similar oedema of the gastric mucous membrane.³ Most reported cases, however, lack these two symptoms.

The swelling most frequently affects the lips, the eyelids, the face, the larynx, the hand, and the genitalia, and more infrequently, the legs.

Affecting the lower lip it is a fairly common affection, and ten years ago Dr. T. B. Curtis reported to this Society some twelve cases of this sort. At that time that affection was considered more a disease by itself than, as now, merely one manifestation of a tendency to local oedema.

Affecting the eyelids and face, the affection presents no points of special interest.

As an affection of the larynx, acute transient oedema becomes at once alarming and very dangerous. Cases have been reported where the swelling after affecting various parts of the face, disappeared to reappear in the larynx and cause intense dyspnoea.⁴ In other cases it was located primarily in the larynx.⁵ Fatal cases have been reported⁶, and in others tracheotomy has been necessary to save life.⁷

In other locations such as the hands and feet, the disease presents no other characteristics than those already named.

The affection may be very transient, lasting only as long as an urticaria; but more commonly it lasts for several days, and rarely may persist for weeks. When once it has appeared, it is likely to be seen again at some future time, and it may reappear at the original place or at some new part of the body. In certain cases it is very persistent, reappearing again and again at regular or irregular intervals, sometimes taking on a well-marked periodicity. Men and women are equally liable to the affection, and young adult life contributes the most cases. In children reported cases are few.

The cause of the attacks is generally obscure in the extreme, and very little is known of the etiology or pathology of the affection. Heredity plays a marked part in the causation of many cases, and Osler has related a very striking instance of this, where circumscribed oedema of various parts of the body has occurred in five generations of the same family. Quincke, Strübing and Falcone have noted in their cases the hereditary influence.

Malaria evidently causes certain cases as in the one reported by Matas,⁸ where a swelling of the lip occurred at noon every day to disappear late in the afternoon. This was controlled immediately by quinine.

nine; but most often even when marked periodicity seems to govern the attacks, treatment by quinine is reported as being unsatisfactory.

In certain cases the attacks are associated with menstrual derangements, and in one case oedema of part of the face occurred after awakening from hypnotic sleep.⁹

In persons predisposed to the occurrence of the oedema, the slightest traumatism is often sufficient to locate an attack, and as in all diseases of obscure etiology many cases are attributed to taking cold.

Most of the reported cases have occurred in the spring and summer.

The question of the pathology of the affection is one of greater physiological than practical interest. As a matter of fact, nothing whatever is known as to the cause of the oedema; and the assumptions of the various authors to explain its occurrence are, for the most part, wholly gratuitous. It is said that paralysis of the vaso-constrictors or irritation of the vaso-dilators is present, which explains nothing, while other writers find an equally obscure explanation in assuming an affection of the trophic nerves.

Experiments have shown well enough the connection of abnormal nervous conditions and local oedema.

Localized oedema occurs in connection with diseases and injuries of the peripheral and central nervous system. In hemiplegia, neuralgia, etc., it is a symptom so well-known that it needs no comment. In the injuries to the nerves of the arm which result from pricking a nerve in bleeding, oedema of the parts supplied by that nerve is an occasional symptom,¹⁰ and the same effect was observed by Weir Mitchell in bullet injuries.¹¹

Experimentally it has been shown that certain irritations of the nerves are capable of producing local oedema. Morat¹² divided the auricular nerve of a rabbit and stimulated the central end, but failed to produce oedema. Ostromouf in a similar experiment after dividing the lingual nerve of a dog produced oedema of half of the tongue by a stimulation of the peripheral end of the nerve with the induced current¹³ and Vulpian in a similar experiment demonstrated that long continuance of the irritation and the oedema, resulted in changes in the finer arterioles.

It hardly seems worth while to take up your time any further in the discussion of this aspect of the subject further than to call your attention to the fact that there is abundance of clinical and experimental evidence¹⁴ to show the connection of local oedema and an abnormal condition of the nerves, and it is in some such vague explanation that one must take refuge in accounting for the occurrence of local oedema.

In the treatment of the affection there is little to be said. It is benign and self-limited and will get well of itself; and medication seems to have no effect upon its course. In fact, except in cases of oedema of the larynx, there is no real need of active measures. Iodide of potash, arsenic, salicylic acid and similar drugs have notoriously failed to have a good effect,

and generally quinine is unsatisfactory. No plan of treatment has been formulated. The recorded cases are merely a list of failures from a therapeutic point of view. Cases where constitutional disturbance has been present, and especially cases where the attacks recurred, have seemed to be relieved by general hygiene treatment.

In cases of edema of the hand or foot, compression by a Gamgee dressing or by a flannel bandage seems to hasten the disappearance of the swelling.

FATAL CASE OF LEAD POISONING IN WHICH ATAXIA WAS THE PRINCIPAL SYMPTOM (PSEUDO-TABES).

BY G. L. WALTON, M.D.,

Instructor in Diseases of the Nervous System, Harvard University; Physician to the Neurological Department of the Massachusetts General Hospital.

A. B., fifty-four years of age, married, was seen in consultation with Dr. S. D. Presbrey, of Taunton, in January, 1890. He stated that three years ago he suffered from numbness in the hands which gradually passed away. Soon after he noticed numbness in the left foot which has persisted up to the present time, and has extended gradually up the leg and into the back. The numb feeling was at first accompanied by a prickling, which subsided. This symptom together with a staggering gait of gradual onset and progressive character constitute the chief complaint at present, excepting that he is rather easily tired, and has an unpleasant sensation in the head increased by walking, and when weary. He does not complain of absolute pain in the head or elsewhere, but of a slight tenderness in the calf. About a year ago he had an acute attack of stomach and bowel trouble lasting a week, accompanied by nausea. Otherwise than this there has been no vomiting and no colic. There has been no double-vision, no vertigo, no blurring of the sight

or other defect of vision, no bladder or rectal irregularity, no darting or other pains, no *crise-gastrique*. There has been no loss of power in the arms or hands, no wrist drop.

No history of cold or other exposure could be elicited; there was no specific history; and no history of any excess, of malaria or the use of tobacco or alcohol. The patient stated that he had always been of a nervous temperament, always sensitive to changes in the weather and to noises over his head. There had been, however, no special accession of trouble in this direction of late, nor any difficulty of devoting his mind to work or accomplishing his business, which was one requiring brain work alone (real estate and insurance). There have been no convulsions. Sexual power was lost four years ago.

Physical examination showed a tall, delicately built man in poor flesh. His gait was so unsteady as to require him to lay hold of objects at times to keep his balance, and he could not stand with the eyes closed and feet together. The tendon reflex was normal, there was no ankle clonus. The pupils were alike and reacted normally to light. The patient found it difficult to step up into a chair with the left foot, and could hardly do so with the right. There was a slight loss of tactile sensation in the left foot, and considerable loss of muscle sense, as evidenced by the fact that he could not tell with the eyes shut whether the great toe was moved up or down. There was some sensitiveness to pressure over the muscles of the calf of the leg, not particularly in the course of the nerves. The muscles were generally rather soft and small, but there was no atrophy of any particular muscle or group of muscles, nor any complete motor paralysis, but considerable general weakness, and marked incoordination. There was no objective loss of sensation discoverable excepting in the left foot. There was no sensitiveness of the back. The urine was found normal. The heart and lungs had been carefully examined by Dr. Presbrey and found normal.

It was decided as a result of this examination that no spinal disease existed, but that the symptoms were due probably in part to nervous prostration, in part to a low form of neuritis of unknown origin. He was put upon nux vomica and compound datura of chinona, exercise restricted, and warm bathing advised. A mild galvanic current was applied to the limbs.

I next saw him in about three weeks, when he reported that he had been better and worse, that riding and electricity made him worse. At times slight numbness has appeared in the fingers. He complains of drawing sensations up the legs and in the abdomen, not fixed in locality. The left calf is quite sensitive. There is a burning sensation in both feet. The sensation of the foot is found somewhat improved, otherwise physical examination reveals no special change. The pulse is 92, of fair character. Electrical treatment had been already discontinued by Dr. Presbrey, and no further change was advised.

Two months later I saw the patient again, and on going over the whole case carefully with him found that the commencement of the trouble occurred soon after moving from one house to another. It also appeared that another member of the family had complained at one time of a slight numbness in the fingers. These facts lead to a suspicion that some form of chronic poison might be at the bottom of the matter, either arsenic or lead. There was no blue line, wrist

drop, nor other typical lead symptom, no question of lead pipe or other known source of this poison, and in view of the fact that numbness and ataxia is more frequent in the neuritis of arsenic than of lead poisoning, the urine as well as specimens of wall paper, was first tested for arsenic by Mr. Thomas Farmer, with negative result. The patient was then put on five grains of iodide of potassium and the urine analyzed for lead after four days by the same chemist, who reported that the urine contained a very large quantity of lead. From this time the iodide was continued and bottled waters alone were used by the patient, and most exhaustive search was made by Dr. Presbrey for any source of lead in his surroundings. The only possible source discovered was a tin-lined copper kettle in which the hot water (which he had been in the habit of using freely) was heated.

Soon after commencing the iodide treatment, he reported that he was worse every day. He became unable to walk, and had to remain away from his office. This was at first considered favorable as showing elimination, though it forced a temporary cessation of the use of the iodide. The medicine was renewed later at intervals, and in still smaller doses, (three and two grains thrice daily), but the patient's condition grew steadily worse, during the intervals as well as during administration, examination of the urine (analyzed three weeks before death) showing decided decrease in quantity of lead.

Four months after the discovery of lead and commencement of the appropriate treatment, the patient was helpless, and death ensued shortly. There was no autopsy.

This case illustrates the importance of looking for lead in obscure nervous cases, even where none of the characteristic symptoms of that poison are present. This point has been exhaustively dwelt on by Dr. J. J. Putnam, to whose investigations are largely due our knowledge of the variations from given types in lead as well as other forms of poison. It is certainly to be borne in mind that wherever symptoms of neuritis appear, in the absence of such apparent cause as abuse of alcohol or tobacco, it cannot come amiss to search for mineral poison.

Axata is certainly an unusual symptom in lead-poisoning, and does not as yet appear in the textbooks, though it is mentioned under arsenic poisoning, for example by Gowers,¹ who calls attention to the similarity between the effects of arsenic and of alcohol, and divides arsenical cases into two classes, "first, a palsy of the muscles of the limbs, especially of the extensors of the hands and feet; and secondly a 'pseudo-tubes'—ataxia, with defective sensibility, especially in the muscles." He quotes in illustration of the second form the cases of Seeligmuller, and two reported by Dana, but states that ataxia is less frequent than muscular paralysis. Such cases as the one here reported show that ataxia should be mentioned, though among the less typical, as one of the symptoms of lead as well as of arsenic poison, and to further illustrate the fact already recognized, that loss of sensation may appear (though exceptionally) in this affection.

That this case is not unique is shown by the five cases of pseudo-tubes from lead which have been collected by Dr. Putnam,² three under his own observation.

¹ Diseases of the Nervous System, 1888, p. 1273. See also Dana, Brain, January, 1881.

² Boston Medical and Surgical Journal, December 2, 1887.

tion, one by Teissier,³ and one by Raymond.⁴ It is probable that future experience will show these cases to be less rare than they seem at present, as the diagnosis of the various forms of neuritis becomes more familiar.

With regard to the source of lead, Dr. Presbrey writes me that the kettle above alluded to, was examined by a chemist, Mr. George F. Chase, superintendent of the Taunton Water Works. He reported that the lining was gone except in the dome and cover, but that he kept the kettle filled with hot water for several hours; that he then evaporated the water, and in the residue found traces of lead.

Dr. Presbrey also writes that he suspects the coating of the galvanized-iron hot-water boilers might have contained lead, and that there might be lead solder within them. He, therefore, directed that water for cooking should not be taken from these boilers. Whether this suspicion be correct or not, the examination of the kettle alone would seem to show ample origin for the poison.

TWO UNUSUAL OBSTETRIC CASES.¹

BY H. F. VICKERY, M.D.,
Physician to Out-Patients, Massachusetts General Hospital; Instructor in Clinical Medicine, Harvard Medical School.

CASE OF FLESHY MOLE.

Mrs. F. H., age twenty-five, previously healthy and vigorous, was married October, 1888. The catamenia remained perfectly regular till the following July, nine months after marriage, when they ceased. Coincidentally, the mammary areola grew dark, the abdomen increased somewhat in size, and there was morning vomiting.

About one week before Christmas (fifth month) she suffered from backache without known imprudence; and then on Christmas day, came a sudden gush of one or two ounces of blood, repeated at irregular intervals for three weeks, but without chills, rise of temperature or other special symptoms. Her physician, Dr. S. B. Lynch of Boston, kept the patient in bed for a month, mainly as a matter of caution than from necessity. Then she resumed her usual occupations.

April 22d (nine months) labor pains set in, the os dilated, and a placental mass presented. The reporter, being summoned in consultation, was struck (as had also been the attending physician) by the small size of the abdomen, and the absence of the ordinary uterine enlargement above the pubes. On digital examination the presenting mass was felt and easily removed. The small uterus contracted well, with little loss of blood. On the following day, a careful pelvic examination under ether revealed nothing abnormal, save a shortening of the right broad ligament.

The specimen now presented to the Society was kindly examined by Dr. R. H. Fitz (whose exact description is unfortunately lost) and pronounced a fleshy mole. When fresh, it was the size of a large fig. No signs of a fetus could be detected. It seems probable that it perished in December, four months before the remnants of the placenta were extruded, and it is this long retention of the mole which seems especially interesting in the case.

¹ Read by invitation before the Obstetrical Society of Boston, June 14, 1890.

² Gaz. Med. de Lyon, 1881-82.

³ L'Intoxication Saturnine, Renant.

A MUCH-ENDURING FETUS.

Mrs. J. L., age thirty-five, by her first marriage had two still-born children at seven and nine months respectively. Since her second marriage, which took place five years ago, she has had two living children, one three years old and one eight months old. This younger child was not weaned till April, 1890, two months before the reporter was called in consultation. It is from the family physician, Dr. S. B. Lynch, that most of the history of the case has been obtained.

In November, 1889, Mrs. L. had a profuse menstrual flow, her baby being about one month old. At Christmas time, however, the menses did not appear. She then took tansy tea, also turpentine. These being unavailing, she procured an English catheter, removed its stylet and made a daily effort for about three weeks to pass it to the fundus uteri. At last, toward the end of January, she felt that she had succeeded. There was almost constant metrorrhagia through February and up to the middle of March. She then was obliged to call her physician, who mitigated the flow by exhibiting the fluid extract of ergot; but there was still some flowing.

Between the 10th and 19th of May, Bonjean's ergotin was tried, seventy-two grains in all being taken, and the vagina was packed in Sims's position. Then the attending physician, who believed that he was treating an ordinary case of retained placenta, used a blunt wire curette (without ether and without assistants) following its use by swabbing the inside of the womb with Churchill's tincture of iodine. It is probable that this operation did not affect more than the cervix uteri. The flow continuing, a gallon of hot water was injected thrice daily for four days. The hemorrhage persisted and the patient had now become profoundly anemic, when the writer was asked to see her immediately and remove this obstinate placenta under ether. When, however, the patient was placed upon the table, the uterus was found reaching nearly to the navel, and evidently pregnant. It seemed the only chance for the mother to empty the womb, which was done at once and successfully. The patient's convalescence was uninterrupted, though slow. The fetus corresponded to about the fifth or sixth month. The points that seem of especial interest in this case are: (1) that conception occurred while the mother was nursing a child only six or eight weeks old; (2) that pregnancy should persist, despite so many adverse influences; and (3) that the woman escaped sepsis or any permanent injury.

REPORT ON LARYNGOLOGY AND RHINOLOGY.

BY FRANKLIN H. HOOPER, M.D.

ON RADICAL OPERATIONS FOR THE CURE OF INTRINSIC CARCINOMA OF THE LARYNX.¹

ONE of the most valuable papers read in the Section of Laryngology, at the Tenth International Medical Congress, was by Mr. Henry T. Butlin, of London, under the above title. Mr. Butlin called attention to the great principle which should underlie the selection of cases for operation. He believes that the operation of excision of the larynx, whether partial or complete, should be practised only in cases of intrinsic carcinoma, in which the disease is still limited to the interior of the larynx. The following evidence was submitted to

prove the justice of his theory, that the selection of cases should be made on pathological grounds. One hundred and two operations for intrinsic carcinoma had been collected from various sources. They were performed on 95 patients by various surgeons in different parts of the world. The 102 operations contain 28 cases of thyrotomy, with the removal of the diseased parts in the interior of the larynx; 23 cases of partial, generally half, excision of the larynx; and 51 cases of complete excision of the larynx. In considering the results, Mr. Butlin took first the deaths which were due to the operations; secondly, the patients regarded as cured by operation; and, thirdly, the relief afforded to patients who were not cured.

(1) Deaths Due to the Operation.—The 28 thyrotomies were performed on 27 patients, of whom three died from the results of the operation. The 23 partial excisions were performed on 23 patients, of whom seven died of the operation. The 51 complete excisions were performed on 51 patients, of whom six had been previously subjected to the operation of thyrotomy. Sixteen patients died of the operation. There were thus 26 fatal cases in 102 operations. The causes to which the deaths were attributed were in one case to an accident, one died of secondary hemorrhage, two of paralysis of the heart, and three of exhaustion. In three cases the cause of death was not ascertained. One patient died of pleurisy, and six of some affection of the lungs. In the remaining nine cases the cause of death was some form of septic poisoning. Mr. Butlin thinks that it is scarcely creditable to us, in these days of antiseptic surgery, that more than one-third of the fatal cases following these operations should be due to some form of septic poisoning. He then points out that the special difficulties with which we have to contend in the management of these patients are of two kinds: (1) The difficulty of maintaining the wound aseptic. (2) The difficulty of preventing the entrance of passages. Mr. Butlin believes that but a small proportion of the patients die from direct wound poisoning. In the majority of the cases of septic poisoning, he believes that the sepsis is indirect and of pulmonary origin. In future, Mr. Butlin states, that he feels disposed to treat the majority of his patients without tracheotomy tube or tampon, after the removal of the first tampon-tube within twenty-four hours of the operation, by frequently dusting the wound with iodoform, or iodoform and borax, and by placing over the external wound a piece of iodoform gauze, which can be changed as often as it becomes soiled. In addition, the patient should be laid well over on one side, and the head placed on a single small pillow, so that the wound may be, in a certain measure, dependent.

(2) Persons who may be Regarded as Cured by Operation.—Those persons only who were free from disease at least three years after the last operation are regarded as cured. Taking first the cases of thyrotomy, the total results were that three persons died of the operation; in 13 cases the disease recurred; eight patients recovered and were well at various periods, but sufficient time had not elapsed to allow of their being regarded as cured. In three cases the operation may be regarded as wholly successful, for one of the patients died four years afterwards of cerebral apoplexy, at the age of sixty-seven; the second was well at the end of eight; and the third, at the end of twenty years.

¹ British Medical Journal, August 23, 1890.

Of the patients (23 in number) on whom partial excision was performed, seven died of the operation, six suffered from recurrence of the disease, five recovered and were well at the end of various periods within three years, and one died at the end of two years and a half without recurrence of the disease. Four patients may be claimed to have been cured, for three were well at the end of three years and a half and four years after the operation, and a fourth died at the end of five years, of apoplexy, at the age of 60.

Of the 51 cases of complete excision, the operation proved fatal in 16, the disease recurred in 17, four patients recovered and were well at the end of various (for the most part short) periods, and six died of other causes. Of these six, four died within a few months — two of pneumonia and two of apoplexy, or more probably asphyxia, the fifth at the end of twenty months of alcoholism, and the sixth at the end of about two years of inanition. In this case no cancer was found after death, although the manner of his death strongly suggests that it was present in one or more of the internal organs. Eight patients may be claimed to have been cured, for seven were well at the end of three years and a half, four years (two), four years and a half, five years, five years and three-quarters, and nine years after the operation, and the eighth died at the end of four years and a half without recurrence of the disease. Some of these patients were employed in avocations which must be regarded as laborious — one man in a riding school, and a woman as a laundress.

The total results, then, so far as cured cases are concerned, are that 15 patients were alive and free from disease, or died of some other disease than cancer, at periods of from three to twenty years after the last operation — a result which will compare favorably with those afforded by operations for malignant disease of the testicle, the tongue, the upper jaw, or even of the breast, were it not that operations on the larynx are so much more fatal than those on the testicle, the tongue, and breast.

The results of operations for recurrent disease are shown to be bad. The best hope of success — nay, almost the only hope — lies in the first operation. If this fails, there is little prospect of relief from surgical interference. With regard to the choice of operation Mr. Butlin urges that the smallest operation consistent with the widest excision of the disease, and the removal of a wide area of the surrounding tissues, should be performed.

(3) *The Relief afforded to Patients who are not Cured.*—Persons on whom thyrotomy has been performed require no instrument for speech, can swallow as well after as before the operation, and experience no difficulty in breathing. The measure of their relief is therefore the measure of the time during which they remain free from recurrence of the disease.

The same may be said of patients on whom partial excision has been performed, for there are seldom any troubles which can be attributed to the operation; but an equal measure of success cannot be claimed for the operation of complete excision. The necessity for the wearing of the tube, the difficulty of maintaining the voice-tube free from saliva and mucus, and the difficulty which some patients have experienced in swallowing, must all be taken into account in considering the value of the operation. Mr. Butlin concludes as follows:

I have limited my remarks to the selection of cases for operation, not because there are no other points in

relation to the diagnosis and treatment of the disease in which I am interested, but because I am anxious to attract the attention of all those who are interested in laryngeal surgery to what I believe to be the great principle which should underlie the selection of cases for operation.

The difference between carcinomas of intrinsic and extrinsic origin is not merely one of limitation of the disease within a certain circumscribed area. It is an essential difference. The former are of slower growth, often taking years to run their course, affecting the lymphatic glands either late or not at all; in fact, less actively malignant than the latter. I would not, however, have it supposed that I regard every case of intrinsic carcinoma as equally suitable for operation, even in its early stages, for occasionally one meets with intrinsic carcinomas which are much more malignant than the rest. Only last year I opened the larynx of a man, and cut and scraped out an ulcerated carcinoma, which in the course of three or four months had spread rapidly over the interior above and below the vocal cords. The tracheotomy tube was soon removed, the wound healed well and quickly, but before he left the hospital the disease recurred. In less than a month it formed a tumor in the neck, and within three months had caused the patient's death. Just as there are now and again very malignant cancers of the lower lip, so there occur from time to time intrinsic carcinomas which are exceedingly malignant, so that rapidity of growth and early ulceration must be taken into account in estimating the fitness of each individual case for operation. On the other hand, while I believe that carcinomas of extrinsic origin are generally wholly unsuitable for operation, I would not say that a radical operation should never be performed in a case of extrinsic carcinoma. For just as there are from time to time intrinsic carcinomas which are exceedingly malignant, so there can be little doubt that occasionally an extrinsic carcinoma of less malignancy may be met with which may be removed with the best hope of success.

THE SURGICAL TREATMENT OF CROUP.²

In a paper under the above title Dr. F. E. Waxham, of Chicago, presents his views on the relative merits of intubation and tracheotomy. A nice question of judgment, he says, often arises as to the proper time for interfering surgically. He considers that when the voice becomes whispering; when the cough becomes suppressed; when, in addition, the dyspnea becomes urgent, and the loud stridor heard both on inspiration and expiration, and when there is marked recession at the base of the sternum and above the clavicles — when all these symptoms are present and continuous, and not relieved by the use of emetics, it is certainly time to operate.

Operations performed early, with the first symptoms of laryngeal obstruction should not be sanctioned, as many will recover under medical treatment. Operative measures, on the other hand, should not be postponed until the patient becomes moribund, for while many will recover even under these circumstances, yet their chances for recovery are far less than when the operation is performed earlier.

Having determined that an operation is imperative, the next question to decide is the choice of operation. Shall we choose the time-honored operation of trache-

² Journal of the American Medical Association, October 11, 1890.

otomy or the more recent operation of intubation of the larynx?

To those competent to do the operation with delicacy and skill, he recommended intubation in preference to tracheotomy at all ages, under all conditions, and under all circumstances. In support of this advice he fully recorded 285 cases with 100 recoveries, or 35 per cent. These cases were not selected, the majority of them being among the poor and destitute, where tracheotomy would hardly have been considered. The ages ranged from five months to twenty years, and the operations were not performed early, but as a last resort. Two hundred out of the 285 cases were under five years of age. Among those to recover were two infants of nine months, and one of ten months. There were 93 cases under three years, with 22 recoveries, or 23.76 per cent. There were 192 cases over the age of three years, with 88 recoveries, or 45.62 per cent.

INTUBATION OF THE LARYNX IN ACUTE AND CHRONIC SYPHILITIC STENOSIS.³

In this paper Dr. George M. Lefferts considers the importance of intubation as a substitute for tracheotomy and the method of Schroetter in certain syphilitic diseases of the larynx.

Dr. Lefferts well says that intubation in the treatment of diphtheritic croup, revived, improved, and popularized by American genius and perseverance, must soon, by its very simplicity, readiness, marvelously quick relief in moments of urgent danger, and brilliant, ever improving statistics of cure, find a world-wide acceptance and become universally practised. On the contrary, our knowledge of intubation as a means of relief or cure in other forms of acute and chronic laryngeal stenosis, especially those of syphilitic origin, is in its infancy, its ultimate possibilities as yet undeveloped.

He believes that intubation certainly offers, in a large proportion of instances, the simplest and most practical means yet devised of quickly and efficiently relieving the dyspnoea of acute laryngeal stenosis, thus avoiding a tracheotomy, and for dilating chronic cicatrical stricture, in its varying grades and forms, with speed and certainty, thus dispensing with the temporary or permanent necessity of a tracheal canula.

The history of the treatment of chronic laryngeal stenosis, especially that of a cicatrical nature, shows no brilliant triumphs and but few lasting successes. Many methods have been devised, many instruments been the outcome of the inventive ingenuity of specialists; but until the latest and well-known one of Professor Schroetter, which necessitates the existence of a tracheotomy wound, no distinct plan of procedure had, or has since, been formulated.

Over the "method of Schroetter," the only one necessary to be considered in this connection, intubation presents the advantages of avoidance of the necessity of a preliminary tracheotomy, and affords a possibility of the continuous and prolonged retention, without risk or inordinate discomfort, of the dilating means.

Doubtless the future will modify, perhaps greatly extend, the limitations here placed upon the procedure, but to-day we may claim certainty of fulfilment in some, reasonable expectation in others, of the following general indications.

CLASS I. The immediate relief of dyspnoea in all

³ New York Medical Record, October 4, 1890.

cases of acute syphilitic stenosis of the larynx, by mechanically and temporarily affording an artificial passage for the respiratory current through the intubation-tube.

CLASS II. Facilitating and hastening, by either equitable and prolonged, progressive, or specially directed pressure of the intubation-tube, the absorption of acute inflammatory effusion, or the thickening and induration attendant upon chronic syphilitic inflammation of the larynx.

CLASS III. Forceful dilatation and continuous distention, by means of the intubation-tube, of slight and recently organized membranoid or band cicatrices.

CLASS IV. Progressive dilatation, by means of a series of intubation-tubes, of cicatrical strictures of the larynx, subsequently to their incision, by some form of cutting laryngeal dilator.

CLASS V. Divulsion and progressive dilatation: Incision and subsequent distention, the former being made through the larynx, or from below, through the tracheotomy wound; or systematic, continuous dilatation, by such specially adapted intubation-tubes as may be required in cases which vary greatly in the nature, extent, and character of the lesions, in all cases of chronic and extensive cicatrical stenosis of the larynx, with displacement and distortion of laryngeal parts, the result of dense cicatrization following gummatous degeneration in tertiary syphilis and where a tracheotomy tube may or may not be worn.

And in the following classes:

CLASS VI. In dyspnoea due to abductive immobility of the vocal cords, dependent upon syphilitic non-suppurative adhesive arthritis of the arytenoid articulations, or their mechanical-fixation by either plastic infiltration of the tissues in their neighborhood, leading to adhesive perichondritis and spurious ankylosis, or cicatrices of the same parts, which bind them in an immobile position, and in which well-directed pressure by the intubation-tube will exert a favorable influence by promoting absorption of effused material, or forcibly break up cicatrical attachments and free articular movement.

CLASS VII. In dyspnoea dependent upon abductor paresis, from commencing degenerative processes of syphilitic origin in the abductor muscles themselves, in which the preservation, by means of the intubation-tube, of even a small respiratory opening may stimulate normal physiological movement and preserve nutrition by maintaining muscular activity.

It is understood that in all the above classes of cases intelligent and energetic anti-syphilitic treatment is employed to combat the accompanying diathesis; and that the tracheotomy canula, if it be worn, is no contra-indication or barrier to the use of an intubation-tube.

Histories of several cases are given in this careful paper illustrating many of these propositions. The technique of the operation is made clear, and the intubation-tubes described.

ETIOLOGY, SIGNIFICANCE, AND TREATMENT OF SPURS AND DEFLECTIONS OF THE NASAL SEPTUM.⁴

A discussion on the above subject was introduced in the Section of Laryngology at the last meeting of the British Medical Association, by Dr. E. Woakes and Mr. W. J. Walsham of London.

Dr. Woakes began by saying that he would limit

⁴ Journal of Laryngology and Rhinology, October, 1890.

his remarks to a simple account of his own experience. He thought it possible that deviation might be congenital. Injury, the most frequent cause, gave rise to most pronounced degrees of deformity.

One feature was common to all cases. However extensive the deviation might be, the mass did not touch the floor of the passage, a circumstance which was of great help to the surgeon. In deviations and spurs of idiopathic origin the cause would most frequently be found in the presence of enlargements of the spongy bones. There was a very intimate association between spurs and deviations, of which fact, Dr. Woakes offered the following explanation: When the cartilaginous septum was pushed to one side, the pressure tended to dislocate it from its line of insertion into the median ridge of the superior maxilla. A slow inflammatory process was set up at this line, which resulted in the formation of a buttress of hypertrophied cartilage and bone. In such cases the spur must be regarded as a conservative formation, and should not be interfered with if it gave rise to no symptoms. Whether spurs on the posterior segment of the septum had the same origin was not clear. In some cases large spurs were found in that situation without any evidence of deviation; they were probably the result of by-gone periostitis.

The significance of deviations and spurs was twofold. In the first place they should suggest a search for pre-existing morbid conditions, for the treatment of which the mere removal or rectification of the deformity did not suffice. This remark applied especially to enlargements of the middle turbinated bone and diseases of the ethmoid region generally. In the second place they might give rise to symptoms. These might be grouped under two heads — obstruction to the nasal channel, and tension of, or pressure upon, nerves. Even partial nasal stenosis necessitated mouth breathing, and the respiration of air deprived of the moisture added to it in the nasal cavities, produced wide-reaching effects on the lower respiratory tract, such as chronic laryngitis, follicular pharyngitis, etc. The Eustachian tube and the auditory apparatus also suffered. The most interesting symptoms were, however, of the nature of nerve reflexes, such as a sense of suffocation referred to the larynx, which occurred mostly in persons under the age of thirty, and was often dismissed as hysterical; weak action of the vocal cords with corresponding weakness of voice. The presence of any of these symptoms justified surgical interference, which should be radical.

For the removal of the spur Dr. Woakes used the saw. Having inserted the saw as far as possible, he directed it first inwards towards the septum, and then used it in an upward direction parallel to the septum, until enough had been removed. A small plug of wood, dipped in carbolized vaseline, was then put in to cover the wound; he sometimes dusted this plug with iodoform before introduction. If there was deviation this must be rectified by means of Adams's dilator, but nothing would keep the septum straight if the spongy bones were hypertrophied; their reduction or ablation was therefore a necessary preliminary. Having cleared the nostrils and placed the septum in the middle line, the next step was to introduce the plugs. He had long discarded solid plugs, preferring fir-wood wool as a material. A piece of this wool was frayed out into a soft long mass, about four inches long. This was then twisted round a piece of ligature silk; it was

then doubled in the middle, and the two portions twisted together loosely and the two silks knotted together where the wool came to an end. There were thus two inches of wool, into the midst of which a thread of silk was inseparably twined, so that the whole could be withdrawn at will by means of these ends. Several of these plugs should be prepared beforehand; they might be smeared with iodized vaseline. One was introduced into each nostril by means of a strong probe or crocodile forceps. It should be carried the whole length of the nostril, and a second thinner one might be introduced above it if necessary. The ends of the silk hanging out of the nose should then be tied together. These plugs might be left in for a week. India-rubber tubing was a good substitute for the wool; it was cleanly, and admitted of irrigation. He had once or twice encountered troublesome hemorrhage in this operation. In such cases, and in all cases of nasal bleeding, he had found Ruspi's styptic superior to any other, especially if used in conjunction with fir wool. With regard to removing the inferior turbinated bone, or a portion of it, to make more room, he held that all the turbinated bodies should be treated with conservative respect when they were in a condition to perform their proper function; if, however, they were diseased, or adherent to the floor or walls of the nasal fossa, they might be dealt with according to the requirements of the case.

Dr. Walsham classified "deviations" as follows: (1) Simple deviations of the cartilaginous septum. (2) Dislocation of the anterior end of the septum from the nasal spine and from between the reflected portions of the lateral cartilages. (3) Deviations attended with cartilaginous and bony outgrowths of the septum.

The first variety was very common, and, when slight, gave rise to no inconvenience. In by far the greater number of the cases he had seen the deviation was the result of former injury, and in most of them it was associated with some slight displacement of the lateral cartilages or nasal bones. In a few there was no history of injury, and in these the deviation was generally first noticed about the age of puberty. He believed that in non-traumatic cases the deviation was the result of some defective development of the bones of the face. At or about puberty the nose underwent a remarkable development, and the accessory cavities (sphenoidal cells, frontal sinuses and antrum), previously hardly existent, rapidly assumed their adult proportions. As the sphenoidal cells were developed, the vomer was pushed downwards and forwards by the rostrum of the sphenoid, carrying with it the superior maxillary bone. This ploughing forward of the vomer carried with it the perpendicular plate of the ethmoid, together with the nasal bones and the external table of the frontal to which these were attached. In this way the frontal cells were developed. If anything interfered with the due development of the jaws or prevented the carrying forward of the external table of the frontal bone, the nasal bones would also be arrested in their forward extension; and, supposing the development of the septum to go on, some deflection must occur, as the sense of smell was becoming of less importance in the struggle for existence, the accessory nasal cavities were slowly becoming smaller, but it did not follow that every septum should be crooked.

By way of treatment Dr. Walsham preferred shaving the cartilage or the use of the saw according to the

variety. In traumatic cases he had found straightening, with removal with knife and nasal saw of any projecting portion of callus, very successful. The septum must be literally smashed by the forceps, with as little laceration of the mucous membrane as possible. It was of no use to twist it straight and leave it, as the deflection was almost certain to recur. To ensure the thorough smashing of the maxillary crest the handles of the forceps should be well raised, or angular forceps should be used. The upper fragments should be bent well over to, or a little beyond, the median line. After the septum had been rectified, it must be kept in position by some form of retentive apparatus. India-rubber inflating plugs would be found serviceable, especially when the cartilages were slightly depressed. When no apparatus was at hand a piece of stout rubber drain-tube might be employed. In non-traumatic cases the cutting away of the outgrowths from the septum with a strong, narrow, probe-pointed scalpel, supplemented by the use of the nasal saw when the projection was of osseous consistency, would usually suffice. He had used the saw attached to the surgical engine, but preferred to use it by hand, and, as he always did these operations under general anesthesia, he preferred the straight saw to that with a nasal angle. For the removal of exostoses, drilling was highly spoken of by some, but he could not speak of it from personal experience. It seemed to him not unattended with risk of septic infection.

The cases he had found most difficult to treat were those in which, in conjunction with a general deviation of the whole septum to one side, there were irregular spurs with localized bulging combined with deflections of both the vomer and maxillary crest. In such cases, forcible straightening with excision of the most prominent spur offered the best prospect of success, and if this failed, the best course was to remove the inferior turbinated body and to leave the septum alone. With regard to the deformity of the nose so often associated with deviation of the septum, when the lateral cartilages were merely deflected to one or other side, they might (after the septal troubles had been dealt with) be bent straight and kept in position by a retentive truss, which should be worn for a considerable time.

When the nasal bones were depressed so that the nose became broad and the nasal processes of the maxillary bones separated, the bones could in many cases be lifted or wrenched into place with forceps. No untoward result, such as necrosis or other injury, had hitherto occurred in his practice, though if too much force were used it might be possible to injure the cribriform plate of the ethmoid, and thus run the risk of septic meningitis.

With regard to depression of the cartilages at their junction with the nasal bones as the result of injury, he had not hitherto been successful in retaining them in position. It was easy to replace them, but they always fell back when the retentive apparatus was removed. In the first case in which he could obtain the patient's permission, he intended, through a median incision, to turn back the skin on each side, and then to raise the depressed cartilages and fix them to the nasal bones by thin silver wire. The wire would be passed obliquely through the bones and cartilages, previously drilled, without perforating the mucous membrane. The wire could then be battened down on the nasal bones and the skin replaced and united by suture.

These operations, and especially forcible straightening, could always be more thoroughly performed under chloroform than under cocaine. There was always considerable hemorrhage, but when the mouth was held open with a gag, and plenty of sponges with handles were in readiness, no trouble need be feared on that score.

Reports of Societies.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

SIXTEENTH ANNUAL MEETING held in Louisville, Ky., October 8, 9, and 10, 1890.

FIRST DAY.—MORNING SESSION.

The Association met in Liederkrans Hall, and was called to order by the President, Dr. J. M. MATHEWS, of Louisville, at 10 A. M. Prayer was offered by the Rev. Mr. Jones, of Louisville.

Dr. I. N. BLOOM, of Louisville, Chairman of the Committee of Arrangements, made his report.

The first paper read was by Dr. FRANK WOODBURY, Philadelphia, Pa., entitled

INFECTIOUS DYSPEPSIA AND ITS RATIONAL TREATMENT BY THE ANTISEPTIC METHOD,

in which he said it was proper to state, at the outset, that our present consideration of the subject is limited to dyspepsia solely as related to the stomach; no reference was attempted, or intended to be made to intestinal indigestion, or to the so-called, intestinal dyspepsia.

With reference to the pathology of dyspepsia, he considered it at least as much entitled to recognition as a distinct disease, in the present unsettled condition of medical nomenclature, as consumption or chorea. Like them, it is characterized clinically by manifestations of nervous disorder; so that Cullen was not very far wrong in considering dyspepsia as a neurosis under the class of adynamie. Like pulmonary phthisis, also, its most marked symptoms are produced (the author believes) by the absorption of the products of parasitic micro-organisms.

Of late years the science of bacteriology has made wonderful advance, and especially in the department of bacterial parasitism, or infection, and its relation to disease. Abelous, a recent investigator of this subject, found sixteen species existing normally in his own stomach, of which two were micrococci, thirteen bacilli, and one vibrio. The presence of saprogenic microbacteria in the stomach, therefore, being constant and not incompatible with health, it becomes necessary to inquire why fermentation or putrefaction of the food does not occur after every meal? In other words, how is practical antisepsis obtained by natural process? Three things are to be considered in this connection: (1) the food, (2) the digestive fluids, and (3) the physical conditions attending the act of digestion.

Laborious, painful, and imperfect digestion occurring habitually, when not symptomatic of other disease, constitutes dyspepsia; and when accompanied by fermentation of the contents of the stomach and general toxic symptoms, the result of microbial development, it may properly be called infectious dyspepsia. The disorder is sufficiently prevalent, and gives rise to enough discomfort and actual suffering in its victims, not only

to deserve our serious consideration, but also to enlist our best therapeutic skill in their behalf. The excessive growth of micro-organisms during digestion is favored by slow movements of the stomach and by defective quantity of the gastric juice. Acid dyspepsia, or sour stomach, may be due to excessive secretion of hydrochloric acid (rarely), but is generally caused by lactic, acetic, or butyric fermentation, due to the presence of appropriate forms of bacteria in the stomach. The object of treatment of infectious dyspepsia is to prevent the excessive development of micro-organisms during the digestion of food. This is sought to be accomplished (1) by the use of articles of diet which are not in a fermenting condition nor readily fermentable; (2) by adopting such hygienic and tonic measures as will invigorate the bodily powers and especially bring the gastric juice up to its normal standard of quality and quantity, and increase the muscular power of the stomach; and (3) by local antiseptic treatment, including the administration of drugs which retard fermentation, and especially by lavage, or irrigation of the stomach, with weak disinfectant solutions, or simply recently-boiled water.

DR. JOHN H. HOLLISTER, of Chicago, contributed a paper on

HELP AND HINDRANCE TO MEDICAL PROGRESS.

He said the possibility of progress depends upon the present imperfection of present attainment; possible results are dependent upon our abilities, upon our methods and upon the obstacles to be overcome. The profession must command a much higher average of native talent; that talent must receive a much higher grade of culture; and the present methods of research on the part of the profession must be greatly modified and improved.

DR. I. N. LOVE, of St. Louis, Mo., in a paper entitled

COFFEE

said that his experience for five or six years past is strongly in favor of taking a cup of strong, black coffee, without cream or sugar, sandwiched in between two glasses of hot water, before rising every morning—at least, one hour before breakfast. The various secretions are stimulated, the nervous force is aroused, an hour later a hearty meal is enjoyed, and the day's labor is commenced favorably, no matter how the duties of the day and night preceding may have drawn upon the system. Another cup at four in the afternoon is sufficient to sustain the energies for many hours. In this way the full effect is secured. The stimulant devotes itself strictly to business; none of it is lost if the proper diet be taken at the proper times; and the ideal diet for those who make large drafts upon their nervous systems and expect to have them honored is hot milk. If the above regimen be followed, and accompanied by at least eight hours of sleep out of every twenty-four hours, the capacity for work is almost unlimited.

DR. GEO. HULBERT, of St. Louis, Mo., read an interesting paper on

MECHANICAL OBSTRUCTION IN DISEASES OF THE UTERUS.

He submitted the following conclusions:

(1) That in the natural or normal order of things, do we find the uterus in form and structure endowed with a power and capacity for the performance of the

function, menstruation, far in excess of any legitimate demand, to the extent that with a one-fourth inch diameter of canal at the sphincters, the excess equals 7724.8 times the demand, and with a one-thirty-second inch diameter, the excess equals 120.7 times the requirement.

(2) That in the pathological conditions, considered as essential for mechanical obstruction, do we find that the conservation of force is capable and does so regulate conditions that the capacity is not abolished, but persistent in an eminent degree, so that in the presence of the normal physiological energy the function is accomplished, save in only one emergency, that of total annihilation of the normal state, namely, atresia?

(3) That the phenomena considered as attendant and dependent upon mechanical obstruction are not due to the forcible expulsion of retained fluids through the uterine canal, but are resident and produced *within the tissues*, and are dependent upon *disturbed rhythm of physiological forces*, evolved through abnormal enervation, muscular action and circulation.

(4) That the demand upon the uterus, for the passage of blood-clots, membranes, mucous plugs, uterine sounds, sponge tents, uterine dilators, etc., in order that the diagnosis of mechanical obstruction may be made, is not only vicious in the extreme, but irrational, illogical and unscientific.

(5) That the correct and rational interpretation of the testimony offered by symptomatology, pathology and therapeutics removes mechanical obstruction from the domain of gynecology as a *demonstrable fact*, save in "atresia uteri."

FIRST DAY.—AFTERNOON SESSION.

The Association was called to order at 3 p. m., by first Vice-President DR. C. R. EARLEY, of Ridgeway, Pa.

DR. R. STANSBURY SUTTON, of Pittsburgh, Pa., made (by invitation) some remarks on

THE SURGICAL TREATMENT OF UTERINE FIBROIDS, and exhibited specimens.

DR. WILLIAM PORTER, of St. Louis, Mo., contributed a paper entitled

PROFESSOR FLINT'S DOCTRINE OF THE SELF-LIMITATION OF PHthisis,

in which he said that some time before his death Professor Flint promulgated the doctrine of the self-limitation of phthisis, and presented it with all his well-known power and great ability to the profession. This very interesting proposition was at the time the subject of free debate in various medical societies. The recent years have been full of the wonderful results of the study of pulmonary disease and bacteriological research, and the possibility of a positive diagnosis has overshadowed the equally interesting question of prognosis.

After having carefully examined the facts cited in support of the proposition, Dr. Porter said he had no hesitation in asserting that he finds no sufficient evidence to warrant us in accepting the statement that phthisis is self-limiting, or that the element of self-limitation has a decided influence upon the result in any given case. He did not mean that all cases of phthisis necessarily die from this disease, but he does mean that where phthisis is firmly established, there is nothing in the nature of the disease itself that indicates in

any stage a fixed boundary — a line of demarcation, as it were, but rather that all of its tendencies are progressive and downward.

Dr. Porter drew the following deductions: (1) That there is no sufficient clinical evidence to warrant us in believing that by self-limitation as defined by Professor Flint, pulmonary phthisis may end in recovery. (2) The pathology of phthisis is equally opposed to the proposition. (3) Although phthisis is not self-limited yet limitation is possible through "extrinsic influence derived from hygiene and therapeutics."

DR. A. B. THRASHER, of Cincinnati, O., read a paper on

COUGH, ITS RELATION TO INTRA-NASAL DISEASE.

He said cough is a reflex phenomenon due to the irritation of a nerve-fibre in the air-tubes, larynx, pharynx, nose, ear, stomach, etc. A normal cough is for the purpose of freeing the air-tract from some foreign body. Irritation of the upper part of the trachea, and the ventricles of Morgagni, most frequently produces cough. An irritation in many other locations may be referred by the sensory centres to this region, and thus give rise to cough. Inflammation of the cavernous bodies of the nose or of the adjacent septum has been known to give rise to a distressing cough, and has been mistaken for evidence of tubercular disease. This is more apt to occur in a person of neurotic temperament. The cough due to nasal disease may sometimes be recognized by its metallic ring, and the absence of expectoration. It can, as a rule, be provoked at will, by touching the irritable spot in the nose with a silver probe. Dr. Thrasher recited three cases illustrative of nasal cough from his private practice.

In CASE I there was no subjective symptoms of nasal disease. The cough had been present for three months and was not benefited by the usual cough mixtures. The lower turbinate was found to be hypertrophic, and touching it with a probe provoked violent coughing. The cauterity was applied and in three days the patient ceased to cough.

CASE II. A young lady had been coughing violently for three months. She referred the irritation to the throat, which had been pencilled and sprayed for some time with no relief. Touching the posterior extremities of either lower turbinate produced violent cough. Treatment as in Case I, with good results in two months.

CASE III. Cough had been present six months, and was not benefited by constitutional or local treatment. The seat of the trouble was found to be in the left middle and right lower turbinate. Treatment similar to other cases was followed by cessation of cough within a month.

A paper entitled

THERAPEUTIC USES OF CARDIAC SEDATIVES IN INFLAMMATION,

by DR. HOBART AMORY HARE, of Philadelphia, Pa., was read by title in the absence of the author.

DR. A. H. OHMANN-DUMESNIL, of St. Louis, Mo., reported

A CASE OF RHINOTHYMA — OPERATION.

FIRST DAY.—EVENING SESSION.

DR. JOHN A. WYETH, of New York, delivered the public address, taking for his subject,

THE MEDICAL STUDENT.

The hall was literally packed with people, and the members of the Mississippi Valley Medical Association, a great many of them, who came to hear the lecture, were turned away, the students of the Louisville University having taken possession of nearly all the seats, thus literally freezing the members out. The address was listened to very attentively, and Dr. Wyeth received applause several times during its delivery.

He said the *first* or preliminary stage of a medical student's life is his preparatory or academic life; the *second*, his medical college life; the *third*, his post-graduate or practical life, and it extends from the day he leaves his alma mater until usefulness ceases. In the acquirement of a practical training three ways were open, and in order of preference they are:

(1) Service as interne, preferably for a term of two years in a general hospital.

(2) Service in some post-graduate institution, where all departments of practical medicine are taught by teachers especially trained in their respective branches.

(3) Service as assistant to one or more well-qualified practitioners in general medicine.

SECOND DAY.—MORNING SESSION.

DR. JOSEPH RANSOHOFF, of Cincinnati, O., read a paper on

CHRONIC DISEASES OF THE JOINTS.

DR. H. C. DALTON, of St. Louis, Mo., contributed a paper entitled

CASES OF PENETRATING STAB-WOUNDS OF THE ABDOMEN; LAPAROTOMY; RESULTS.

Dr. Dalton reported six cases of laparotomy in which there was visceral injury. There was one death and five recoveries.

CASE I was a wound of the descending colon and ileum; recovery. B. T., colored, aged sixteen, was admitted to the City Hospital of St. Louis, July 23, 1890. Patient stabbed two hours previously with long-bladed knife. Wound at free extremity of the twelfth rib; several inches of omentum protruded; general condition excellent; pulse 62, respiration 23, temperature 100°. Incision in the left linea semilunaris; blood and fecal matter in the cavity; there were two holes in the descending colon, and one in the ileum, which were closed with continued iron-dyed silk sutures. Discharged from hospital eleven days after admission.

CASE II. Stab-wound of liver and intestines; recovery. A. V., aged 21, admitted August 21, 1890, received three stab-wounds an hour and a half before admission. One was an inch below the costal border, four inches to the left of median line; three inches of omentum protruded. The second was an inch above and two inches to the right of the umbilicus. The third was in the seventh interspace, in the right axillary line. The wound of the jejunum was closed by an interrupted silk suture. Four inches of the seventh rib were resected, the diaphragm split up three inches, and the wound in the liver closed by one catgut suture. Diaphragmatic and cutaneous wounds closed by continuous catgut suture. Patient's temperature rose to 102° on the second day, after which he recovered rapidly.

Dr. Dalton laid particular stress upon the necessity of following the wounds to the bottom and making

ocular inspection of the same, and severely condemned the method of trusting to the introduction of the finger in the *tactus eruditus*. He deprecated depending implicitly upon Senn's hydrogen-gas test on account of its fallibility.

These cases were generally discussed and the doctor highly complimented on his good results.

DR. M. T. SCOTT, of Lexington, Kentucky, reported a case of

GUN-SHOT WOUND OF THE INTESTINE,

in which there were four perforations by a large bullet, various complications, and complete recovery following laparotomy.

DR. B. MURDOCH, of Pittsburgh, Pa., contributed a paper on

TORSION OF ARTERIES AS A MEANS FOR THE ARREST OF HEMORRHAGE.

He said there is no subject of greater interest to the practical surgeon than the arrest of haemorrhage. This remark is equally true whether the haemorrhage comes from a wound accidentally inflicted, or one made intentionally, by the surgeon's knife.

There are two methods by which the torsion may be applied: (1) limited torsion, and (2) free torsion. In the first method, two pairs of forceps are required. The first pair grasps the vessel at its cut extremity, and pulls it from the sheath. It is then seized by the second pair at a point from one-half an inch to an inch above the cut extremity of the artery; this second pair being held at right angles to the long axis of the vessel. The first pair is then given three or four sharp turns. By the second method (free torsion) only one pair of forceps is required. It is the one recommended by Mr. Bryant as not being so likely to injure the external coat of the artery. And this is the method which was adopted in the cases which are given here-with.

The following is a table showing the number of arteries divided in cases of amputation, where torsion had been resorted to for the arrest of haemorrhage at the Western Pennsylvania Hospital:

Femoral	116 times.
Popliteal	18 "
Axillary	18 "
Anterior tibial	317 "
Brachial	81 "
Posterior	317 "
Radial	45 "
Ulnar	45 "

Dr. Murdoch said, in conclusion, that the advantages of torsion as compared with ligation are: (1) The greater facility with which it can be applied. (2) Torsion is a safer method, being less liable to be followed by secondary haemorrhage. (3) Healing is facilitated because the wound is free from any irritating or foreign body.

DR. G. FRANK LYDSTON, of Chicago, Illinois, exhibited the skulls of a number of the most notorious criminals of the world, and made some very instructive remarks with reference to their peculiarities, shape, size, etc.

(To be continued.)

Internal Prophylaxis. — "Why, Pat, for Heaven's sake, what is the matter?" — "Well, sorr, I swallowed a pertater-bug; and although, sorr, I took some Parrus-green widin five minutes after, ter kill th' baste, shill he's just raisin th' devil inside o' me, sorr." — *Sanitarian*, October, 1890.

AMERICAN GYNECOLOGICAL SOCIETY.¹

DR. F. H. DAVENPORT, Boston, reported a case of **INCONTINENCE OF URINE DUE TO MALPOSITION OF THE URETER.**

The patient was twenty-nine years of age, and gave a history of having suffered from incontinence of urine all her life, being constantly wet. The leaking was constant, and not affected by position or by straining or coughing. The amount varied within certain limits, from two to eight napkins being used daily. Menstruation and pregnancy increased the flow.

There was no cystitis in this case, and her usual medical attendant had corrected a malposition of the uterus, and had used electricity, belladonna and other remedies, but without appreciable effect.

Examination revealed a malformation of the ureter. Instead of turning into the bladder at the normal position, the ureter was continued along in the septum between the bladder and the vagina, and emptied by a special opening near the meatus.

The treatment indicated in this case was, if possible, to dissect up the ureter from its bed in the anterior vaginal wall, to a point corresponding to where it would normally enter the bladder, make an opening into the bladder, turn the ureter in and fasten it there, and then close the fistula. This operation was performed, sutures of silver and catgut being used. Subsequent retraction of the ureter rendered a second operation necessary, in order to fix the end of the ureter. This operation was a complete success.

Dr. Davenport stated that this variety of ureteral malformation is extremely rare, and that there are records of only a few cases in which operation has been attempted. He referred to the cases of Dr. W. H. Baker, Dr. T. A. Emmet and Dr. Von Massari.

DR. W. W. JAGGARD, of Chicago, thought that injuries to the ureters were quite common during pregnancy, and that those existing before pregnancy might become intensified, but that they were not common during labor, as at that time the bladder is drawn up into the abdominal cavity and becomes an abdominal viscus, and the ureters are out of the way of the pressure from the head of the child; that they are rarely injured by the dilatation of the cervix or the application of the forceps before the engagement of the head. In 1878, a German observer called attention to compression or dilatation of the ureters as a cause of eclampsia, and years before Morgan had noticed the same thing. The speaker had seen one case where compression was believed to be the principal causative element in eclampsia. Recent anatomical investigations with frozen sections of women dying early and late in the puerperium, particularly in cases of difficult labor, have demonstrated that the bladder is an abdominal and not a pelvic organ. Among the causes specially operative in producing injury of the ureters during pregnancy, he mentioned (1) increased abdominal tension; (2) presence of small ureteral calculi (calcareous pyelitis), having seen two cases in which calculi were probably the cause of a dilated ureter. He believes that palpation of the ureters during the puerperium is an extremely hazardous proceeding, productive of no good and entirely a work of supererogation, as an examination per vaginam and of the urine will disclose the necessary information.

¹ Fifteenth Annual Meeting, Buffalo, N. Y., September 16-18, 1890. Continued from page 460 of the Journal.

DR. A. W. JOHNSTONE, of Cincinnati, related a fatal case of injury to the ureter after laparotomy for multilocular ovarian cyst, where furious mania was developed forty-eight hours after the operation. The tumor pressed on the ureter just where it passed over the pelvic brim, and from that point up to the kidney it was so enlarged that it would admit the finger; and there was purulent inflammation of the ureter and hilum of the kidney; and the kidney itself was seriously disorganized. The lower portion of the ureter was normal. He believes that many of the cases of mania after laparotomy are due to some such condition as this. General tuberculosis is a very frequent disease of the ureters, and was noticed in a young girl who was supposed to be dying of phthisis, who presented no complication of the lung whatever, but had all the symptoms of tuberculosis. The post-mortem revealed the bladder, ureters, hilum of the kidney, and kidney itself studded with miliary tuberculosis. The ureters are a frequent source of trouble, and should not be overlooked in gynecological work.

DR. HENRY T. BYFORD, of Chicago, thought that in many cases of pelvic diseases, death was due to ureteral troubles such as uremic convulsions, etc., whereas they were attributed by the ordinary practitioner to the earlier disease which caused the ureteral trouble. Catheterization of the ureter is a difficult proceeding, and requires a practiced hand; but it is unreasonable to doubt that it can be done.

IS THE MORTALITY AFTER GYNECOLOGICAL OPERATIONS AFFECTED BY CLIMATIC INFLUENCES?

By **HENRY C. COE**, M.D., New York.

The writer was led to inquire into this subject by reason of the fact that not only in his hospital experience had he observed an apparent increase in the mortality during the early spring, but some of his most respected teachers in gynecology still believed that this season of the year was especially unfavorable for operative work. Modern surgery demands of us the exercise of every possible precaution in order to insure the best results. If there are other unfavorable influences beside sepsis which may vitiate these results, it is important that we should discover, and learn how to avoid them. With this object in view, the writer addressed the following queries to a large number of prominent gynecologists in America and abroad:

- (1) Have you noted any increase in your mortality, either in hospital or private practice, during any particular month or months?
- (2) If so, do you attribute this fact to climatic influences, or to the greater prevalence of sepsis at the season in question?
- (3) Have you ever suspended or limited your operative work during any month or months because of the increased mortality?

Replies were received from three-fourths of those who were thus addressed, the majority of which were in the negative. The general drift of the more extended answers to the above questions showed that the writers believed that if there was an increased mortality during the early spring, it was due, not so much to climatic influences, as to the uncleanliness of hospitals and operation-rooms after the winter's work, or to relaxation of the usual stringent precautions against sepsis. The most prominent and successful laparotomists scouted at the idea that their results were worse at any particular time of the year.

The reader agreed with the latter opinion. He had noticed no difference in private practice, and in those hospitals in which he had noted an increased mortality during February, March and April, he regarded it as clearly traceable to sepsis from preventable causes.

DR. HOWARD A. KELLY, of Baltimore, read a paper entitled

CEPHALHEMATOMA.

Dr. Kelly claimed that although this is one of the most important diseases of early childhood, it is rarely recognized, and few men outside of the ranks of pure specialists are aware that it exists. Cases which occur in the practice of the general practitioner are diagnosed and treated by him upon "general principles," the information which he possesses upon this subject being comparable to that of a physician practising early in the last century.

Cephalhematoma (cephalocephalhematoma) is a well-defined disease which appears soon after birth, runs a brief, definite course, tending, as a rule, towards resolution, but capable of seriously affecting the health or even of implicating the life of the child. The relative frequency of the disease is one in every two hundred and fifty obstetrical cases.

Dr. Michaelis, of Harburg, was the first to describe this disease. His description appeared in *Loder's Journal*, at the close of the last century, and was followed for thirty years by reports from many other contributors to German Journals. The name cephalhematoma was given to the disease by Naegele, in 1822.

Cephalhematoma is a circumscribed effusion of blood between the periosteum and one of the flat cranial bones, appearing usually the day after birth, and gradually increasing in size until it forms a tense, prominent, rounded or ovoid swelling. Its commonest seat is over one or both parietal bones. It is always lateral, never crossing a suture. The skin over the tumor remains movable and unaltered in appearance. The tumor is not painful, and does not decrease in size upon pressure. After two or three weeks, as a rule, it gradually disappears by absorption. Instead of being absorbed, the collection of blood may undergo suppuration, perforating the cranial cavity, or rupturing externally.

One of the most important diagnostic signs of cephalhematoma is the existence of a bony wall, one or two millimetres in height, which surrounds the whole outer circumference of the tumor. This can be distinctly felt through the skin, and gives at once the impression of a depressed fracture. Injury has no apparent connection with the origin of this tumor, which often appears after natural, easy and short labors, and upon a part of the head which was not prominent in the birth.

The earlier observers frequently incised the tumor, cleaned out the blood, and applied a compress. The best treatment to-day is to wait for two or three weeks for resolution by absorption, and, if this should not take place, to incise and empty the sac under strict antiseptic precautions, and apply an antiseptic dressing. Whenever signs of suppuration arise, the tumor should be freely opened at once, well washed out, and drained.

Dr. Kelly cited cases illustrating the symptoms of cephalhematoma and the advisability of following the treatment recommended.

DR. W. W. JAGGARD, of Chicago, believes that external cephalhaematoma occurs in many labors, and is healed spontaneously, attracting little or no attention. The internal variety where the tumor is between the inner layer of the periosteum and the bone, sometimes causes strabismus and death; it is not difficult to diagnose, but usually difficult to cure. He is of the opinion that injury is always the cause of these tumors, and that it occurs during labor by reason of the stretching downward of the periosteum and rupture of its blood-vessels, or by reason of the bringing together of the bones of the fetal head by the application of the forceps. It is essentially traumatic, and occurs in a slight degree in many labors, but reaches a perceptible size in about the proportion stated by Dr. Kelly. It is nearly as frequent in the after-coming head and transverse presentations, as when the vertex presents.

DR. EDWARD W. JENKS, of Detroit, remarked that Dr. Buecheu referred to cephalhaematomata in his "Diseases of Children" (1888), as having a very unfavorable prognosis and being difficult to differentiate from the spurious or ordinary caput succedaneum.

DR. FREDERICKS, of Buffalo, reported three cases of cephalhaematomata:

(1) The cephalhaematoma nearly covered the left parietal bone, and proved fatal on the fourth day, the child dying in convulsions produced by the pressure on the dura mater of the blood-clot which collected between it and the parietal bone. Labor normal, manual delivery; no treatment.

(2) The cephalhaematoma covered the parietal and frontal bones and orbita. Bleeding occurred at a cut made by the forceps on the frontal protuberance, and antiseptic dressing was applied. The child died at the end of the fourth day. The bony ring was clearly defined; labor long and difficult, with forceps delivery.

(3) The cephalhaematoma was larger than a silver dollar, upon the right parietal eminence; well defined bony edges and, contrary to the general rule, there was a bluish discoloration through the skin. No treatment; and at the end of six weeks, the tumor had entirely subsided, the only trace of it being the thickening of the periosteum over the area it had occupied.

DR. KELLY was convinced that these tumors were not the result of traumatism from severe labors or instrumental deliveries, being most frequently observed after simple and easy labors. They have been detected on the head of the child before birth, on the head of a five or six months' fetus, and in one case on the head of a child born by Cesarean section, all of which would lead him to believe that there must be some predisposing cause which is not as yet understood.

DR. THOMAS A. ASHBY, of Baltimore, read a paper entitled

DRAINAGE AFTER LAPAROTOMY.

Dr. Ashby stated that the occurrence and subsequent healing of fecal fistule in two cases, after operation, where there had been a delay in the removal of the drainage-tubes, had taught him the value of employing drainage for a length of time sufficient to insure a proper condition of the contents of the abdominal cavity. He had observed that in cases in which the abdomen was closed primarily, there was higher temperature, more pronounced nausea, and indications of a higher inflammatory action within the abdomen. He recommended no original method of

draining. The doctor claimed for drainage, that it is safe, that it promotes cleanliness and asepsis within the abdomen, that it provides a way of escape for intra-abdominal products, that it keeps the surgeon informed in regard to conditions in the pelvis, and that it reduces mortality.

DRAINAGE AFTER LAPAROTOMY.

DR. A. PALMER DUDLEY, of New York, in a series of seventy-nine cases of abdominal section including eight hysterectomies, one Cesarean section, two extra-uterine pregnancies and five pyo-salpinx, had used the drainage-tube in but two cases (fibroids), both of which died on the eighth day. The first from a circumscribed abscess of the omentum without general peritonitis, and the second from intestinal obstruction caused by adhesion of the intestines around the tube. Sixty-nine of these abdominal sections were made without the use of a drainage-tube and without a death, although in many of them there was a large quantity of fluid. The drainage-tube should only be used under two conditions: (1) where there is general peritonitis, and hemorrhage is suspected; (2) where the peritoneum is congested from a recent peritonitis, and bleeds if irritated with a sponge. Under all other conditions the proper toilet of the peritoneal cavity before closing the abdomen will accomplish more than any drainage-tube. The drainage-tube is dangerous in the hands of those who think they can accomplish with it what they should have done before closing the cavity. The dangers of the drainage-tube are: (1) intestinal adhesions from the formation of lymph around the tube; (2) fecal fistula; (3) occasional hernia. Where there is sufficiently grave septic inflammation in the pelvic cavity to endanger life, the tube is useless, as it very soon becomes walled in by a rapidly forming lymph cavity and cut off from the pus which is collecting around it. The success of the laparotomist is due to great care in the toilet of the peritoneum. He has great faith in washing out the abdominal cavity with a stream of hot water. The greater drainage-tube—the intestinal tract—he takes advantage of by the administration of saline cathartics just before operation to institute the vermicular action of the intestines which still goes on after the operation, and affords ample drainage, especially in cases of intestinal fistula. This, together with the use of hot water and careful closure of the peritoneum is safer and better than any form of drainage-tube. He uses the pure catgut sutures, which do not have to remain and be buried.

DR. E. C. DUDLEY, of Chicago, referred to the inadequacy of the ordinary glass drainage-tube for extensive drainage, on account of its being surrounded in a few hours by the agglutinated surfaces of the peritoneum, and believed that the system of drainage devised by Michaelis, which consisted in packing the part to be drained with iodoform gauze was a good one, and that the mistake most frequently made was in removing the gauze too soon, causing the adhesions around the gauze to break, with subsequent infection of the peritoneal cavity. He would use this system of drainage in all bad cases where there was a large surface to be drained, but that where there was doubt as to the necessity of drainage, the trial of the glass tube would serve to indicate or contra-indicate the necessity of more extensive drainage by the application of Michaelis's drainage.

DR. H. P. C. WILSON, of Baltimore, agreed with Dr. Dudley that the glass drainage-tube was utterly inadequate to drain large surfaces and that the Michaelis drainage was an excellent one. He referred to the frequency with which some of the European operators (Bantock and others) used the drainage-tube, the latter saying that he always felt safer when he had in a drainage-tube.

DR. M. D. MANN, of Buffalo, thought the drainage-tube was used too much. He has almost abandoned it; and if he did use it, he always felt uneasy while it was in. Unless it is watched with the greatest care, very great harm may result from it. He never uses it where it is possible to do without it. He would reverse the rule, "When you are in doubt, drain," and say, "Where you are in doubt, wait. Don't close the abdomen too quickly unless there is great shock; put in a sponge and use hot-water irrigation, and very frequently the hemorrhage will stop, and the abdomen may be closed without the necessity of drainage." He agreed with Dr. Dudley that drainage by the intestines or general system is an excellent plan. He starves his patients for forty-eight hours, giving them only a little water to moisten their lips; and by thus depriving the system of fluids, a great call is made on the lymphatics, which will take up the effused serum from the abdomen much safer than any tube.

(To be continued.)

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING, June 14, 1890.

DR. VICKERY reported, by invitation,

A CASE OF FLESHY UTERINE MOLE,¹

and showed the specimen.

DR. CHADWICK spoke of the great interest of the case, never having himself seen a case where the blighted ovum was carried so long.

Dr. Chadwick then reported

TWO CASES OF HYDATIDIFORM MOLE,

which he had seen recently in consultation.

The first case was that of a woman, of twenty-five years of age, in the fourth month of her first pregnancy, a patient of Dr. R. D. Elliott; he had recognized a uterus rather smaller than the period assigned. Throughout the pregnancy there had been occasional sero-sanguineous discharges. For a week there had been edema of the genitals, and albumen had been discovered in the urine. A few days later vomiting and headache had supervened. On Sunday, at 12 P. M., convulsions came on and lasted, with but little intermission, until Monday at 8 A. M. I was summoned in consultation, and reached her bedside at 10 A. M. As her head was again beginning to ache, it was manifest that another convolution was imminent, so I proceeded to empty the uterus without having sought to make any diagnosis of the degenerate condition of the ovum. Under ether the cervix was rapidly dilated by Goodell's dilator and the fingers. The hydatidiform cysts at once began to escape with much blood as usual. The uterine cavity was hastily emptied, curretted and washed out with acetic acid and a solution

of corrosive sublimate. The childbed was normal, and there were no subsequent convulsions.

The second case was seen only three days ago, in consultation with Dr. C. C. Street, and I have brought a specimen of the first cysts to exhibit. The patient was also at the fourth month of her first pregnancy, but the size of the uterus corresponded to that of the seventh month of pregnancy. There had been excessive hemorrhage from the uterus for a week. The diagnosis of hydatidiform mole was made. She was etherized and the uterus emptied, as in the last case. The convalescence was speedy and normal, except that the next menstrual period was profuse and some cysts discharged which had escaped the curette.

In one of these cases two characteristic symptoms of the disease were well-marked, namely: An enlargement of the uterus out of proportion to the length of pregnancy, and secondly, the hemorrhage at the time of delivery requiring speedy and energetic action. In the other the size of the uterus had been less than normal for the period. The occurrence of albuminuria and convulsions in one, so early in pregnancy, is extraordinary and militates against the absurd theory that mere physical pressure of the pregnant uterus is a factor in interfering with the normal function of the kidney. Acetic acid, undiluted, he had in these cases injected into the uterus, and was much pleased with its prompt action.

DR. J. G. BLAKE delivered a patient about a year and a half ago of a large number of hydatidiform cysts among which was a small atrophied fetus. In another case he had removed about half a bucket-full of cysts. Both cases recovered and these are the only cases of this trouble he has seen in a pretty large experience.

DR. EDW. REYNOLDS referred to the peculiar doughy feel on palpation which was quite distinctive in a case of his own. An important diagnostic point in his case was the escape of a watery, slightly bloody fluid at the catamenial period.

DR. VICKERY then showed a photograph of a double monster sent him by Dr. Fraser of Weymouth.

Dr. Vickery reported a case of

A MUCH-ENDURING FETUS.²

DR. GREEN said that the case illustrates very well how much the uterus will bear without aborting. It is never safe to infer that because sounds have been passed, the uterus has been emptied.

DR. H. C. BALDWIN, present, by invitation, then spoke on the

TREATMENT OF ABORTIONS.

He said: In March, 1889, Dr. J. P. Reynolds read a paper on the "Treatment of Abortions." In the *Medical and Surgical Journal* of June 13, 1889, a letter on the subject of the Bozeman Catheter appeared. Dr. Reynolds showed me this letter, and called my attention to the following statement of Dr. Macan which appeared in the report of the Rotunda for 1884. During this year, sixteen women were admitted for abortion, in none of whom was plugging of the vagina practised. The treatment is expectant as long as possible. If the hemorrhage is excessive before the cervix is large enough to allow the removal of the ovum, the cervix is either plugged with a tulip tent or dilated with Hegar's dilators and the ovum then removed. If there are symptoms of putrid absorption or of hemorrhage

¹ See page 412 of the Journal.

² See page 413 of the Journal.

rhage, the uterus is washed out with corrosive sublimate solution (1 to 2,000), the interior of the uterus curetted, after which the cavity is again disinfected and an iodoform suppository introduced.

Dr. Reynolds asked me, first, to show him and the Society the Bozeman catheter; secondly, to give an account of the treatment of abortion in the Rotunda.

The catheter which I have brought is one that was presented to me on leaving the Rotunda by the assistant master, and has seen much service in the hospital. I found the catheters at Codman & Shurtleff's, but the screw of the Codman & Shurtleff instrument does not slide up and down and allow so thorough a cleansing of the catheter as the one I brought with me from the Rotunda.

In regard to the treatment of abortion at the Rotunda I will read a letter from Dr. Macan who has just ended his mastership.

53 MERRION SQUARE, }
DUBLIN, February 19, 1890. }

DEAR DR. BALDWIN:—I am afraid I shall find it a little hard to give you our treatment of abortion in a short, concentrated manner, for I have never written any account of it before.

You ask if it is one of our rules never to plug the vagina. I do not think it is. We can only say that we very seldom find it necessary to do so. This is due to the fact that in the hospital some one is always on the spot, and we can plug the vagina the moment it is obviously necessary to stop profuse hemorrhage. But this enables us to omit it in all ordinary cases. In private you plug because you want to go away, and you cannot leave the patient if she has free hemorrhage. A very moderate-sized plug, if pressed into the cervix, will stop the hemorrhage. I always carry tupelo tents for the purpose. If the os is dilated, and there is much hemorrhage, I would pass in my finger as far as possible, and if I found the ovum detached, I would try to twist it off by rotating it round with my finger. If I could not do this, I would plug the ovum were still unruptured, and wash out with a Bozeman if the ovum is already broken up. If this does not get everything away, I would use Rheinstier's hollow curette, which has a hollow stem through which a stream of water is passed all the time you are curetting. Of course, if, when you are called in, you find the os well dilated and the ovum broken up, you would try and remove anything that was left behind in the uterus with the finger. The two essential things are to empty the bladder and to push the fundus down over the finger in the vagina by external pressure over the fundus. In cases of imperfect abortion with fetid discharge, we wash out first with a Bozeman, and then curette the interior of uterus. It is but rarely necessary to dilate the cervix in these cases. If it is, we can do it quickly and safely with a few of Hegar's dilators. In the early months, we try and preserve the ovum entire, to avoid leaving anything behind in the uterus.

I hope you will be able to make out our treatment from this rather confused account of it.

With kind regards to all my old friends and pupils, believe me,

Yours truly,

ARTHUR V. MACAN, M.D.

DR. G. HAVEN said that the Bozeman catheter of Codman & Shurtleff was made from one he had brought from Vienna. He regarded it as a very useful instrument, particularly for washing out the débris after curetting, the only objection being that the delivery tube is so small that it may become plugged. There is a modification of the instrument which is more easily cleaned.

DR. CHADWICK uses a simple male catheter with less curve than usual, being sure that the size of the os is larger than the catheter. He has never had any

trouble with this instrument and does not consider a double catheter, such as the Bozeman, at all necessary.

DR. EDW. REYNOLDS considered the Bozeman catheter to be of use in the treatment of the non-pregnant uterus. In the pregnant uterus he would agree with Dr. Chadwick that a simple catheter or tube is all that is needed. He had found that a tampon stops the hemorrhage in the case of an abortion and on the removal of the tampon the ovum was generally found to be expelled from the uterus.

DR. CHADWICK showed the catheter which he said he would use for washing out the uterus only after the extraction of the ovum. This he did with the fingers, forceps or sharp curette. The injection of acetic acid would stop the hemorrhage, and would not form foul clots as in the case of stypic iron.

DR. BLAKE uses Loomis' forceps which is easily converted into a curette.

DR. BLAKE had always believed that the blue tint was well-nigh infallible as a sign of pregnancy, but his faith had been recently shaken by a case where a robust girl, nineteen years old, who menstruated regularly but was afraid of pregnancy, presented a marked bluish coloration of the vagina. She was not pregnant but he found a small ovarian cyst.

DR. CHADWICK said he had never seen this coloration due to cysts, but he had seen it in a few instances in very erotic women, who were not pregnant, and he supposed that Dr. Blake's case came under this class. It is not an infallible sign; its absence does not exclude pregnancy, but its presence, when marked, is with but few exceptions a sure sign of pregnancy. The exceptions he had found to be in very erotic women.

He also reported

TWO CASES OF TUMORS COINCIDENT WITH PREGNANCY.

CHLORATE OF POTASSIUM AS A PREVENTIVE OF INTRA-UTERINE DEATH.

DR. GREEN spoke of a case in which he had used chlorate of potassium as a preventive of intra-uterine death. The patient had borne two dead children in the eighth month; and finding herself again pregnant, and wishing for a living child, she sought advice. No evidence of syphilis could be found in either parent, and there was no other apparent cause for fetal death; but it was arranged that the patient should be seen every few weeks during her pregnancy for observation and advice. During the early months treatment was directed to the alleviating of nausea, vomiting and constipation: a tonic pill of iron and quinine was given, and the patient was advised in matters of diet and personal hygiene.

Beginning at the end of the fourth month, chlorate of potash was prescribed in fifteen-grain doses three times a day. This drug was continued throughout the pregnancy, and the patient bore a large, healthy boy at full term. Whether or not the chlorate was the efficient cause in this happy result the reporter was unprepared to say. He used it on the recommendation of Prof. Simpson, of Edinburgh, and of others who had thought it efficacious in such cases in which intra-uterine death is thought to be due to non-specific disease of the placenta.

DR. EDW. REYNOLDS exhibited a specimen of

A CANCER OF THE BODY OF THE UTERUS
which he had removed by vaginal hysterectomy, and

said that the specimen was chiefly interesting in connection with the clinical history of the case. The patient sought relief for slight dyspepsia and some debility, and suspicion of the real lesion was only awakened by a routine inquiry suggested by her age, when it was discovered that although the menopause had occurred three years ago, she had twice, within the last six months, noticed a slight show of blood and was aware of disagreeable discharges, which were, however, so slight that she had not considered them worth mentioning. On examination, the vagina was found to be in a condition of marked senile atrophy and the vaginal portion of the cervix had disappeared. Abdominal and rectal examination, however, disclosed the existence of an extremely hard uterus, of rather more than the normal size, and retroverted, but freely movable. On examination under ether no involvement of the broad ligaments could be detected, and on the introduction of a curette the whole interior of the organ was found to be in a disorganized and pulpy condition.

Scrapings from the posterior wall was sent to the microscopic laboratory of the Harvard Medical School from which the following report was received:

"Microscopic examination shows a mass of epithelial cells invading the fibro-muscular tissue in all directions. Section seen by Drs. Fitz and Whitney, diagnosis, cancer."

The operation was rendered difficult by the extremely small size of the vagina, absence of the vaginal cervix, and the friable condition of the uterine body. The patient was but little collapsed after the operation and the convalescence was uncomplicated by any untoward symptom. Examination of the specimen showed no evidence that the disease had involved the external walls of the organ, and the case seemed to offer a fair prospect of radical cure.

— A characteristic circular letter has been issued by the minister of the interior in France, in which he proclaims that the attention of the government has on several occasions been called to the prevalence of puerperal fever in the practice of midwives. Thanks to the progress of science it is possible to trace these epidemics to the absence of antisepsis, which the midwives, not being physicians, officers of health or veterinary surgeons were by the law of 1846, forbidding the sale of poisons, unable to procure. After deliberation the government applied to the *Académie de Médecine* for advice. This august body replied that: (1) It was indispensable that midwives should be allowed to have antisepsics. (2) That to prevent accidents only one substance should be sold to them, preferably corrosive sublimate, in packets of uniform quantity. (3) That they should always have an antiseptic within reach. The committee on public hygiene concurred in the conclusions of the Academy. Backed by the advice of these two bodies, the president of France issued a proclamation that apothecaries are allowed to sell to registered midwives corrosive sublimate colored red, in packages of twenty-five centigrams, and an ointment containing one percent of the same substance. All prefects are ordered to publish this order and to impress on the midwives of their prefecture the necessity of antisepsis in midwifery.

THE BOSTON

MEDICAL AND SURGICAL JOURNAL.

THURSDAY, OCTOBER 30, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE RESPONSIBILITIES AND LEGAL DANGERS OF COTTAGE HOSPITALS.

COTTAGE Hospitals are becoming quite popular in communities not large enough for hospitals of different construction and management. Their blessings are obvious, but little is thought of their defects and dangers. At the recent railroad accident at Quincy, Mass., the hospital at that spot proved a great boon, as was abundantly recognized. But there are rumors to the effect that an obvious defect in the hospital was manifested in the want of a responsible head, and that little misunderstandings as to responsibility and duties did not become serious, simply because of mutual forbearance. It did show that serious difficulties may arise over the assignment of patients where there is no authority to assign, and that a system which works well where the requirements are simply those of everyday life may prove deficient when put to the test of extraordinary emergencies.

Another incident serves to emphasize the fact that the responsibilities of larger hospitals for the results of treatment are also attached to the cottage hospitals of smaller centres. An interesting suit for malpractice has recently been brought against the Newton Cottage Hospital of which the details are as follows:

The patient entered the Newton Cottage Hospital on November 24, 1888, as a charity patient, with a fracture of the tibia of the right leg at the external malleolus and with a compound comminuted fracture of both tibia and fibula at the junction of the middle and lower thirds of the left leg. The upper fragment of the fibula was thrust directly through the comminuted portion of the tibia and the skin on the inner aspect of the leg and even penetrated the trousers. The anterior tibial artery was also divided.

One of the surgeons was called and the patient was told of the severity of his accident. Under ether, the projecting bone was removed to the extent of half an inch (for in no other way could the fibula be replaced), the artery was tied, and a drainage-tube was inserted. The leg was then straightened, and placed on a posterior

Levis splint, and an anterior felt splint was applied. Careful antiseptic precautions were followed.

Patient and family were carefully instructed as to the danger to which the leg was exposed. However, the case did well. The right leg was finally put in plaster, and the result was very satisfactory.

The left leg, with its compound fracture, was the one which caused the subsequent trouble. There was no suppuration to speak of. The patient was delirious much of the time during the first week; but the leg was kept in good position without much difficulty. On the eighteenth day (December 12, 1888) it was placed in plaster, and it was straight (as affirmed by the defendants). A fenestrum was left in the plaster over the healing wound.

On January 1, 1889, the surgeon's service ended and the patient came under the care of another member of the staff. The second surgeon removed the plaster on February 20, 1889. He found a straight leg with a large callus over the site of fracture. He replaced the leg in plaster. At his own request the patient was sent home. Strict injunction was given him as to the care of the leg; and particularly was he told not to have the plaster removed by any one, other than one of the hospital staff and not earlier than May 1, 1889. He was also told by the second surgeon that some kind of support must be kept on his leg for months as the union was plastic and might remain so for a long time.

Notwithstanding this, the patient had the plaster removed by a fellow carpenter some time in April, 1889, and two weeks later returned to the hospital with the leg bent outwards at the seat of fracture.

Suit was brought by the patient against the surgeon who had charge of the case during the first five weeks, and against the second who had charge of the case for about three months, and against another practitioner who saw the case once in consultation. The damages claimed were \$20,000. After nearly a year's delay, the case was called, in the superior court at Cambridge, under Judge Dunbar. The plaintiff alleged that the left leg was never properly set, and that it was never straight. The plaintiff's wife, daughter, sister and fellow carpenter testified that they had seen the leg at various times during its treatment at the Newton Cottage Hospital, and that it was always crooked. After the case of the plaintiff was all in, the presiding judge directed the jury to find for the defendants, which they did without leaving their seats.

The case seems to have been treated with care, in full recognition of the grave character of the injuries, which were of so serious a nature as to make the preservation of the limb a doubtful matter; and the result, in the opinion of experts who examined the case, is a serviceable leg. In short we have the same old story, too often repeated, of a serious injury, in itself of such a character as to preclude a perfect result; months of care followed by recovery, with a leg which in view of the injury is, at least, no discredit to the surgeon, and as compared with the wooden leg which the patient should have expected, probably much more

serviceable; ingratitude on the part of the patient, who holds his doctor responsible for an imperfect result, when he should be grateful that his life has been preserved.

It is evident that cottage hospitals must be prepared to face ingratitude; and in planning for the establishment of such hospitals, proper provisions must be taken to meet the legal responsibilities incurred alike by small and large hospitals. It is doubtful if either doctor or charitable institution could be found that would desire to escape legal responsibility; but if the spirit that influenced the plaintiff in this case is general in our smaller cities, the time is not yet ripe for the general introduction of cottage hospitals.

SOME NEW CLINICAL EXPERIMENTS WITH DIURETIN.

KORITSCHONER has recently made numerous clinical trials at the Medical Clinic of Professor Schröter, of Vienna, with the new diuretic, *diuretin*, which is a mixture of sodium salicylate and theobromine. These experiments pertained to thirty-eight cases of general dropy. Ten of these were cases of cardiac dropy from chronic valvular disease; twelve were cases of dropy from Bright's disease in some stage; in six the general anasarca was due to dilatation of the heart following emphysema or arterio-sclerosis; in four the cause of the dropy was degeneration of the myocardium; in three it was hepatic cirrhosis; in two it was tuberculosia of the lung and serous membranes, and in one cancer of the liver.

The formula which Koritschoner uses is as follows:

Salicylate of soda and theobromine,	4 to 8 grammes.
Warm water,	" 150 " M.
Dose, a tablespoonful every hour or every two hours.	

Diuretin should be given in rather large doses; little benefit can be expected from less quantity than four grammes (sixty grains) a day; ordinarily to get the full advantage of the drug, medium doses amounting to five or six, and maximum doses amounting to eight or ten grammes, in the twenty-four hours should be administered.

Diuretin is generally well supported, even when its use is prolonged for months. It rarely causes nausea, even in chronic Bright's disease when the appetite is gone, and but little food is tolerated. It does not cause vertigo; in rare instances patients complain of palpitation and temporary cardiac distress. Sometimes diuretin provokes diarrhoea.

As a result of these trials by the Vienna physician, the salicylate of soda and theobromine was found to be a very powerful diuretic, and in only five cases did it prove to be without action; these were cases of chronic Bright's disease, arterio-sclerosis with fatty myocardium, tuberculosia of the lungs and serous membranes — all had arrived at the last degree of cachexia, and succumbed a few days after their admission to the hospital. In ten other cases, the action of the salt was much superior to that of digitalis, acetate of potash,

and all other diuretics that had been administered, though but moderate benefit followed the administration of the remedy. In the majority of the patients, (twenty-three out of thirty-eight), the effect obtained was excellent, the dropsical effusions rapidly disappeared, and general amelioration followed. There is even danger that under the influence of the abundant diuresis caused by the drug, the ascites and oedema may disappear so speedily as to cause dangerous collapse. On this account, Koritschoner urges that in cases of abundant effusions, the remedy should be given with considerable caution; he would, in fact, advise always to begin the treatment by a dosage of four grammes a day, and if this quantity makes no sensible increase in the urine, it may be augmented by one gramme a day till a sufficient result is obtained.

The diuretic action of this medicine is said to be more marked in cardiac dropsies than in renal or hepatic, yet it may render precious service in chronic Bright's disease. In fact, in this disease where all the ordinary diuretics are apt to fail, the quantity of urine excreted often becomes augmented five or six times under the influence of the salicylate of soda and theobromine. In some cases of Bright's disease, the remedy seems to exert its principal action on the intestines, producing an abundant serous diarrhoea, which in a very short time causes the oedema to disappear, without too great enfeeblement of the patient.

According to the researches of Schröder and Gram, the diuretic effect of the salicylate of soda and theobromine is due to the excitant action of the drug on the renal epithelium. As the epithelium is the principal seat of lesion in chronic parenchymatous nephritis, it might be feared that diuretin would be injurious in Bright's disease. The observations of Koritschoner show that this fear is not well founded, and that diuretin excites the renal functions without irritating the kidneys. Thus, in two cases of acute scarlatinous nephritis when Koritschoner gave diuretin in large doses, the patient recovered with astonishing rapidity, and without any complications. Under the influence of the medicament, the blood corpuscles and hyaline casts were seen from day to day to disappear from the urine. This same favorable action of diuretin on the nephritic processes has also been noted in chronic Bright's disease.¹

The new drug has not as yet—as far as we have been able to ascertain—been much introduced into this country, and as theobromine is very expensive, and as the cost of a drug is an important item in the economies of many physicians and their patients, it is doubtful whether many serious trials will be made with diuretin for some time to come.

—The French journals recommend, as a simple method of obtaining local anaesthesia of the skin, playing the contents of two or three syphons of soda-water upon the spot to be operated on. The anesthesia lasts about five minutes.

¹ Wiener Klin. Wochschr., September 25, 1890. Semaine Médicale, October 15, 1890.

BERI-BERI ON FISHING VESSELS FROM THE GRAND BANKS.

A SERIES of about twenty cases of probable beri-beri, eleven occurring in one vessel, is reported by Dr. W. S. Birge, of Provincetown, as having landed at that port, during the past week, from the fleet returning from the Grand Banks. The cases are similar to the series of seven, occurring in his practice, reported as originating at the same place a year ago, to which reference was made by Dr. James J. Putnam in a paper which appeared in the JOURNAL of September 11, 1890. These cases seem to be increasing, and are apparently due to the diminishing thoroughness with which some vessels are got ready for sea.

We hope to publish a full report of Dr. Birge's cases in an early issue.

MEDICAL NOTES.

—It is reported that the sum of \$100,000 having been raised for the purpose of founding a medical college in connection with the Johns Hopkins University, into which women would be admitted, and having been placed at the disposal of the university trustees, the latter have decided to invest the money, and when, through interest and other additions, it has reached \$500,000, it will be used for the purpose proposed.

—The Paris correspondent of the *Chronicles* states that Sister Rose Gertrude is about to return to Europe and resume her occupation as accountant in a Paris house of business. She will also, we are gravely informed, in the intervals of her employment, fill up her spare time by continuing "her researches for the cure of leprosy." What the young lady's qualifications may be for engaging in so difficult a branch of medicine, it is not easy to say; but that a question which has long engaged the attention of men fitted by laborious training for such pursuits, can be solved by a young-lady bookkeeper in her spare time, passes our capacity for believing.—*British Medical Journal*.

—The German Congress of midwives has decided to petition the Empress and the government to alter the official designation of a midwife from "Hebamme" to "Geburtsshelferin."

—The little island of Heligoland is an exceptional bit of territory in many respects, amongst others in this, that never in the recollection of the "oldest inhabitant" has it been the seat of professional jealousies. Why is it so favored? Because only one medical man (dentist, surgeon, general practitioner all in one) is to be found the length and breadth of the island. No sooner, however, had Germany taken possession of her new appanage than this delightful state of things seemed destined to come to an end. An announcement appeared in the *Heligoland Gazette*, stating that a second German M.D. would shortly take up his residence in the island. Of course, the Heligoland doctor was up in arms at once. He appealed to the new governor, quoting the Emperor William's dictum that the rights and privileges of the Heligo-

landers were to be respected and to remain unchanged "for the present," and the result is a decree leaving him in undisturbed possession of the sole right of practice in the island.

— At the meeting of the Michigan State Board of Health, at Lansing, October 14, 1890, the following preamble and resolutions were adopted :

Whereas, It is agreed by all classes of people that the public health would be much better protected if none but properly qualified persons were permitted to practice medicine, and thus to have in their keeping measures relative to life and death,

Resolved, That it is believed to be practicable, through judicious legislation, to so organize the present legal medical practitioners in Michigan, so that through representatives elected by themselves, they shall guard the entrance to the profession, by a preliminary examination of students, and a final examination of graduates of colleges and of proposed practitioners who come from other States, so that the entire medical profession of this State shall be united in the effort to improve the qualifications of its new members.

Resolved, That the secretary of this Board be directed to transmit a copy of the foregoing preamble and resolution to the chairman of the committees on public health in the Senate and House of Representatives in the State Legislature as soon as it is in session.

— The Lycoming (Pa.) Medical Society must treat its guests remarkably well. One of them writes to the *Sunbury Daily* as follows :

"Those of the Sunbury physicians who attended the Lycoming County Medical Society on Monday, will long remember the event as one of those profitable rests that come occasionally to make cheerful the routine meter of their trying and responsible experiences. There is something about the meeting together of an organized body of scientific physicians for the betterment of mankind that is impressive and august. Unhampered by any shackles; untrammeled by the ignorance of a bigoted past; unsworn to the sheening fatuous distorted into being by illusions of dreamers and fostered by nursed delusion, when an assembly of physicians meet to-day, conscious of their freedom, ready for the possible, and competent to meet the exigencies of rushing progress — be it to lace the smile of God's sunshine or to chain the essence of his storm-clouds to their purpose and assistance — they embosom all the sciences used by other men, weave them into the woof of their pristine intent, and, standing in closer communion with the Planner of them all than is possible for His other creatures, reflect them out again into intelligent channels to do good unto even 'the least of these' — the suffering and needy. It is thus that the lectures of Professor John B. Roberts, of Philadelphia, will bless the entire people of the West Branch Valley, when his brilliant suggestions are used in the work of his many admirers."

— We have received from a correspondent an account of the Sixteenth Annual Session of the Mississippi Valley Medical Association, which was held in Louisville, Ky., October 8th, 9th and 10th, 1890. The meeting was one of the largest and most successful of the many meetings of that character in the history of the Association. The physicians were entertained at a reception given by Drs. Yandell and Rob-

erts; a reception at the Galt House, followed by an elegant banquet; and a number of private dinners and entertainments. The visiting ladies had several entertainments arranged in their honor — receptions; an interesting excursion to the Blind Asylum, where a concert was given by the pupils; gymnastic exercises, etc. The social arrangements were admirable, and the Kentucky belles captured more than one bachelor doctor.

The address of Dr. John Wyeth on "The Medical Student" was a masterly effort, full of wit and wisdom. Professor Wyeth graduated at Louisville, and the citizens vied with the profession to do him honor. His operation of bloodless amputation of the hip-joint was witnessed by a large number of medical men and students at the Medical Department of the University of Louisville. Dr. Wyeth dwelt at length on the value of practical work in the acquisition of a knowledge of anatomy. He said he could shut his eyes and pick out the best men of the class by the sense of smell alone. It takes a sublime enthusiasm to enable one to forget the disgusting stench of decomposition in his efforts to master the magnificent labyrinth of bones and muscles, nerves, brain, arteries, veins and organs which you have brought here with you to-night. He favored two sessions of purely clinical didactic teaching and a third in which the instruction would be purely clinical. Too much time he thought was usually given to chemistry. For the practice of medicine, surgery, etc., a limited knowledge of the subject is all that is necessary, and that should be learned principally in the laboratory. Three months in actual practical pharmacy he thought would be of immense benefit to the student. The nearest approach to the ideal clinical training he considered to be service as interne in a large general hospital. Dr. Wyeth, who had his first medical practice in the mountains of Tennessee, Alabama, and the swamps of Arkansas, said that the Southern doctor could hold his own in the land of the golden calf. As proof he cited the names of Marion Sims, Emmett, Thomas, Metcalfe, Bozeman, Polk, Wiley, Gibney, Gray, Dew.

The Convention passed a unanimous vote thanking its officers for their very efficient and successful work in bringing the meeting to a successful termination. A report of the proceedings will be found on page 417 of the JOURNAL.

BOSTON AND NEW ENGLAND.

— At a dinner of the Beacon Society last Saturday Dr. S. H. Durgin spoke at length of the sanitary condition of Boston. Remarks were made by Dr. J. H. McCollom, Dr. J. C. Warren, and Professor Parker of the Institute of Technology.

— The British steamer *Arisaig* arrived at this port a few days ago from Havana in charge of the first mate, the captain having died of yellow fever last week during a heavy gale. The steamer was detained at quarantine and fumigated. The steward was also sick on board with fever, but is recovering.

— The captain of the whaling barque *Petrel*, indicted for neglecting to provide his seamen with anti-scorbutics, under the United States laws, was recently discharged from custody by Judge Nelson, not for want of evidence to convict, but because of a legal technicality. The judge said, that, much as he regretted to find that the seamen on our whaling vessels are without the protection that is given by law to other sailors, he must decide that the statute of 1874 having been repealed by the statute of 1878, it could not be revived by the statute of 1884. "We have to take the law as we find it," he said, "however unjust it may seem; and I can find no statute in force making it a criminal act for the captain of a whaling vessel not to carry anti-scorbutics. I must, therefore, instruct you, gentlemen of the jury, to find the prisoner not guilty."

— *Transcript.*

— The Mayor of Somerville expresses the utmost confidence that the necessary subscriptions to insure the proposed new city hospital of that city will be received by next week, or in ample time to take advantage of the special and conditional offer of \$10,000. At the time the last report was made, there were about \$3,000 to be raised.

— It is reported that an effort will be made during the present session of the Vermont legislature to incorporate various kinds of alleged medical colleges.

NEW YORK.

— The following officers were elected by the New York State Medical Association for the ensuing year: President, Dr. Stephen Smith, of New York; Vice Presidents, Drs. A. F. Van Vranken, of West Troy, J. D. Tripp, of Auburn, and R. J. Menzie, of Caledonia; Secretary, Dr. G. D. Ferguson, of Troy. Dr. J. H. Hinton refused to accept another nomination as Treasurer, and the position was left temporarily vacant.

— The Hospital Saturday and Sunday Association held its first meeting for the season on October 20th, at St. Luke's Hospital. A special committee, consisting of the Rev. G. S. Baker, the Rev. Thomas M. Peters, D.D., and Dr. Richard H. Derby, which had been empowered by the Association to offer prizes of \$100 and \$50, respectively, for the best and second best hymn suitable to be sung in the churches and synagogues on Hospital Sunday and Hospital Saturday, made their report, awarding the first prize to Miss Harriet McEwin Kimball, of Portsmouth, N. H., and the second prize to Miss Emily Vernon Clark, of New York.

— The first reception of what is known as the "Students' Movement" was given on Saturday evening, October 18th, at the Assembly Room of the Metropolitan Opera House, to the new members of the colleges and professional schools of the city. Eighteen institutions were represented by a large body of students, and addresses were made by Dr. Harry McCracken, of the University Medical School, Dr. F. D. Weisse, of the New York Dental College, Dr. A. A. Smith, of Bellevue Hospital Medical College, and others. On

the following evening there was a students' meeting at the same place, which was addressed by Prof. Wm. H. Thomson, of the University Medical School.

— The corner-stone of the new Children's Hospital at Albany was laid with suitable ceremonies on October 18th, by Bishop Wm. Croswell Doane. In 1879 this institution was established under the name of St. Margaret's Home, but for several years the accommodations have been inadequate for the work that has developed. The handsome new hospital, which is one of the charities connected with All Saints' Cathedral, is to cost \$50,000, and the plans are by Mr. Robert W. Gilson, the architect of the Cathedral.

— The fourth annual meeting of the New York State Medical Association was held at the Mott Memorial Hall on the 22d, 23d, and 24th of October, and was opened by the President, Dr. John G. Orton, of Binghamton, Broome County, in an address on "The Medical Profession as a Public Trust." A very large number of papers were read, and special features of the session were elaborate discussions on Intra-cranial Lesions and Obstetrics. The first embraced the means of locating intra-cranial lesions, the nature and discrimination of such lesions, the indications and contra-indications of operative interference, the best modes of operating, and the immediate and remote results of operative treatment. The discussion on Obstetrics embraced the more extended application of prophylactic measures, the management of labor and convalescence in accordance with sound physiological principles, the question of surgical interference in labor complications, and the question, What influence would a more advanced obstetrical science have on the biological and social conditions of the race? The JOURNAL will publish a report of the proceedings.

Miscellany.

PREGNANCY AFTER THE REMOVAL OF BOTH OVARIAS.

DR. J. ANDERSON ROBERTSON, in the *British Medical Journal* of September 27, 1890, reports the case of a woman, of twenty-three years of age, who menstruated regularly, and became pregnant nine months after the removal of both ovaries.

The patient was first seen on May 4, 1888. She began to menstruate at thirteen and one-half, and was regular (three or four days, quantity moderate, pain day before and on first day, occasional clots) until three years and a half ago, when she began to be irregular. From this time the quantity became less and less, and the length of time between the periods became greater until September 14, 1887, since which date she has not menstruated. The pain during these three years and a half has continuously increased in strength and duration until now, when, she says, "I am never free from it." It extends from both ovarian regions round to the top of the sacrum, and is always worst in the left ovarian region. For some time past, the patient has been "spitting blood every day"; at times merely a trace, but occasionally as much as

"three tablespoonfuls" of bright red blood. Constant leucorrhœa; bowels loose; micturition normal. Patient is a warehouse girl, and has to support a younger brother and sister; but latterly has not been able to work regularly. She is pale and ill-looking, and very thin.

On examination both ovaries were found to be enlarged and very tender. As some of patient's friends objected to surgical interference, medicinal treatment was again tried.

In January, 1889, patient came back, saying that she was quite unfit for work, and that she would rather die than live in such constant pain and misery. Her friends were now willing to have anything done, and agreed to the utter futility of further treatment by medicines.

On January 29th, both ovaries were removed. The left was much enlarged and cystic. The right was also considerably enlarged, with the capsule much thickened, affording evidence of a long-continued ovaritis. The patient made an uninterrupted recovery. Her temperature never rose above normal, and her pulse was only once above 80, namely, on the evening of the day after operation, when it reached 90. She rapidly improved in health and appearance; the pain entirely ceased, as did also the "spitting up" of blood; and she soon got plump and well-looking.

On April 25th she began to menstruate (four days, quantity moderate, no pain). Normal and painless menstruation for a like period again took place in May, and continued regularly until October. In June she married, and in September was looking strong and well, and feeling, as she said, "better than I have been for years; indeed, I am quite well and happy." She ceased menstruating on October 25th; and on August 13th, 1890, was confined. The child (a male) was twenty-four inches long, and weighed nearly ten pounds. The labor — a difficult and protracted one — had to be terminated by the aid of forceps, and the child, unfortunately, was stillborn. The mother is doing well.

From this very interesting case the author emphasizes the following facts:

"(1) The truth of Mr. Lawson Tait's teaching regarding the starting point of menstruation, namely, that the ovaries are not causative of it. In fact, in this case the presence of the diseased ovaries prevented it, and when they were removed normal menstruation followed.

"(2) The possibility of vicarious menstruation. The woman had brought up blood daily for months, but this ceased after removal of the ovaries, that is, when normal menstruation became possible, and it has not recurred.

"(3) The proof that removal of both ovaries does not necessarily render a woman impotent. (An interesting medico-legal discussion might be raised on this point.) I was not aware of leaving any ovarian tissue. Indeed, my aim was to extirpate the ovaries thoroughly, and I thought I had done so. I suspect, however, that a small portion of healthy ovarian tissue had reached up to or beyond the hilus of the right ovary, and that this may have taken on regular ovarian functions. This, of course, is merely conjecture.

"(4) That in performing double oophorectomy, excepting in cases of uterine fibroid, any apparently healthy portion may perhaps be left. I shall, at all events, keep this in mind in future operations."

THE POISON OF BACILLI.

BRIEGER and Fraenkel¹ have successfully isolated and studied the poisonous substance formed by the action of certain bacteria. Without describing their biological or clinical work, it is sufficient to say that the substances so isolated from cultures of bacilli from, for instance, twenty-two cases of diphtheria, produced the same general toxic symptoms as are found in the disease. The formation of a membrane is seen only in the presence of the bacteria themselves. This poison is chemically an albuminoid substance similar to serum albumin. Similar poisons are produced by other bacteria, noticeably those of typhus, cholera and tetanus, and are called by the authors toxalbumin. They differ somewhat from each other in their solubility in water, and probably in their toxic action. They are similar to certain animal poisons, such as that obtained from the cobra. When a culture of bacilli has become physiologically inert, it is found that this poisonous albumin has given place to a similar one which is non-poisonous.

Correspondence.

UNNECESSARY NOISE AN AVOIDABLE EVIL IN CITIES.

BOSTON, October 25, 1890.

MR. EDITOR: — Any one who is familiar with the novels, or with some of the histories of the last century, knows how horribly dirty were its large cities, how offensive to smell, and dangerous to health. The farther back one goes, the worse becomes the record of filth; but by the eighteenth century, at least, there is evidence that the advantage of "pure country air" was recognized; and by to-day, the best cared for cities are much more decent and salubrious than quite small places where less care exists. Although a thinly settled community produces less dirt than a thickly massed one, yet it is possible, by care, in avoiding what is not necessary, to reverse the natural conditions, and the advantage being recognized this care is sometimes taken.

With regard to noise, the conditions are different, different, as I believe, only in that the nuisance and harm are not recognized, alike in that much of the noise that attends the concentration of mankind in large cities is avoidable, and also alike in that it is often a nuisance and sometimes a danger. It is true that the nuisance and danger are not very much recognized as yet by the community at large; but it is also probably true that the Saxon Englishman thought his more refined Norman conqueror needlessly fastidious, when he ordered citizens to cry "garder l'eau," before emptying slops into the streets from upper windows. The world moves, and most of us to-day would probably sympathize with the lawgivers of that age, rather than with those who made the law necessary; so I hope that the world will keep on moving until such quiet, as it is reasonably easy to get, shall be recognized as the right of those citizens who want it.

Within a few years the Providence Railroad regularly waked up all the poor sleepers of the South End with three or four prolonged whistles, as the New York night train approached the Albany crossing. This was supposed, if I remember, to guard against collision, but combined action on the part of some of the distressed caused the whistling to stop, and I believe there has been no collision in consequence. Our horse-cars, however, have for a generation jingled a bell for six days out of seven, to give warning that they were coming, while, for about the same time, it has been proved on one day of every week that the

¹ Berliner Klin. Wochenschrift, No. 11, 1890, and Centralblatt f. Klin. Med., No. 36, 1890.

warning was not needed. How many sick people has that jingle kept awake on summer nights? The horse-cars are going. The electric-cars are coming. Is their gong needed at night? A gong is certainly noisy. It is to many ears an especially irritating noise, and one would think that a car, which when at speed can be heard for one or two blocks away, does not need any extra noise to make its presence known. It is probable enough that we might get rid of it were the case properly stated to the company. Our milk wagons commonly use a loose box, allowing the wheels to rattle like an old-fashioned stage coach, and making ten times the noise of hack wheels. They pass through the streets when most of us are asleep, and I myself am wakened by them many times in every month. It would not cost much to supply them with noiseless boxes, but it will not be done until public opinion demands it. Peddlars crying their wares are entirely unnecessary. If they serve as a check on the prices of stores, it would still be quite possible to make known one's wants of them by cards in the windows, as is done in some neighborhoods for ice men.

Yet these same hucksters are a torture to invalids with aching heads. In one German town I know that the buglers of the garrison were, a few years ago, obliged to do their practising on an island about two miles from the city, and I have been told that in at least two others piano practise is illegal, except between definite hours. That law would be a blessing to many an invalid, if it could be enforced here during the months of open windows.

The readers of a medical journal probably do not need to be reminded of the nuisance to all and the occasional great distress and danger to the sick from one or another of these causes, but perhaps we do not all appreciate the ease with which relief can be got, as soon as the community chooses to do so. The Board of Health would seem to be a proper body to systematically set about the work, and it is, to my mind, a duty which we owe to our families and our patients, to quietly do our part in creating a sentiment that would warrant a Board of Health in attacking this evil.

Very truly yours,

EDWARD M. BUCKINGHAM, M.D.

REPORTED MORTALITY FOR THE WEEK ENDING OCTOBER 18, 1890.

Deaths reported 2,744; under five years of age 858: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 478, consumption 290, acute lung diseases 261, diarrhoeal diseases 155, diphtheria and croup 126, typhoid fever 87, whooping-cough 35, malarial fever 29, scarlet fever 22, cerebro-spinal meningitis 11, measles 8, puerperal fever 3, erysipelas 2.

From whooping-cough: Brooklyn 10, New York 6, Baltimore 4, Chicago 3, Philadelphia, New Orleans and Springfield 2 each, St. Louis, Boston, Charleston, Lawrence, Fitchburg and Quincy 1 each. From malarial fever: New Orleans 9, New York 8, Baltimore 5, Brooklyn 4, Philadelphia 2, Charleston 1. From scarlet fever: Brooklyn 7, New York, Chicago and Philadelphia 4 each, Washington, Lynn and Fitchburg 1 each. From cerebro-spinal meningitis: Washington 3, Chicago and Brooklyn 2 each,

New York, Baltimore, Cincinnati and Lynn 1 each. From measles: New York 1, Chicago 1. From puerperal fever: Washington 2, Springfield 1. From erysipelas: Boston and Fall River 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,559, for the week ending October 4th, the death-rate was 19.3. Deaths reported 3,590: infants under one year of age 1,173, acute diseases of the respiratory organs (London) 362, diarrhoea 371, measles 74, scarlet fever 61, fever 58, diphtheria 49, whooping-cough 40.

The death-rate ranged from 10.3 in Derby to 34.3 in Preston, Birmingham 16.7, Bradford 23.1, Hull 18.8, Leeds 19.9, Leicester 15.5, Liverpool 22.0, London 16.7 Manchester 30.6, Nottingham 18.7, Sheffield 25.6, Sunderland 26.0.

In Edinburgh 19.0, Glasgow 19.1, Dublin 19.4.

The meteorological record for the week ending Oct. 18, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending	Barom. eter.	Thermometer.			Relative Humidity.		Direction of Wind.		Velocity of Wind.		State of Weather.*		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 18, 1890, TO OCTOBER 24, 1890.

Leave of absence for one month, on surgeon's certificate of disability, is granted Assistant Surgeon N. S. Jarvis, S. O. 167, Department of Arizona, October 14, 1890.

By direction of the Secretary of War, leave of absence for four months is granted Captain James E. Pilcher, assistant surgeon. S. O. 244, Par. 12, A. G. O., October 18, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 25, 1890.

F. J. B. CORDEIRO, passed assistant surgeon, detached from U. S. S. "Nipic," and granted three months' leave of absence.

A. C. HEFFENGER, passed assistant surgeon, placed on the retired list October 20, 1890.

SOCIETY NOTICES.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY. — There will be a Meeting of this Section at 19 Boylston Place, on Wednesday evening, November 5th, at 8 o'clock.

Communications: Dr. R. W. Lovett, "Hydrocele in Children, with a Report of Cases." Drs. E. G. Cutler and M. H. Richardson, "A Case of Digital Dilatation of the Pylorus for Cicatrical Stenosis." GEORGE H. MORRIS, M.D., *Secretary.*

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting of the Society will be held at 19 Boylston Place, on Monday evening, November 3d, at 8 o'clock.

Readers: Dr. Joseph Sedgwick, "Cerebral Tumors with Clinical Cases." Dr. F. E. Bundy, "A Report of Two Cases of Diphtheria." T. F. SHERMAN, M.D., *Secretary.*

OBITUARY. CHARLES EDWARD SPRING, M.D., M.M.S.S.

Dr. Charles Edward Spring, of Holliston, Mass., died on Saturday, October 25, 1890. He was born in Grafton, Vt., March 19, 1842, and graduated from the Albany Medical College in 1865, serving as assistant surgeon in the army in 1866. He practiced in Jamaica, Vt., until 1874, when he removed to Holliston. He served as Representative to the General Court in 1888 and 1889.

BOOKS AND PAMPHLETS RECEIVED.

Paraneuric Cysts. By Robert Abbe, M.D. Reprint. 1890. The Medical News Visiting List for 1891. Philadelphia: Lea Brothers & Co.

Homonymous Hemispheric Hallucinations. By Frederick Peterson, M.D., New York. Reprint. 1890.

Abstract of the Health Laws of the State of Maine. Compiled by the State Board of Health. 1890.

Latin as a Compulsory Qualification in the Medical Student's Preparatory Education. By A. J. Howe, M.D.

A Rare Form of Intestinal Strangulation by a Band. By Robert Abbe, M.D., Surgeon to St. Luke's Hospital, etc. Reprint. 1890.

Text-Book of Materia Medica for Nurses. Compiled by Lavinia L. Dock. New York and London: G. P. Putnam's Sons. 1890.

The Medical Student's Manual of Chemistry. By R. A. Wittman, A.M., M.D., etc. Third edition. New York: William Wood & Co. 1890.

A Manual of the Practice of Medicine. By Frederick Taylor, M.D., F.R.C.P. With illustrations. Philadelphia: P. Blakiston, Son & Co. 1890.

Diagnosis and Operative Treatment of Gunshot Wounds of the Stomach and Intestines. By N. Senn, M.D., Ph.D., of Milwaukee, Wis. Reprint. 1890.

Progressive Exercises in Practical Chemistry. By Henry Lehmann, M.D., Ph.D.; and William Bean, M.A. Illustrated. Philadelphia: P. Blakiston, Son & Co. 1890.

The Latin Grammar of Pharmacy and Medicine. By D. H. Robinson, Ph.D., with an Introduction by L. E. Sayre, Ph.G. Philadelphia: P. Blakiston, Son & Co. 1890.

Functional Albinismus; or, Albinismus in Persons Apparently Healthy. By William B. Davis, A.M., M.D., of Cincinnati. Cincinnati: Robert Clarke & Co. 1890.

A Compend of Human Anatomy, including the Anatomy of the Viscera. By Samuel O. L. Potter, M.A., M.D. Fifth edition. Philadelphia: P. Blakiston, Son & Co. 1890.

The Treatment of Syphilis of the Nervous System. Read before the International Medical Congress at Berlin, August, 1890. By Julius Althaus, M.D., M.R.C.P. London: Longmans, Green & Co. 1890.

Proceedings of the National Conference of State Boards of Health at the Seventh Annual Meeting held at Nashville, Tenn., May 19-20, 1890. Published for the State Board of Health of Pennsylvania.

Diagnosis of the Eye. By Edward Nettingship, F.R.C.S., etc. Fourth American from Fifth English Edition, with a Chapter on Examination for Color-Perception. By William Thompson, M.D., etc. Philadelphia: Lea Brothers & Co. 1890.

The Actions of Drugs which are Believed to Conserve the Tissues: Alcohol, Tea, Coffee, Coca, Maté, Kola, Guarana, Hemp, Tobacco, Opium, etc. By Edward T. Reichert, M.D., Professor of Physiology, University of Pennsylvania. Reprint. 1890.

Saunders' Pocket Medical Lexicon; being a Dictionary of Terms and Terms used in Medicine and Surgery. By John M. Keating, M.D., Fellow College of Physicians of Philadelphia, etc., and Henry Hamilton. Philadelphia: W. B. Saunders. 1890.

A Treatise on the Diseases of Infancy and Childhood. By J. Lewis Smith, M.D., Clinical Professor of Diseases of Children, Bellevue Hospital Medical College, etc. Seventh edition, thoroughly revised, with fifty-one illustrations. Philadelphia: Lea Brothers & Co. 1890.

Saunders' Question Compend of Essentials of Practice of Medicine. Arranged in the Form of Questions and Answers, Prepared Especially for Students of Medicine. By Henry Morris, M.D., etc. With a very complete appendix on the Examination of Urine. By Lawrence Wolff, M.D. Philadelphia: W. B. Saunders. 1890.

Ointments and Ointments Especially in Diseases of the Skin. By John V. Shoemaker, A.M., M.D., Professor of Materia Medica, Pharmacology, Therapeutics and Clinical Medicine, and Clinical Professor of Diseases of the Skin in the Medico-Chirurgical College of Philadelphia, etc. Second edition, revised and enlarged. Philadelphia and London: F. A. Davis. 1890.

Original Articles.**CASE OF SARCOMA OF THE TONSIL REMOVED BY EXTERNAL INCISION: RECOVERY.**

BY JOHN HOMANS, M.D.,
Surgeon to the Massachusetts General Hospital.

Mrs. H. L., age fifty-nine, entered the Massachusetts General Hospital May 30, 1890. About eighteen months before entrance she noticed swelling and ulceration of the right tonsil, which subsided under treatment. A few months later, the swelling again returned and ulceration again disappeared. In February, 1890, the tonsil again increased in size and, as she says, "pressed farther into the throat, and she had a nervous feeling extending over the gums and jaw." Thinking this trouble might come from the teeth, she had them all removed, a proceeding which much facilitated the subsequent operation. She had no real difficulty in swallowing, but the passage of food through the pharynx was uncomfortable. In the Out-Patient Department for Diseases of the Throat, on May 20th, Dr. Langmaid cut off half the tonsil with a tonsillotome, and sent the part removed to Dr. Whitley, the Pathologist to the Hospital, who reported as follows :

"Of tonsil. Harriet L. An irregularly lobulated growth, homogeneous and medullary looking on the section surface. Microscopic examination showed a structure of relatively large round cells with fine fibrillated intercellular substance replacing the normal tonsil structure. In places there were relatively dense bands of fibrous tissue traversing the growth irregularly. The diagnosis is a round cell sarcoma."

The growth soon reappeared, and Dr. Langmaid sent the patient into the house for more radical treatment. The right tonsil was now enlarged to about twice the size of the left : it was not inflamed : projecting from its centre was a soft, red mass of about the size and color of a wild strawberry, and shaped like a pineapple.

On June 6, 1890, an incision was made two and a half inches long from the right side of the hyoid bone to the mastoid process. The fascia were divided one after another, the edge of the parotid was pushed upward, and the submaxillary gland with the tendon of the digastric muscle downward. With the point of a director, the constrictor of the pharynx and the mucous membrane in front of the tonsil were torn through. Scissors were used in the mouth to divide the pillars of the palate and the mucous membrane around the tonsil. Forceps were then introduced through the wound in the neck and the loosened tonsil pulled outward while its attachments, which were on the stretch, were divided by scissors introduced through the mouth. Only two small vessels required ligatures, a superficial branch of the facial, and a small artery in the soft palate. The split in the pharynx, which was about two and a half inches long, was united by a continuous silk suture, and a quill drainage-tube was introduced through the external wound. Dry iodoform gauze with compression was applied over the wound in the neck. The complete absence of fat and of teeth in a thin, but tough and wiry subject, made the operation extremely simple.

June 7th. Reports a comfortable night. She had

a mouth-wash of permanganate of potash, and was fed solely by nutrient enemata every four hours.

June 8th. Considerable swelling in the right pharynx, but no great discomfort.

June 9th. Took three ounces of milk every two hours, and swallowed well. The swelling in the pharynx had much diminished.

June 10th. External wound united by first intention, but little swelling; drainage-tube removed.

June 15th. Patient was up and dressed.

June 20th. The stitch in the pharynx was easily removed and the patient was discharged well.

Perhaps this operation ought to be called "Removal of the tonsil by the combined method of external and internal incision."

In 1863, Dr. David W. Cheever of Boston, Professor of Surgery in Harvard College, removed a malignant tumor of the tonsil by cutting down on it from outside the neck and opening the pharynx. So far as he could then learn, the operation was original. Subsequently, several treatises on surgery, such as Bryant's, Gross's, and others, sustained his belief that the operation had not been performed before. Dr. Cheever found later that Dr. Hueter states in the *Jahresbericht der gesammten Medicin* for 1869, that he saw Von Langenbeck operate externally and by sawing the jaw, in 1865, and that he himself performed a similar operation in the same year. Both were cases of sarcoma. Langenbeck's recovered; Hueter's died. In 1878, nine years later, Dr. Cheever operated again. In 1886, Dr. M. H. Richardson operated at the Massachusetts General Hospital, successfully, by external incision. The growth was a round-celled sarcoma. The patient recovered rapidly, and has remained well ever since. This case is reported at length in Vol. CXVIII, *Boston Medical and Surgical Journal*, February 23, 1888.

From what has been written on this subject it is evident that the prognosis of cases of removal of the tonsil is much more favorable for sarcoma than for cancer. Dr. Richardson's case and my own were cases of sarcoma, and in neither of them has there as yet been any recurrence. Dr. Richardson's patient has been well for four and a half years, and may be considered cured, but only five months has elapsed since the operation in the present case.

In order to be certain of the patient's present condition, I went to Stoughton, where she lives, and found her in excellent health. There was a firm linear cicatrix externally and in the pharynx, but no sign of return of the growth.

Butlin gives twenty-three cases of removal of tumors of the tonsil ; of these ten were operated on by external incision, and thirteen from within the mouth ; two of the former proved fatal, and one of the latter. Richardson's case and my own make the number twenty-five — twelve by external incision and thirteen from within the mouth. One case (Mr. Barker's, quoted by Butlin) was well a year after the operation. One by Dr. Gorecki (quoted by the same author) was alive and well two years later. One by Butlin himself was well four months after operation. Dr. Richardson's case is well four and a half years after operation, and mine shows not the slightest tendency to return after five months.

All these were cases of sarcoma, the other twenty cases, mostly, I presume, cancer, are all dead. So far as I know there is not a single cure of cancer of

the tonsil by operation. I think that Mr. Butlin's conclusion, that "removal of the disease through an external incision (pharyngotomy) has hitherto proved a dangerous proceeding, and has not yielded as good results as operation through the open mouth," should be qualified, for of these five recoveries, two were cases of external incision, and as the whole number is only five, there must be three of one kind and two of the other. I am, however, free to say that my patient might perfectly well have been operated upon through the mouth, but I chose the external method because I thought I could get more room, and control hemorrhage easier, and remove a healthy margin with more boldness.

In conclusion I desire to express my thanks to Mr. Butlin for the article he has written on the tonsil, as well as the obligations I am under to him for what I have learned from his work on "The Operative Surgery of Malignant Disease," one of the most thoroughly satisfactory books that well-applied observation has ever given us.

THE VALUE OF "PRIMARY ANÆSTHESIA" IN MINOR SURGICAL OPERATIONS.¹

BY F. D. HARRINGTON, M.D.,
Surgeon to Out-Patients at the Massachusetts General Hospital, Assistant in Clinical Surgery in the Harvard Medical School.

In every out-patient surgical department there is a large number of minor operations which must be performed in that department, both because of the lack of hospital accommodations and because the patient desires to go home and can be allowed to do so with safety. There are two important reasons why operation without anesthesia is undesirable. First, because it gives unnecessary pain; and second, because the operation is likely to be less perfect and less thorough.

Nitrous oxide is rapid and safe, but the duration of its effect is so short that it is not desirable for minor surgical operations. Chloroform I have never used either for brief or prolonged anesthesia. Cocaine is of great value in many cases, but it is not without danger and it not infrequently fails.

Profound ether anesthesia is not desirable for the work for several reasons. It requires much time and previous preparation of the patient. The recovery is tedious, often requiring many hours. Nausea and vomiting are not infrequently greatly prolonged.

The rapidity of the appearance and disappearance of the anesthetic effect of ether first struck me during its use for the pains of child-birth. It is here that the woman feeling the approach of the pains, seizes the sponge and with a few rapid breaths is almost completely relieved of her pain. Her consciousness returns immediately if the ether is judiciously used.

Making use of this "primary anesthesia," as it has been called, I have operated on several hundred patients during the last three years. I have never seen any ill effects from the use of ether in this way.

During a portion of last year's service I tabulated forty successive cases with the following results: thirty-five successful, three partially successfully, two failures. By failure I mean that the patient felt the operation,

and complained of the pain, either at the time or afterward.²

The method of procedure which I have adopted is about as follows: As far as is possible in a short time, the confidence of the patient is gained. They are told that a few breaths will make them insensible to pain and that in a few minutes they will be in a condition to go home. Women and children are, as a rule, less alarmed if they are allowed to inhale the ether in a sitting posture. The effort of keeping erect takes the attention and the position is less suggestive of complete helplessness. This is not a desirable position for strong men unless they are held in by a strap. It is well always to have assistants at hand, although a large number of cases might easily be handled alone. An ounce or more of ether is poured on a sponge or towel. This is given to the patient with directions to breathe rapidly and deeply.

It is important to teach the patient how he is to breathe before applying the ether. I tell them to breathe as a dog pants. The rapid and moderately deep breath I think is the best one, not only for rapid primary anesthesia, but also for the induction of profound anesthesia. It is a well-known fact that rapid breathing of air itself produces a certain degree of anesthesia. Another reason for rapid breathing is that there is a tendency to continue any muscular act in an automatic way after consciousness of the act has ceased. We see this in the repeated use of certain words or phrases, or the continuance of a motion of the leg or arm. I often see patients wholly unconscious of pain breathing at the rate of forty per minute the impulse to such breathing having been given during consciousness.

The tendency is naturally toward slow breathing and much more time is required if the breathing be slow. The sponge should be held a short distance from the face and should not cause coughing.

Everything should be in readiness for the operation. After a dozen or more rapid breaths I ask the patient if he is ready. The reply is usually "No." This question is constantly repeated until the patient says "Yes," or until there is no response. If the operation is merely a single incision or one with little exploration, the ether is at once removed. If more time is required the ether should be kept applied. The duration of insensibility to pain is from twenty seconds upward.

Vomiting rarely occurs. It never occurs unless profound anesthesia is approached. I have had two patients who said that they vomited after reaching their homes. The pupils are not affected. The pulse is slightly accelerated.

Patients are, almost without exception, pleased with the action of the ether. An intelligent patient with good control of himself makes the best subject for rapid anesthesia.

It is an undoubted fact that more ether is used by surgeons than is necessary. The dread which many patients have a second time is often only fear of the distressing "coming out." It is, of course, very convenient for the surgeon to have his patient profoundly etherized, but the loss to the patient may be great, both in comfort and in strength. Often profound anesthesia cannot be avoided; sometimes it may.

¹ Read before the Boston Society for Medical Improvement, October 13, 1890.

² In the table, under the head of "Inhalations" the "number" and "time" refer to the number of inhalations and the time required before insensibility was produced.

No.	Name.	Sex.	Age.	Operation.	Frame of Mind.	Position.	Inhalations.	Period of Insensibility.	Remarks.	Result.
							No.	Time.		
1	N. F.	F	24	Needle in finger.	Willing.	Sitting.	73	2½ m.	1 m.	Needle found. Got up and walked.
2	M. D.	F	31	Needle in finger.	Willing.	Sitting.	26	45 s.	45 s.	Got up and walked immediately.
3	A. L.	F	23	Felon.	Unwilling.	Sitting.	61	4½ m.	..	Cried and struggled.
4	M. S.	F	7	Fracture of external condyle into joint. Examination.	Willing.	Sitting.	..	7 m.	2 m.	Arm examined and put into splints.
5	T. H.	F	53	Adhesion of knee ankylosis.	Willing.	Sitting.	33	110 s.	70 s.	Patient had before taken ether very frequently. No bad effect. Went out immediately.
6	M. H.	F	21	Felon.	Timid.	Sitting.	27	160 s.	30 s.	On coming to consciousness cried, but not from pain.
7	A. D. See No. 9	F	21	Felon.	Reluctant.	Sitting.	..	4 m.	..	Made an outcry when cut. On the following day said the ether helped her.
8	E. H.	F	30	Curetting tuberculous sinus.	Reluctant.	Sitting.	30	2 m.	5 m.	A thorough curetting.
9	A. D. See No. 7	F	21	Removal of necrosed phalanx.	Willing.	Sitting.	50	3 m.	6 m.	Second etherization. Went home ten minutes later.
10	R. R.	F	35	Abscess of breast.	Unwilling.	Sitting.	..	70 s.	..	Ab'e to walk in three minutes.
11	L. A.	F	35	Perineal abscess.	Timid.	Reclining.	20	65 s.	3 m.	Drew away a little when the cut was made, but had no recollection of pain. Came out at once.
12	N. J.	F	18	Alveolar abscess.	Fearful.	Sitting.	Began at once to cry and push away sponge. An incision was made which gave pain.
13	A. M.	F	24	Deep abscess of breast.	Timid.	Sitting.	28	90 s.	2 m.	On returning to consciousness complained of feeling weak. This passed off quickly.
14	N. C.	F	20	Cheesy gland of neck.	Willing.	Sitting.	29	85 s.	3 m.	Gland thoroughly curedtted.
15	A. P.	F	17	Abscess of neck.	Willing.	Sitting.	20	35 s.	1 m.	Went away immediately.
16	M. T.	F	15	Felon.	Willing.	Sitting.	25	45 s.	1½ m.	Nail removed, and deep incision.
17	J. S.	F	66	Impacted Colles' fracture.	Willing.	Sitting.	58	110 s.	..	The patient was perfectly relaxed.
18	E. F.	F	60	Colles' fracture.	Willing.	Sitting.	6	20 s.	35 s.	Conscious, but felt no pain.
19	D. W.	F	39	Tubercular glands.	Timid.	Sitting.	29	67 s.	105 s.	Thoroughly curedtted and packed.
20	M. S.	F	28	Axillary abscess.	Willing.	Sitting.	37	70 s.	2½ m.	..
21	J. P.	F	31	Felon.	Fearful.	Sitting.	47	150 s.	80 s.	There was a stage of excitement after a few breaths. No pain.
22	A. S.	F	17	Axillary abscess.	Willing.	Sitting.	35	90 s.
23	M. H.	F	23	Felon.	Willing.	Sitting.	34	45 s.
24	S. E. S.	M	25	Removal of necrosed phalanx.	Willing.	Reclining.	80	..	2½ m.	..
25	W. A.	M	20	Abscess of ankle.	Willing.	Reclining.	30	..	1½ m.	..
26	J. G.	M	23	Felon.	Willing.	Reclining.	37	..	3½ m.	The felon was incised and curedtted.
27	J. Q.	M	Adult	Inflamed bursa.	Willing.	Reclining.	..	2 m.	2 m.	Incised and curedtted.
28	S. S.	M	Adult	Felon.	Willing.	Reclining.	..	1½ m.	3 m.	Noisy on coming out. Quickly quieted.
29	W. L. S.	M	Adult	Foreign body in palm.	Willing.	Reclining.	12	60 s.	1 m.	If the search had not been quickly discontinued, the period of anesthesia might have been easily prolonged.
30	M. P.	M	Adult	Felon.	Willing.	Reclining.	18	15 s.	50 s.	The patient breathed rapidly and became unconscious very rapidly. No pain. Recovery in fifteen seconds after the removal of the ether.
31	J. M.	M	16	Felon.	Fearful.	Reclining.	32	2 m.	3 m.	The patient was deaf and dumb.
32	J. H.	M	15	Amputation of finger.	Willing.	Reclining.	48	1½ m.	2½ m.	The amputation required one minute. There was no pain, and the boy walked out as soon as the dressing could be finished.
33	M. J.	M	7	Felon.	Willing.	Sitting.	12	45 s.	2½ m.	Perfectly quiet. Recovered at once.
34	W. M.	M	27	Obscure injury to wrist.	Reluctant.	Reclining.	26	1½ m.	2½ m.	Felt sleepy, and was nauseated for half an hour. Struggled a good deal, and into pain.
35	J. M.	M	..	Abscess of hand.	Willing.	Reclining.	12	30 s.	..	A quick incision was made, and the operation was over in thirty-five seconds from the beginning of the etherization.
36	B. F. B.	M	19	Felon.	Willing.	Reclining.	17	30 s.	..	The operation was over in forty seconds, after twenty inspirations had been taken.
37	F. N.	M	33	Colles' fracture.	Willing.	Reclining.	The fracture was reduced in forty-five seconds from the beginning of the etherization. The patient struggled, but was conscious of no pain afterward.
38	S. B. J.	M	24	Alveolar abscess.	Willing.	Sitting.	16	30 s.	..	The patient was conscious of the cut, and struggled a little. No real pain.
39	P.	F	50	Colles' fracture.	Willing.	Reclining.	25	1½ m.	2 m.	Immediate recovery.
40	S.	M	35	Felon.	Reluctant.	Reclining.	44	2½ m.	1 m.	The patient began to move the legs regularly and to feel pain. Remembered the cut, but did not feel pain.

A DETERMINATION OF THE MUSCULAR STRENGTH OF GROWING GIRLS AND ITS RELATION TO THE ETIOLOGY, TREATMENT AND PROGNOSIS OF CASES OF LATERAL CURVATURE OF THE SPINE.¹

BY CHARLES L. SCUDER, M.D., BOSTON.

In order that the surgeon may treat each case of lateral spinal curvature intelligently, and that scientific data may be accumulated by which a study of the etiology of this disease may be furthered, greater precision and a more extended observation is demanded in the recording of such cases. Hitherto careless methods or no method at all have been used. A rough sketch, a photograph, a general impression have served as records; or after Mr. Roth of London, a tracing has been made of the rotation present. In all the past the object has been, in making these records, simply to have a rough guide as to the progress of the disease. Instruments of more or less precision are now being used by a few in the study of these cases. It is in this direction, rather than in any other, that we must look for progress, in our knowledge of lateral curvature.

The value of most statements, hitherto, upon the muscular element in the etiology has been greatly lessened by an entire absence of carefully recorded facts. The muscular theories have been numerous. The following are the views held by a few:

Guerin attributed lateral curvature to active muscular contraction. The muscles on the concave side of a curvature are actively contracted, and become permanently fixed in this position.

Malgaigne taught that lax ligaments and weakened muscles form the predisposing causes to spinal curvature.

Bernard Roth² thinks that lateral curvature is predisposed to by weakness of the spinal muscles, combined with long-continued sitting or standing in stooping or relaxed positions. He has observed an inherited weakness of muscles and ligaments, associated probably with excessive softness of bones. He writes, "anything which weakens the muscular system tends to produce lateral curvature."

Adams³ believes that in the early stage of lateral curvature the spinal muscles on both sides are, as a general rule, decidedly passive; but that as the curvature advances, the muscles on the convexity are called into increased action and serve the purpose of limiting the extent and preventing the increase of the spinal curvature.

Dr. L. A. Sayre⁴ believes that rotary lateral curvature depends entirely upon abnormal muscular contraction. The spinal column is held in its normal position by the contractions of muscles situated upon either side of it, which should exactly balance each other. If, for any reason, one set of muscles overcomes the set upon the opposite side, the spine yields and a curve is produced with its concavity toward the side upon which the stronger set of muscles is situated. Dr. Sayre differs from Adams in placing the strong muscles upon the opposite side of the body.

Schreiber⁵ believes that in the early stages of the scoliosis there are no changes in the muscles. The muscular changes, he thinks, are due to long-continued stretching and disuse.

¹ Read at the Fourth Annual Meeting of the American Orthopedic Association, Philadelphia, Pa., September 17, 1890.

² The Treatment of Lateral Curvature of the Spine with Appendix.

Bernard Roth, F.R.C.S., London: H. K. Lewis, 1889.

³ Curvature of the Spine. ⁴ Orthopedic Surgery.

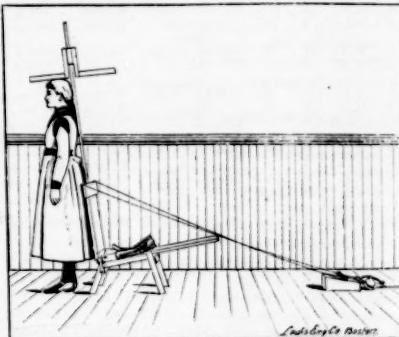

Eulenburg⁶ holds that slight continuous muscular action is necessary for the maintenance of the upright position of the body. This action must be equal on either side of the spine. The most frequent cause of deviations of the spine is a disturbance of the power of the spinal muscles. By the frequently repeated passive torsion, necessary in assuming faulty positions, gradually the trunk muscles are weakened.

Lorenz⁷ is correct in his criticism of the Eulenburg theory, when he says that muscular insufficiency is quite a voluntary and unproven assumption.

Lorenz sums up his criticism by the statement that anatomically, pathologically and clinically there is no foundation for the theory of a disturbed muscular antagonism.

That there is an element of muscular weakness present in cases of lateral curvature, pure and simple, has hitherto been assumed.

Believing, as I do, that it has been pretty satisfactorily demonstrated that two important factors in the production of the deformity are (*first*) the superincumbent weight of the head, neck, upper extremities and trunk falling upon (*second*) a spinal column which is out of plumb, the question arises, What position should the muscular factor occupy in the etiology? Is the assumption of muscular weakness in cases of lateral spinal curvature justifiable?

Chair for measuring the strength of the spinal muscles.

Before being able to determine the presence or absence of muscular weakness, it is necessary to establish a standard of strength for the back muscles for each age of the growing child. In order to establish this standard I have made an examination of the backs of one thousand one hundred and forty-one of the school girls of Boston. There was constructed for these examinations a chair with hinged and movable back, at right angles to a seat slightly inclined from the floor and long enough for the child to comfortably rest the legs upon. The back, at the level of the shoulders, is connected by stiff iron rods to the handle of a dynamometer, graduated in kilogrammes and fractions. Attached to the back of the chair is an upright with a cross-piece, movable up and down, by means of which the height both standing and sitting was taken. (See photograph.)

⁵ Real-Encyclopädie : Bd. II, p. 360, under Rückgratsverkrümmungen.

⁶ Pathologie und Therapie der Seitlichen Rückgratsverkrümmungen, Wien, 1886.

Each child was in turn weighed, and her height taken both standing and sitting. Then, upon sitting in the chair, a strap was passed over the hips (to prevent slipping forward), the arms were folded, and the child forcibly extended her back upon the thighs. The back of the chair was then raised to above the level of the occiput, and again the muscular strength was taken — this time testing principally the trapezius and deep muscles of the neck and upper back. The muscles used in the first test are chiefly those of the lower back. The action of the thigh and leg muscles is as nearly as possible eliminated by raising the legs on the inclined seat. The amount of the pull or the strength of the back muscles is recorded upon the self-registering dynamometer.

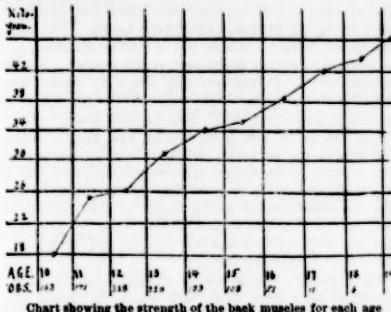

Chart showing the strength of the back muscles for each age of healthy girls.

The results of these observations are seen, in part, upon the chart. There is found to be a gradual increase in the strength of the back muscles of growing girls with each year's increase in age from ten to nineteen. There were no marked cases of deformity amongst these children; and the results are taken to represent the average strength of the backs of growing girls, irrespective of nationality.

We possess then an index of muscular strength for each age in healthy girls from ten to nineteen.

It is now necessary to measure the strength of the backs of lateral-curvature patients during all stages of the disease from its inception — when it has been assumed by some that there is and by others that there is not muscular weakness present — to the period of osseous change, when it has been proven by autopsy that the spinal muscles are so altered or replaced as to have no contractile power.

These two groups of observations — *first*, of normal backs; *second*, of backs with lateral curves — when completed and compared, will demonstrate the presence or absence of muscular weakness in the different stages of lateral spinal curvature. It will thus be possible to determine the history of the muscular strength through the various stages of the disease. And the muscular element in its etiological importance may then be discussed intelligently in one of its aspects.

Muscular exercise indiscriminately prescribed in cases of lateral curvature is irrational. The presence of habitual faulty attitudes does not necessitate the assumption of muscular weakness. The importance of determining the presence of muscular weakness and of measuring it, is greatest when the deformity is slight and the child is apparently strong. Treatment by

posture and exercise is successful in the great majority of cases in the non-osseous stage. But I am convinced that the application of this treatment will be more rational if each case shall be compared with, what may be designated, the physical index of development. This physical index, for any child, is the height and weight and strength which that child ought to have at its age as determined by the tables of Bowditch and the table given above.

From the researches of Dr. H. P. Bowditch, of Boston, it is known what the height and weight of growing girls should be at each age. It is known approximately, from the results of the investigation presented to you to-day, how strong the back muscles should be for each age. With these data at hand it is possible to determine whether a given patient is up to the standard of development or not. Special muscular exercise can then be prescribed when it has been demonstrated that it is needed. Mr. B. Roth's method of determining the need for muscular exercise is an excellent one, but with this additional test treatment is placed upon a firmer and more accurate basis.

The ordinary method of marking improvement or not is by comparing the rotation tracing taken at intervals. In some cases, however, the rotation may remain constant, and yet the attitude of the child improve with the increase of muscular strength. The tracing, in such cases, will not be of great value. But a measure of the muscular strength at intervals will serve a valuable index of progress. Then, again, in those cases in which there is no rotation present, by making measurements of the muscular strength at intervals the value of the muscular treatment will be demonstrated. And, again, in those cases in which the rotation diminishes by treatment, the tracing may be supplemented by a test of muscular strength.

A committee on lateral curvatures of the spine appointed by the Clinical Society of London, reported that "the amount of improvement which may be hoped for in any given case may not unsafely be gauged by the improvement which the patient can voluntary effect (directed or helped by the surgeon) in her position when first seen." In addition to this, the relation existing between the age, the height, the weight and the muscular strength of any given individual will assist in forming a prognosis.

There is, of course, a normal relationship between the several factors of the physical index. If, upon examining any given child, she is found to vary in any one or more points from the standard, it may then be considered whether this variation is to be taken as one of the etiological factors or not.

In conclusion:

(1) To-day has been established a scientific basis for the study of the muscular element in the etiology of lateral spinal curvature.

(2) Suggestions have been offered as to the bearing of these observations upon (a) the treatment, (b) the records, (c) and the prognosis, in cases of this disease.

— According to an official return of deaths due to wild beasts and snakes in India during the last year, it appears that 1,972 persons were killed in the Madras Presidency, of which number 1,587 were due to snake bites. The number of cattle destroyed in this way was 12,555.

APPENDICITIS: OPERATION.

BY EDGAR GARCIAU, M.D., LEOMINSTER, MASS.

THE patient, L. B., is a man, thirty-five years old. By occupation a loom repairer. He has always been healthy. His family history is good, and his habits also good.

In the evening of August 2d, about four and a half hours after supper, he was seized with a sudden violent pain in the bowels, almost wholly confined to the right side. There was vomiting also. His supper had consisted of a hearty meal of baked beans, which he said were "hard and not well cooked." During the night he took an injection, which moved the bowels freely, but the pain persisted, so, early in the morning a physician was called, who gave him a subcutaneous injection of morphia, after which he felt much better, and the pain subsided.

Thinking himself well, he got up, but he found that this brought on the pain again, which ceased as soon as he lay down. The pain had now localized itself in the right iliac region. He persisted, however, in getting up until an increase in the pain, and a moderate fever, which had now declared itself, forced him to take to his bed. Then he came home. He was working at some distance from home when he was taken sick.

The physician who treated him now, applied the usual remedies, and in the course of three weeks, or so, he was so much better that he got up and began to take gentle exercise. He had been up a week when he again began to feel worse. The pains recurred, and he was miserable.

Then the writer was called. When I learned the circumstances of the case I advised the patient to summon the previous physician. But as he persisted in changing, I undertook the case. This was on September 8th, about five weeks after the onset of the sickness.

In the right iliac region was a tumor about the size of two oranges. It followed Poupart's ligament, and extended from it about two and a half to three inches towards the linea alba. The inner edge was sharply defined. There was considerable tenderness on palpation, especially in the centre. Fluctuation was absent, both externally and by rectum. Indeed, by rectum the tumor could be but indistinctly felt. There was no tympanites, nor was there tenderness anywhere except in the place mentioned.

The bowels were free, and had been since the beginning of his sickness, and there had been at no time obstruction to the passage of flatus. In general appearance the patient seemed weak and sick, and his face was sallow. The tongue was coated moderately, and the fever ranged between 100° and 99°.

Poultices were applied, which gave relief. Morphia was given in sufficient doses to control pain. He took three-fourths of a grain in the twenty-four hours. Castor oil was also given in the dose of one teaspoonful every eight hours. The next day he seemed better. The tumor remained the same. On the day following a softening was felt in the centre of the indurated area, which increased on the next day. Fluctuation was absent. This was the spot of greatest tenderness.

After holding consultation, operation was decided on. Ether was given. An incision was made over the soft spot, two inches long, parallel with Poupart's

ligament, and half-way between the anterior superior spine and the pubes. Dissection was carried down with director and scalpel until a cavity was opened. About a teaspoonful of pus appeared. The finger was introduced and discovered a space surrounded with walls, which seemed to shut it off completely from the general peritoneal cavity. A quantity of grumous semi-solid material, mixed with blood, was discharged from the cavity. The appendix was not discovered nor any foreign body. Then the cavity was washed out with corrosive sublimate solution (1-5,000) and two tubes, perforated at the ends, were introduced and a dressing applied.

The patient recovered well from the ether. That evening his temperature was 102°. There was a good deal of pain, and he required one and a half grains of morphia during the first twenty-four hours. The next day he was better. There was slight tympanites, but no tenderness except at the seat of the wound. Flatus passed freely. In the evening the temperature was 104.5° and the pulse high. The following morning the temperature was 100°, and he felt much better. There was much less pain, and he had slept a little. The wound was irrigated twice daily with corrosive. The amount of discharge was very small, and had a faint fecal odor. The next day the suspicion of fistula was confirmed by seeing feces in the discharge. This showed that the appendix had suffered perforation, but no great fear was felt as to its not closing up, and it did so after five days.

For dressings, simple cotton cloths soaked in corrosive (1-5,000) were used, and when the fistula appeared, a small amount of thymol added to the corrosive solution effectually counteracted the odor.

The subsequent history is uneventful. The cavity is rapidly closing up, pushing out the tubes as it closes. The patient has much improved in general appearance. His appetite is excellent. There is no fever. The bowels respond promptly to a teaspoonful of castor oil. A speedy and complete recovery is looked for.

This case may be classed with those which run a slow course, appear to get well, and suddenly light up again. While in the present case the appearance of softening, so opportunely, at once decided the question of operative interference; yet in a great number, no such aid is given, and it is in these that delay is often so fatal.

But little dependence is to be placed on the height of the temperature and pulse as indicative of the presence of pus. More reliance is to be placed on the general appearance of the patient, combined with the behavior of the tumor. If the tumor remains stationary even if softening does not occur, and if the patient does not look well, does not improve in general appearance, it is pretty positive evidence that an operation is advisable.

If operation is not done, the fire frequently smoulders insidiously, until sudden collapse from a general peritonitis calls for a hasty operation, only to terminate in death in the vast majority of cases.

It is the early operative interference which has been so often emphasized that will save the greatest number of lives. It is much better surgery to find only a teaspoonful of pus than to find half a pint. Fatal shock may be best avoided when the patient is not exhausted by a protracted course of waiting.

The operation, by antiseptic precautions, has been

rendered comparatively safe, and even if the peritoneal cavity is opened, adhesions form so quickly that the inflammation is generally prevented from spreading. Fecal fistula, when it occurs after operation, is not much to be dreaded. It generally closes.

REPORT ON THE RECENT PROGRESS OF ORTHOPEDIC SURGERY.

BY EDWARD H. BRADFORD, M.D., AND ROBERT W. LOVETT, M.D.

LATERAL CURVATURE.

Of late, renewed attention has been devoted to the subject of scoliosis, stimulated by the writings of Sayre, Roth and more recently of Lorenz. Not only has the pathology been more thoroughly investigated than ever before, but new methods of treatment have been suggested as well as a more careful classification of cases.

Golding Bird¹ in a well-written article advocates the Sayre method in the treatment of lateral curvature defining this method, as the support of the enfeebled spinal column by means of a corset and the prevention of the atrophy of the muscles by means of calisthenic exercises including self-suspension.

Cases which are particularly suited to this method of treatment are those of comparatively "feeble persons, especially girls of deficient muscular development in whom physical exercise has been neglected by their parents, while their intelligence, often precocious, has been unduly developed." They are unable to withstand the daily fatigue of life, assuming an attitude "hanchée" (that is, by standing on one leg) like a soldier at rest — an attitude calculated, if too long continued, to develop a permanent deformity." Sayre's method will not correct the evil unless aided by the good will of the patient and the constant attention of the parents.

The writer classifies patients in three groups, according to the resistance of the curves. In cases of the second class he uses plaster corsets less than formerly, for the reason that, although he considers them the best support, less rigid appliances are in many instances better borne by patients. This is true also and to a greater degree in cases of the third class.

As to results: In thirty-three cases of the first class, Golding Bird reports 26 cures. One neglected treatment, and suffered a severe relapse; six began to improve, but were lost sight of; 19 of the 26 were treated for twelve months, four for one or two years, and three for more than two years.

As a rule, active treatment for a year is sufficient. Consecutive treatment carried out by the family will be needed to prevent a relapse for a longer or shorter time according to the patient's condition.

In patients of the second class it is difficult to specify in statistics the results of treatment, as the opinion of the surgeon as to improvement is not readily defined. Out of a dozen cases of this class two were followed for five months only, and though improved during this time, they should be disregarded in the list. Of the other ten, six were benefited to a permanent extent after an active treatment of from nineteen to twenty-four months; four relapsed (after three months improvement during active treatment) from neglect of consecutive treatment, improvement lasting three months in two, eighteen months in one, twenty months in the last.

¹ Revue d'Orthopédie, 1890, No. 1, p. 35.

In three cases of the third class a general improvement in condition was noticed after continued treatment by daily suspension, and plaster or felt corsets.

RACHILYSIS.

Barwell² also divides the cases of scoliosis into three classes: first, those in which the patient can rectify the curve by voluntary effort; second, those where the curve can be modified but not entirely changed by such effort; and third, those in which voluntary effort will produce little or no change. In cases of the second class, Barwell recommends as of assistance what he terms "rachilysis." The trunk is pulled into a corrected or over-corrected position by means of straps and pulleys, and this exercise is repeated daily.

Rédard,³ in describing the technique of orthopedic corsets, gives a hearty support to the use of plaster-of-Paris in preference to all mechanical corsets in the treatment of scoliosis.

Beeley⁴ recommends the employment of Fischer's method of hanging weights upon the curves of kneeling patients with scoliotic curves. By an arrangement of straps and suspended weights, pressure of from sixty to one hundred kilogrammes can be brought to bear upon the projected ribs for an hour or so with ten minutes rest.

LATERAL SUSPENSION IN SCOLIOSIS.

Rédard⁵ modified Lorenz's apparatus (adopted from Wolm's appliance) for lateral suspension of patients over a padded bar, and recommends the method as being the best means of correcting the rotation. Rédard's modification consists of a board supporting the limbs. This board can be lowered at will; and in this way the amount of strain and pressure can be graduated and made less trying for the patient.

APPLIANCE FOR MEASURING LATERAL CURVATURE.

Barwell⁶ described a simple means of recording the amount of rotation in lateral curvature, as well as the lateral deviation. It consists of a stand with a rule to mark the obliquity of the pelvis, and with arms to steady the pelvis; from this rises a rod carrying at its top a short bar which rotates horizontally round a screw clamp, and is armed with a needle playing over a sextant. The patient's back is placed against the bar, the pelvis being held in line by the aid of the pelvic indicator. The projection of the ribs (that is, the rotation), if present, presses the top bar back on one side, the amount being recorded on the sextant; this can be noted and used for comparison. An arrangement is added for the purposes of marking the centre line of the pelvis and thorax and the distance of the latter from the spinous process.

Mr. Barwell has observed in a certain number of cases how many as yet, he does not know — that in lateral curvature the limbs do not stand perpendicularly to the floor. The cause of this is not understood; and cases of what he terms "amesial" pelvis of this sort are difficult to treat.

Hoffa⁷, of Würzburg, reports a good deal of success in the treatment of lateral curvature in cases of the first and second class. He uses an arrangement by

² Barwell: Lancet, April 27, 1889, p. 631.

⁶ Clinical Society Transactions, vol. xxii, p. 314.

Münchener Medicinische Wochenschrift, 1889, p. 463.

which the patients during suspension are held in a corrected position. A light removable plaster jacket is applied, which he terms a torsion corset. Such a corset cannot, however, be applied until after a preparatory treatment of a few weeks, for the purpose of making the spinal column as flexible as possible. Lorenz and Beely's method is employed — self-correction and gymnastic exercises and faradization. A torsion corset is then applied and worn chiefly in the morning. A lighter steel appliance is worn later.

He reports number of cases benefited by this method of treatment.

HIP-JOINT DISEASE.

W. Blanchard⁸ writes of the mechanical treatment of hip disease, advocating fixation, and describing a splint which he has used for many years, which is similar in construction and application to that so well-known in England by Mr. Thomas's name.

J. E. Goldthwaite⁹ has reported a case of acute hip disease where no deformity was present, in which night cries of a severe character were controlled by elevating the leg, which probably served to relax the Y ligament. Every other means had been previously tried to arrest the cries.

The question of the merits of traction *vz.* fixation, is discussed at length by Ridlon¹⁰ with which may be compared an article by Willard,¹¹ dealing with the operative treatment of hip disease.

Mr. Croft,¹² in a lecture before the Royal College of Surgeons, gave a careful consideration to the results of the mechanical and the operative treatment of hip disease and concludes "that there is a great future for the policy which was laid down that tubercular disease in its caseating and liquefying stage shall be completely excised, etc."

As an offset to this, one has a most admirable paper by Shaffer,¹³ dealing with the principles of the mechanical treatment of hip disease from the American standpoint, and a direct reply to Mr. Croft's paper by Howard Marsh¹⁴ as a representative of English conservative methods.

Some very valuable evidence of the value of traction in hip disease was given in Dr. Brackett's paper¹⁵ relating some experimental work in that direction, made both on the living subject and on the cadaver. In six experiments on the cadaver, traction of twenty-five pounds caused a distinct lengthening of the leg and an increase of the distance between the two great trochanters, showing that the relations of the joint had changed. That is, it showed that in separation of the joint surfaces, the first step is the outward displacement of the head of the femur, sliding on the oblique acetabulum. In the living subjects the distance between the trochanters was increased by moderate traction, showing also a change in the joint relation. The outcome of the research is the conclusion that distraction of the joint surfaces is possible under ordinary conditions.

Phelps,¹⁶ in writing on the treatment of hip disease from an anatomico-pathological basis, advocates both fixation and traction in the treatment, but he believes

for anatomical reasons that traction should be made neither in the line of the neck nor of the shaft, but in a direction between the two. This he would accomplish by making outward as well as downward traction. He has devised a portable bed which is much the same as the wire cuirass but is less cumbersome and expensive.

The mechanical treatment of senile coxitis is advocated by H. L. Taylor,¹⁷ who describes the apparatus to be used and gives illustrative cases.

An interesting hip-joint was shown by Dr. Myers¹⁸ at the New York Pathological Society. Excision of the hip-joint had been done nine months previously, and the result of the case had been so favorable that the child (four years old) was able to bear weight on the limb, and motion at the hip was very good. Dissection of the joint after death showed that the posterior and upper rim of the acetabulum was well defined and had not suffered from the disease, to which fact the stability of the joint was probably due. The muscles and ligaments had adapted themselves to the new conditions, and the joint surfaces were covered with a strong, smooth, fibrous membrane.

The value of femoral osteotomy for flexion of the leg after hip disease, is brought out in the paper of Vance,¹⁹ who does the Gant operation with very satisfactory results. He makes no incision, but drives the chisel straight to the bone through the sound skin. The same method is especially applicable in MacEwen's osteotomy.

CONGENITAL DISLOCATION OF THE HIP.

Mr. William Adams²⁰ reports satisfactory results from the treatment of congenital hip dislocation by extension, following the lead of Dr. Buckminster Brown. The method of treatment is similar to Dr. Brown's. Mr. Adams' cases are four in number, two unilateral, and two bilateral dislocations, and the head of the femur seems to be retained in its proper place in each of them. As yet it is too early to judge of the real success of the treatment, as in the longest case only two years and seven months have elapsed since the beginning of treatment. In view of this Mr. Adams promises a later report.

Krause²¹ records two cases of acute purulent arthritis of the hip, occurring in the subjects of congenital dislocation.

A very careful and systematic consideration of congenital dislocation of the hip is contributed by Dr. Evans²² which brings forward nothing new but which deals at length with the pathology and etiology and describes the recorded dissections. In the matter of etiology, he inclines to the view of Grawitz (which may, in fact, be spoken of as the modern view), that mal-development of the acetabulum lies at the root of the deformity. The question of treatment is dispatched with very scant consideration.

Teufel²³ reports an excision of the hip which proved of much benefit to an adolescent patient with congenital dislocation of the right hip, but knock-knee and club-foot were present on the same side, so that he was not able to walk without Taylor splint, but even this was a decided improvement over his original

condition. He follows the account of the case with a consideration of the etiological theories. Under the head of treatment all operations (by German surgeons at least) are considered and tabulated.

KNEE-JOINT DISEASE.

Gibney²⁴ writes of the treatment of knee-joint disease in children, and advocates conservative treatment which he finds easily applicable by means of carefully applied plaster bandages. But in addition to mere fixation he would afford protection to the diseased joint by taking off the body weight by means of a Thomas splint or a perineal crutch. Flexion deformity is treated by means of the "Billroth splint" which is a plaster bandage hinged laterally at the knee which can be extended at will. Abscesses he would let alone until they became troublesome.

ANKLE-JOINT DISEASE.

The question of excision of the ankle-joint has occupied a more prominent place than usual in the medical literature of the last year. Articles have been numerous which dealt with the indications and especially the technique of the operation. The more important of these are by Kirmison,²⁵ Ollier,²⁶ Poulsen,²⁷ Rédard,²⁸ Serr,²⁹ and Trouillet.³⁰

C. L. Scudder³¹ reported eighteen cases of excision of the ankle-joint operated on at the Boston Children's Hospital and gave a general consideration of the question of excision. Of fifty-four excisions these were the only cases where the end results could be reported. The cases found had for the most part useful feet and the results of the operation were eminently satisfactory. After a careful review of the whole subject he makes a plea for complete excision instead of the partial operations so much in vogue, and calls attention to the good results after early excision. Operative treatment is not, however, to be recommended until expectant treatment has definitely failed.

Arthur Neve³² in a consideration of the same question advocates extensive removal of the soft parts as well as of the bones, and is also a believer in extensive and thorough operations. He uses a posterior incision which seems to him much better than the common ones. It begins well up the leg on the posterior surface of the tibia and sweeps down to the insertion of the tendo Achillis and up the back of the fibula. The deeper structures at the inner aspect of the leg are dissected off the bone and turned forward. The foot is strongly flexed, the lateral ligaments cut and the joint exposed.

It does not seem possible that this method can give so good a view of the joint as the external semi-lunar incision of Kocher, of which Mr. Neve makes no mention. Nevertheless, he claims that it is very satisfactory, and easy of performance.

(To be continued.)

— A Chicago paper tells of a Missourian who died from having gorged himself with veal and hard cider. He was a member of several societies, all of which passed resolutions imputing his removal to Divine Providence.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, October 13, 1890.
DR. W. L. RICHARDSON in the chair.

DR. F. B. HARRINGTON read a paper on
THE VALUE OF PRIMARY ANESTHESIA IN MINOR
OPERATIONS.¹

DR. F. H. WILLIAMS: It is very desirable that this form of anaesthesia should be more used than it has been. I should like to ask what amount of ether was necessary.

DR. HARRINGTON: I have always used a sponge which was saturated. I suppose about an ounce of ether is poured upon it. I think a much smaller quantity could be used. The patients remain very quiet, and if you ask them if they are ready, they will sometimes say yes when they are not quite ready. I have had them talk through the cutting, evidently not suffering pain, and it is a very unusual thing for them to draw away the hand, for instance, that is being operated on.

DR. WILLIAMS: Do you hold the arm up in order to test whether the patient is etherized? We know that sensation is lost sooner than motion, so that one of the tests, of course, is to have the patient hold the hand up, and as soon as it falls you are sure that he cannot feel pain.

DR. OTIS: Dr. Harrington has referred to the use of nitrous oxide. In one of my terms of service at the Dispensary we had an apparatus, and I used it off and on for three months. One of my assistants was the son of a dentist and he took charge of it. I found it unsatisfactory because the time of anesthesia was exceedingly transitory, and gave hardly time to get the knife in the hand before the return of consciousness; and besides this they became so stiff and the whole appearance was so ghastly, that it was uncomfortable and unsatisfactory.

DR. S. J. MIXTER: I quite agree with what Dr. Harrington has said about etherization for minor operations. There is no reason why a patient should be profoundly etherized for such operations as opening felonies and palmar abscesses, excision of the lip for cancer, or any others requiring a short time for their performance. The dread of nausea, vomiting and a long period of discomfort following ether makes both patient and surgeon avoid its use in many cases where it could be given to the greatest advantage to both. Primary ether-anesthesia and the use of cocaine has done great service in surgical out-patient clinics, and the choice of one of these methods depends largely on the personal experience of the operator. I have used cocaine in many hundreds of cases, on one day doing twelve minor operations with it, and have never had any unpleasant results from it. I, therefore, use it when the field of operation can be anesthetized by a small amount of cocaine, especially if fine dissecting or much time is required, while for more severe operations such as extensive palmar abscesses, etc., I use primary anesthesia. Operation for removal of cancer of the lip, even where the whole lower lip is to be removed, can be done without pain after the proper use of

¹ See page 434 of the Journal.

cocaine. Internal urethrotomy and divulsion of stricture I almost always do under cocaine.

DR. MORTON PRINCE: I should like to call attention to the use of cocaine in connection with the electrical current for producing anesthesia. It is a method I have used myself a good deal in my office the past year, and have found it very successful. I have not had occasion to use it in connection with cutting operations, but for purposes of electrolysis I have found it of great value. It is a well-known fact that if solids in solution are connected with the positive pole of a constant battery, they are carried through the skin, and by this means cocaine can be made to penetrate the epidermis, and local anesthesia be produced. The method was first suggested a good many years ago, I think about 1865, by Richardson of England, who claimed that local anesthesia could be produced in this way by chloroform. His results, however, were denied, and the practice fell into disuse. Later, Mickelowicz took it up and claimed that local anesthesia could be produced in this way by means of chloroform. His statements also were very strongly denied. A year and a half ago, I think it was, Peterson, of New York, undertook to reinvestigate the whole subject, and he found that it is perfectly true that cocaine or chloroform can be made to penetrate the skin by means of electricity, but that it was impossible by means of the Mickelowicz electrode to obtain anesthesia for the reason that owing to faulty construction, no electricity passed through the liquid. The principle, however, is correct. I have not had occasion to use this method for cutting operations, and therefore, cannot speak positively of its value for such purposes, but I have almost daily used it for electrolytic operations. Now the pain from electrolysis I suppose is as intense, or may be so, as is likely to be produced by almost any minor surgical operation, and I find that cocaine used in this way gives the greatest relief. I do not know from personal experience, whether absolute anesthesia can be produced or not, as I have never found it necessary to carry the effect so far. Peterson, if I remember rightly, obtained it. It certainly decreases pain to a great extent, so that in some cases where I have not been able to operate at all without it, by its use I can do so with the greatest ease. A little girl, for example, who was always thrown into an hysterical condition by the pain of the electrolytic needle before I used cocaine, afterwards bore the operation with the greatest ease. It seems to produce loss of sense of pain without much loss of the tactile sense. I do not believe that the method is applicable in surgical operations where there is much local inflammation, for instance, but I should think there might be a good many cases in which it could be used.

DR. CUTLER: I should like to ask how Dr. Prince applies this, as a solution or solid body?

DR. PRINCE: All that is necessary is a small electrode with a piece of absorbent cotton soaked in a ten or twenty per cent. solution of cocaine. Peterson has constructed a special electrode which he says is very good. Practically I cut a piece of cotton the size of my electrode, and wet it in cocaine. This is then placed on the skin and the electrode on the cotton, and a current from the positive pole allowed to pass, anywhere from two to six minutes, according to the effect desired. The longer the duration of and the stronger the current, the deeper the anesthesia ob-

tained. The negative electrode is wet with water and put on the palm of the hand or anywhere you choose to put it. I use an electrode for my purpose one-half to three-fourths of an inch in diameter. On the upper lip I use an elongated electrode. It works well for my purposes, and I don't see why it shouldn't for other operations.

DR. CABOT: I have used primary anesthesia a good many times, but I confess that Dr. Harrington in his paper this evening has shown me that I have made what I have called primary anesthesia more profound than is always necessary. My test has been the one Dr. Williams spoke of — having the patient hold the hand up and operating the moment it dropped. I have never operated while the patient could still answer questions. In trying this test of holding the hand up, I have been surprised to see the patients, when partly etherized, get into a state very similar to what I have seen here shown by some of the neurological members, in hypnotism, that is, a perfectly cataleptic state. Put the arm in any position, and it will stay where it is put. Another similarity between partial anesthesia and hypnotism is, that an idea impressed upon the patient before anesthesia is acted upon during the early stages of anesthesia before the power of movement is lost. A patient who promises before etherization to lie still usually does so, and it is very seldom necessary even to touch the hand.

DR. WILLIAMS: In the exercises of the medical student in which opportunity is given them to see the various forms of anesthesia and compare them, I have preferred primary anesthesia to the use of nitrous oxide, as being more convenient, as Dr. Harrington and Dr. Otis have suggested.

I should like to ask Dr. Harrington the amounts of cocaine used in those cases in which he got unpleasant results.

DR. HARRINGTON: A case of alarming symptoms following the use of cocaine, occurred during my service in the Out-patient Department of the Massachusetts General Hospital, last year. I have many times injected two drachms of a five per cent. solution of cocaine into the urethra for the purpose of passing sounds. On this occasion that amount was injected. In less than a minute the patient's arms and legs began to twitch and the face became contorted. I suppose that the attack was hysterical. The patient was a young delicate man of about twenty-five years. I endeavored to arrest the attack by shaking the patient and speaking sharply to him. It had no effect. Intense spasms, tonic and clonic by turns, came on. At one time the respiration ceased, and the face became very black. Artificial respiration was produced. The urethra and the bladder were immediately washed out. During this process there was an emission of semen. The pulse became very rapid and feeble. The eye became widely dilated. For five minutes the condition was very alarming. The attack gradually subsided and the patient was able to go home in two or three hours. He stated that he had never suffered from epilepsy. The seizure resembled very closely an epileptic attack. The amount of cocaine which was absorbed must have been extremely small, and the attack may have been mere coincidence.

DR. GREEN: Concerning the test of the required amount of anesthesia for the momentary operation, I have been accustomed for years, in occasionally drawing teeth or opening a felon, to tell the patient that he

or she would be aware of what was going on, but would not suffer pain, and my standard has been the insensibility of the conjunctiva to the touch. My results have almost invariably been successful.

DR. MIXTER: It seems to me that the importance of primary anesthesia in capital as well as minor operations should be more generally recognized. We become so accustomed to operating only when the patient makes no sign when cut, that any outcry or struggle seems to call for more ether, and when there is much shock, the extra amount of ether may be sufficient to turn the scales against the patient. In such cases I have everything ready for the operation, and while the patient is perhaps still talking, the operation is performed as rapidly as possible. In one case I did a herniotomy while the patient was protesting against the suffocating sensation produced by the ether. I have also performed high amputation of the thigh, amputation of both legs, etc., in a similar manner. The patients tell you afterwards that they did not feel the operation.

In regard to the bad effect of using cocaine in the urethra of a patient at the hospital, mentioned by Dr. Harrington, I can say that the service passing to me soon after, I was warned by the assistant in regard to the use of cocaine in this case, so I passed the sound without it. He had a somewhat similar convulsive attack at once, though not so severe as before. Soon after, I had another patient with stricture where there was a most unpleasant convulsive attack following the passage of the sound, either with or without cocaine. Judging from these and similar cases, I think that many (not all) of the accidents ascribed to cocaine are merely coincidences.

Dr. ARTHUR T. CABOT showed a plaster cast of a case of

FORWARD DISLOCATION OF ONE OF THE CARPAL BONES.

He said that this injury was so rare that Hamilton had been unable to find a single instance of it reported.

The cast was taken from the wrist of a patient of Dr. G. W. Mills of Medford. The man, a carpenter, fell from a house, suffering an injury of his wrist. Dr. Mills examined him under ether, and found an impacted fracture of the radius [Colles'] and also the displacement forward of one of the small bones of the wrist, which was well-shown in the cast. During anesthesia this bone could be pushed down somewhat into place in the carpus, but the moment the pressure was taken off it popped out again. Persistent efforts were made to hold it in place, but only resulted in a pressure sore over the projection without reducing the deformity in the least. The man recovered with a useful wrist, though much misshapen. It was not possible to tell which bone of the carpus it was that was displaced, but its size and position suggested the os magnum.

— The Medical Council of St. Petersburg is considering a project for the regulation of doctors' fees, by dividing patients into three classes, according to their pecuniary ability. There will be great scrambling for enrolment in the third or free-patient class by many people who would otherwise scorn to be regarded as poor.

AMERICAN GYNECOLOGICAL SOCIETY.¹

THIRD DAY.—MORNING SESSION.

THE COMPARATIVE VALUE OF BINIODIDE AND BICHLORIDE OF MERCURY AS SURGICAL ANTISEPTICS, by CHARLES JEWETT, M.D., of Brooklyn.

Dr. Jewett asserted that the biniodide of mercury as a germicide is as potent as the bichloride of mercury, if used in proper concentration, and that it possesses important advantages as a practical antiseptic. The bichloride is an unstable chemical compound, decomposing on contact with instruments, soaps or albuminous fluids, and is gradually reduced to calomel in the presence of certain organic bodies. It must frequently happen in practice that the trusted solution has long since become inert, not to speak of the injury done to instruments.

The addition of acids prevents the precipitation of albumen, but it is more unpleasant to the surgeon's hands, and accelerates the decomposition of the solution in the presence of ordinary metals. The biniodide of mercury is comparatively stable. Its solution is not destroyed by soaps or albuminous fluids, and it is more feebly affected by metals. Steel instruments may be left lying for a few minutes in a one two-thousandth solution without material harm, and may be brushed and sterilized with it in preparation for use. The slight blush which appears after a time may be wiped off leaving the polish intact.

The biniodide is less irritating than the bichloride to the surgeon's hands, to wound surfaces and to mucous membranes, and, also, probably is less toxic, both as an irritant and as a systemic poison.

From 226 experiments made at the Hoagland Laboratory the following conclusions were drawn:

- (1) In equal concentration the biniodide is slightly inferior to the bichloride in germicidal power.
- (2) The difference in the efficacy of a one two-thousandth and a one one-thousandth bichloride solution is insignificant.
- (3) The activity of a one one-thousandth solution of the biniodide is materially greater than that of a one four-thousandth solution.
- (4) For equal potency as a sterilizing agent the biniodide should be used in a little greater concentration than the bichloride, presumably one eighteen-hundredth.

A REPORT OF MY RECENT EXPERIENCE IN RESTORING LACERATIONS INVOLVING THE SPHINCTER ANI, BY THE FLAP-SPLITTING METHOD,

by HORACE TRACY HANKS, M.D., New York.

Dr. Hanks stated that the operations of Thomas, Emmet, Brown-Baker and his own would have had good results, as a rule, could the operation have always been performed by a skilled surgeon, and the patient nursed by a reliable nurse. The after-treatment of the writer, namely, keeping the bowels loose for ten days, is a feature quite essential to success. He believes that the Tait operation, when perfected, will prove to be the best yet devised. It is the most simple, the most quickly done and the surest in its results.

Dr. Hanks cited the last five cases in which he had operated. He performed the usual flap-splitting operation, removing the sutures after ten days. Every case

¹ Fifteenth Annual Meeting, Buffalo, N. Y., September 16-18, 1890. Concluded from page 423 of the Journal.

recovered and the results were perfect. The operation, as performed by Dr. Hanks, is as follows:

The patient is to be in the best possible physical condition, the bowels to be thoroughly moved each day for several days, and the rectum to be unloaded with an enema the morning before the operation. The hairs should be removed from the labia and mons, and the parts washed with a one one-thousandth or one two-thousandth bichloride solution. The patient is put in the lithotomy position, and the vagina and rectum douched with a one four-thousandth bichloride solution. The upper rectal pouch is filled with few cotton balls, wrung out of hot antiseptic water. Then with tenacula inserted at the parts which represent the carunculae, the labia must be approximated, and the vagina thus closed for inspection. Begin the operation by making an incision with scissors near to, but below the end of the torn sphincter on the patient's left, and cut or slit the rectum from the vagina, from the torn sphincter up to the angle of the tear in the recto-vaginal septum. Then carefully split it for a full half-inch at the angle. Follow the same procedure on the opposite side of the anus. The points where the incisions begin must be on a level with the lowest part of the anus. An incision one-quarter inch deep is usually required; the object is to reach the end of the sphincter, whether the cut be deep or shallow. After irrigation with hot water, vertical incisions are made, the parts dissected back a little, and then prepared for the sutures. The rectal wall is then sewed to the anus with a No. 1 continuous catgut suture. The small Hanks-Pearse needle is used in placing the most important suture. The first suture enters the undenuded tissue below the level of the anus, the needle being directed downwards at first, that there may be no doubt about catching all the fibres of the sphincter ani. Silver wire sutures are put in proper place, and these should remain for ten or twelve days.

DR. E. C. DUDLEY, of Chicago, had performed Tait's operation formerly, and always succeeded in getting union, but had since discarded it as it did not sufficiently bring together the torn parts — not being a restorative operation. He believed the condition of a lacerated perineum through the sphincter ani indicated simply an operation which would restore the parts to the condition they were in before the tear occurred. The first step is to bring together the lowest carunculae myrtiformes with two tenaculae, when the direction of the original rent and cicatrix can be made out. The perineal body is then restored by the method suggested by Emmet. In thirty-six to forty-eight hours a cathartic is given, and before movement an enema of warm water, and the bowels are kept open until union is complete. He believed no particular operation could be laid down as applicable to all cases, but he had adopted in these cases a plan which was a slight modification of Emmet's. He considered it most important to restore the rectal site of the rent. He does not think that the size of the perineal body has so much to do with its efficacy as its location. If it is small and located well up, hugging the pubes, it is all right, but, if it be ever so large and located down toward the tip of the coccyx, and relaxed, it will not perform its functions, and operation on the vaginal outlet is quite as important as if the perineal body had been torn.

DR. POLK, agreed with Dr. Dudley, and thought the most important factor was the levator ani muscle which passes from the body of the pubic bone and

meets the same of the other side, at the side of the rectum. When this is not relaxed, but is well up near the pubic bone, it pulls the posterior wall of the vagina with it, which, of necessity, catches the pelvic pressure.

DR. DUDLEY, of Chicago: In operating, after the sutures had been tied, he would catch their free ends with a lock forceps, and thus get them out of the way. He found this also to be of an advantage in grasping the freed end of each suture after it was introduced and tied, upward traction could be made by the assistant, who held the forceps which grasped the free ends of the sutures, which would bring the perineum up until it hugged the pubes. When this is done the perineum will almost exert pressure on the anterior wall of the vagina and pubes. Emmet followed the practice of introducing all the sutures at one time, tying them afterward, but the speaker had found it of much greater advantage to insert one suture at a time, tying as he went along, thus bringing the perineum up into the position described. If this plan is followed the operator will rarely fail to get the perineum into the proper position.

MEASUREMENTS OF THE UTERINE CAVITY IN CHILD-BED,

by DRs. W. L. RICHARDSON and A. D. SINCLAIR, Boston, Mass.

This paper was an analysis of 540 observations made at the Boston Lying-in Hospital, and was intended to make a complete record of 1,080 cases, the others having been presented to the profession in 1879, 1881 and 1882, and subsequently published in the Transaction of the Society, Vols. IV, VI and VII.

Of the 1,080 cases, the average age was 23.55 years; 746 were primipara, with an average age of 22.11 years; 334 were multipara, with an average age of 26.53 years. The average number of days in child-bed, at the time of measurement, was 16.32. The smallest measurement of the uterine cavity in a primipara was $1\frac{1}{2}$ inches; in a multipara, two inches. The first measurement was made on the fifteenth day, the second on the sixteenth day. The greatest size of the uterine cavity was $5\frac{1}{2}$ inches for a primipara and $4\frac{1}{2}$ inches for a multipara, the observations having been made on the thirteenth and twenty-fourth days respectively. The average length of the uterine cavity was 3.27 inches for primipara and 3.29 inches for multipara.

In the course of their analysis, the writers found that the first stage of labor averaged fourteen hours in the primipara, and ten hours in the multipara; the second stage of labor averaged one hour and fifty-six minutes in the primipara, and one hour and eight minutes in the multipara.

LAPAROTOMY FOR INTRA-PELVIC PAIN.

DR. THOMAS A. ASHBY, of Baltimore, read a paper with the above title.

Dr. Ashby stated that intra-pelvic pain is associated with a number of intra-pelvic conditions, of structural, inflammatory, and neuralgic origin, and that the severity of the pain bears no appreciable relation to the magnitude of the disease. Pain, as a symptom, may be considered to stand alone, and not necessarily to be considered as an index of lesion. In cases of ovarian neuralgia, the nervous and hysterical elements should always be eliminated before deciding upon an opera-

tion. Aside from pains of a strictly neuralgic character, there are many in which the lesion can be definitely located only by an abdominal incision, among which are chronic inflammations, adhesions and vascular disturbances.

Dr. Ashby advised the employment of an exploratory incision in all cases not well defined, and considered such procedure warrantable for the purpose of making a diagnosis. He cited cases to uphold his position.

DR. KELLY, of Baltimore, eliminating personalities, would strongly condemn the practice of performing *laparotomy for pain*, notwithstanding that in some cases it affords the most typical relief. He believes oöphoralgia is rarely heard of, the condition which characterize it generally arising from some other disease of the organ. The admission of laparotomy for this condition would lead to the practice of seven or eight years ago when laparotomy was performed for every known disease. These ovarian troubles can always be diagnosed by bi-manual palpation or bi-rectal and bi-vaginal examination in anesthesia. The uterus can be brought down to the vaginal outlet with the corrugated tenaculum, when the ovaries can be easily gotten at. If extensive adhesions exist, the uterus may be brought down into retro-position and bi-rectal examination will disclose the ovary, a little, characteristic, almond-shaped body. If it is not found in this way the utero-ovarian ligament may be looked for running out to the right or left of the uterus. When this is found by pushing it up, it is easy to ascertain whether the ovary is adherent or not. Radical measures should not be resorted to until all other forms of treatment are exhausted.

DR. PALMER DUDLEY, of New York, was in favor of laparotomy for the relief of the conditions which produced pain, after all methods of treatment had failed. He believed it was impossible to diagnose certain diseased conditions of the ovary by bi-manual touch, and that laparotomy was the only proper procedure in such cases. Vascular disturbances is the foundation of the majority of pelvic diseases in women. There are no valves to the ovarian veins from the ovary up to the renal vein, and they are pressed upon by the sigmoid flexure of the colon and the transverse circulation of the kidney, sometimes causing what may be considered a varicocele. This condition has been noted by Skene, Lusk, Polk, Currier and Neilson as well as by the speaker. This pressure upon the vessels also produces sub-acute inflammation and formation of adhesions, which can only be broken up by laparotomy. The speaker had three cases where after a long-continued palliative treatment without relief, he had performed laparotomy, drained the cysts found in the ovary, allowed them to refill with blood, and then returned them to the abdominal cavity with immediate relief of the pain and rapid convalescence.

DR. POLK, of New York, understood Dr. Ashby to refer simply to an exploratory incision in these cases, and in that sense he thought he was entirely right. He did not believe it was possible in all cases to make out the diseased conditions of the ovaries by bi-rectal or bi-vaginal touch. He agreed with Dr. Dudley that in many cases an "exploratory incision" could be made into the ovary to discover the trouble, just as well as into the abdominal cavity, with the possibility of correcting the trouble, sewing up the ovary and replacing it thus avoiding complete amputation,

which he thought should never be done when it could possibly be avoided. He believed that catarrhal salpingitis does not justify amputation.

DR. HENRY T. BYFORD, of Chicago, believed that laparotomy should not be resorted to for the cure of pain that can be cured otherwise. He reported a case in which he at first performed Alexander's operation without relief; used palliative treatment, and finally laparotomy, removing both ovaries which contained small cysts. The patient's mind was affected, and now after the lapse of a year is in no better health. When the ovary is cut with a knife or suture it will form adhesions which may afterwards necessitate its entire removal. He had done this, and afterwards had to remove it on account of the adhesions, curing the disease.

DR. MATTHEW D. MANN, of Buffalo, did not believe that diagnosis was possible in all cases before the abdomen was opened. He believed in the exploratory incision as means of diagnosis. He doubted whether minute disease of the ovary could be recognized by a simple incision of the organ and was inclined to believe that the whole organ ought to be removed. He was confident that in a number of cases the ovaries and tubes have been removed when the trouble was entirely in the ureters.

DR. JOHNSON, of Washington, disagreed with Dr. Polk and believed that if the adhesions were broken up without taking out the ovary that the disease would return, and cited a case where he had taken out one ovary and broken up the adhesions, the patient apparently recovering, but six months afterwards the disease returned, necessitating a second operation in which he removed both ovaries and the woman has been perfectly well ever since. They should both have been removed in the first place and would have been but for the wish of the attending physician to save one of them. The first operation caused the bands of adhesions to shorten and bind the viscera closely together, presenting a difficulty at the second operation which would have been avoided had they both been removed at one time. If there is much disease it is better and safer for the patient to lose both ovaries than to be subject to the dangers of a second operation.

DR. POLK, of New York, recognized the justice of Dr. Johnson's remarks and believed that the condition he mentioned made it all the more necessary to carefully examine the opposite ovary for traces of any disease. If there was cystic degeneration to any extent it would be unwise to leave it in, but there are many cases in which there are not more than one or two good-sized cysts which can be removed in the manner suggested by Schroeder, and very few adhesions result; it not being necessary even to close the incision in the ovary with sutures unless it be necessary to control hemorrhage from the cut ovarian surfaces. He believed that adhesions sometimes exist forever, but that they were a matter of no importance except for a short time after the operation, and frequently in performing a second operation no traces of them are found except the lines along which the drainage-tube had rested.

At 1 p. m. the Society adjourned to meet in Washington, during the Triennial Congress of American Physicians and Surgeons, September 17, 18 and 19, 1891.

The following officers were elected for the coming year: President, Dr. A. Reeves Jackson, of Chicago; Vice-Presidents, Drs. Joseph Tabor Johnson, of Wash-

ington and William H. Baker of Boston; Secretary, Dr. Henry C. Coe, of New York; Treasurer, Dr. M. D. Mann, of Buffalo; Members of Council, Drs. H. P. C. Wilson of Baltimore, W. H. Polk of New York, E. C. W. Dudley of Chicago, and F. H. Davenport of Boston.

During the session of the Society lunches were tendered to the members by Drs. Mann of Buffalo, Dr. W. C. Ford of Utica, and Dr. Stansbury Sutton of Pittsburgh.

At the close of the morning session on the third day, at the invitation of the Buffalo Medical Club, the members made a trip to Niagara Falls, returning in the evening to attend a banquet given by the Buffalo Medical Club at the handsome club-house of the Buffalo Club on Delaware Avenue.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

SECOND DAY.—AFTERNOON SESSION.

DR. W. P. KING, of Kansas City, Missouri, contributed a paper entitled

WIRING THE SEPARATED SYMPHYSIS PUBIS, SUPPLEMENTED BY A NOVEL PELVIC CLAMP.

He reported a case of separation of the symphysis pubis, with fracture of the interposed fibro-cartilages, fracture of the descending ramus of the pubis, with deep lacerations of the surrounding parts, and, more particularly did he refer to the methods resorted to in order to support the pelvis and reinforce the stitches after the pubis had been wired together.

The case suggested the following points:

(1) The operation of wiring in a case of separation of the symphysis pubis so completely coaptates the parts that it would seem that scarcely any other method of dealing with this condition can be equal to it.

(2) The manner of applying the plaster-of-Paris support in the first place, with the use of the water-bag to make an arch under which to dress the wounded parts, is new and original so far as the author knows, and it is a method that may be adopted and easily practised by any one who knows how to use plaster-of-Paris.

(3) The steel hip clamp as a permanent support in separation of the pubis is also new, so far as he knew, and is a means that may be adopted with benefit in any case of fracture of the pelvis wherein immobilization of the fractured part will contribute to the comfort of the patient and to the union of the fracture.

DR. C. H. HUGHES, of St. Louis, Missouri, read a very elaborate and profound paper entitled

PSYCHO-PATHIC SEQUENCES OF HEREDITARY ALCOHOLIC ENTAILMENT,

which was followed by a paper on

UREA AND SEROUS MEMBRANES,

by DR. C. S. BOND, of Richmond, Indiana.

DR. ARCH DIXON, of Henderson, Ky., in a paper on

INGUINAL COLOTOMY,

said the subject of colotomy, always one of interest, has, during the past decade, demanded much attention

¹ Sixteenth Annual Meeting held in Louisville, Ky., October 8, 9, and 10, 1896. Concluded from page 420.

from the surgical world. As a measure intended to ward off imminent death, colotomy is called for in all cases of obstruction in the colon from whatever cause arising. For imperforate anus, the operation holds a special position. It is intended to prevent impending death, but it may or may not be regarded as a cure for the disease. In many cases it is the first step in the process of cure. In every infant born with imperforate anus, an operation of a local nature is first attempted, if this fails, colotomy by some method is performed to ward off death. Later on an attempt may be made to get the bowel to discharge through the anus. In a few words, it may be said that the indications to operate in any given case depend, in the first place, on the chance which the patient has of getting well without operation; and, in the second place, upon the degree of probability with which success follows the operation. To cases of acute obstruction of the sigmoid flexure, or elsewhere, there is practically but one termination—death. No case of volvulus, whether of large or small intestine, has as yet been known to recover under treatment purely medicinal. Here then, the indication is clear enough, as clear as the indication to tie a bleeding carotid—operation.

DR. DIXON reported an interesting case, after which he dwelt upon the comparative merits of the two operations, *inguinal* and *lumbar* colotomy.

DR. EMORY LAMPEAR, of Kansas City, Mo., read a paper on

HYPNOTISM IN ITS RELATION TO SURGERY,

and reported cases.

He reported a case of double talipes, in which the subject had a chronic Bright's disease which contraindicated the use of ether, and, at the same time, had an organic heart trouble, which prevented the safe use of chloroform. The patient wanted to be operated upon, and the doctor hesitated to give the ordinary anesthetic, and so hypnotized him. This was the first seance, and contrary to the generally accepted idea that at the first seance a sufficient degree of anesthesia cannot be produced to effect an operation, even at the first seance the doctor got a sufficient degree of anesthesia by suggestion by which he performed the operation for talipes, and the patient lay upon the table as fixed and immovable as a piece of marble during the whole operation.

Another case (reported by the permission of Dr. Shaw of St. Louis) was a patient suffering from Jacksonian epilepsy due to brain tumor. He was hypnotized. The scalp cut, an inch and a half trephine used, the dura mater opened, and a brain tumor weighing one ounce and a half removed. The bone was replaced, and the operation completed, occupying an hour without either chloroform or ether being used, the patient being simply hypnotized.

DR. THEO. POTTER, of Indianapolis, Ind., presented a paper entitled

CERTAINTY IN THE DIAGNOSIS OF TUBERCULOSIS, in which he said there was no important chronic disease in which our opinions, as physicians, are more frequently sought, are more weighty, and more subject to present and future criticism, than tuberculosis. The lack of specific curative treatment and of any great tendency to self-limitation after once well under headway; the destruction of tissue; the existence of subtle, predisposing as well as exciting, elements; the

establishment of the vicious circle, including the organs and channels of nutrition; the strange and often persistent delusion of hope; and, finally, the possibility of arrest or real cure; these factors call, in a peculiar way, for early treatment. But this must depend upon early diagnosis.

In spite of the constant progress from Laennec and Flint, there is no one sign and no combination of signs which is absolute. There is always some uncertainty, and in the early or unusual cases we are and often long remain uncertain. These are the golden weeks and months. But now, with the new light of the present added to the knowledge of the past, we are able to make the diagnosis in the great majority of cases, not only early, but with absolute certainty.

THE HYPODERMIC USE OF ARSENIC.

DR. HAROLD N. MOYER, of Chicago, Ill., contributed a paper on this subject. He said the hypodermic use of Fowler's solution has been recommended by various writers, among others, Hammond, who claimed that the dose which could be administered in this way was much greater than could safely be administered by the mouth; Hammond having given as high as fifty drops of Fowler's solution as an initial dose. Again, he has often carried the amount given by the mouth to the utmost bounds of prudence, till the eyes were puffed and vomiting was almost incessant, and then has continued the arsenic in larger doses, by the hypodermic injection, with the result of the cessation of all gastric symptoms and the cure of the disorder.

In a case of chorea, aged fourteen, female, the patient was placed immediately upon the hypodermic, beginning with three minims of the five-per-cent. solution, and increasing every second day, until three weeks after beginning treatment she was receiving thirteen minims of the solution at each injection, with an arsenic equivalent to about thirty-six minims of Fowler's solution. At the ninth injection she was discharged cured.

In the case of a woman who presented herself at the clinic, in Rush Medical College, with an enormous lymphadenoma of the side of the neck, after a few deep injections into the glandular mass it began rapidly to diminish; when it had lessened one-half, the patient ceased attending, and further results could not be noted.

Dr. Moyer's observation is in accord with numerous writers who have reported equally good results from the use of Fowler's solution in various forms of glandular enlargement passing under the terms, lymphoma, lymph adenoma, Hodgkin's disease. He said the action of arsenic given under the skin, if it have any virtue, must certainly be greater than when taken by the stomach. Thrown into the cellular tissue in the form of a feeble alkaline and readily soluble salt, it is at once absorbed by the blood and carried to all the tissues, administered in this way.

THIRD DAY. — MORNING SESSION.

DR. H. O. WALKER, of Detroit, Mich., read a paper on

PERINEAL CYSTOTOMY VERSUS SUPRAPUBIC CYSTOTOMY.

He said in the choice of method of operation we should be governed (1) as to its safety; (2) as to its simplicity of performance; (3) as to its rapidity of

result; (4) as to its general applicability in the majority of cases. Dr. Walker reported several cases in which he resorted to the perineal method.

The treatment of enlarged prostates with cystitis is equally efficacious by the perineal section and drainage, in furtherance of which he reported a very interesting case.

The perineal method of reaching the bladder is the oldest known to us, although numerous modifications have been made since the haphazard "cut on the gripe," for stone was first done. For the removal of stone litholapaxy undoubtedly stands preeminent, and can be done upon subjects from three years of age upwards, yet there are numerous restrictions to this method, such as stricture of the urethra, large-sized stone, an enormous prostate, etc. There can be no question, when cutting has to be done, that the medio-bilateral method presents the best advantages.

In looking up the literature at his command upon suprapubic operations since 1883, Dr. Walker finds in the record of between three and four hundred operations an average mortality of thirty per cent. A few operators have had a series of cases ranging from three to ten without a death, the most remarkable record in this respect is that of the distinguished surgeon, Dr. Hunter McGuire, twenty-one operations with but a single death. By the perineal method we find a mortality of but five, six, and seven per cent., rarely ever going beyond nine per cent.

DR. EDWIN WALKER, of Evansville, Ind., read a paper entitled

TWO CASES OF TUBAL PREGNANCY.

The first case was Mrs. E. S., age twenty-seven, married four years; sterile. She had a history of uterine and tubal trouble before marriage. Since marriage she had been an invalid, suffering pain in right groin. Menses always irregular, often missed a month or two. Was unwell June 29, 1890, but in July missed her menses. A few days later she began to suffer severe pain in the right groin. August 1st, sanguinous flow began and continued to time of operation. An examination under ether revealed a soft tumor the size of the fist, to the right and behind the uterus. August 17th, abdomen was opened, and the right tube, which was very large, found ruptured and a large amount of clotted blood in the pelvis; fetus not found. Abdomen irrigated with hot water; glass drainage-tube used. Some vomiting and pain, but recovery ensued without a bad symptom. Drain removed on the third, and sutures on the twelfth day. Highest temperature was 101.1°.

The author thinks that the present status of the question is, that with such a class of symptoms as presented in this and other cases, laparotomy is the safest procedure to adopt.

DR. WILLIAM T. BELFIELD, of Chicago, Ill., in a contribution entitled

RÉSUMÉ OF EXPERIENCE TO DATE, ALL OVER THE WORLD, IN THE VARIOUS OPERATIONS FOR CYSTITIS FROM PROSTATIC HYPERSTROPHY,

collected 133 cases of operations upon the hypertrophied prostate, including eight of his own as follows: 41 by perineal incision, mortality nine per cent.; 88 by suprapubic cystotomy, mortality sixteen per cent.; four by combined perineal and suprapubic incision, none fatal.

In 56 of these cases the essential facts before and after operation are furnished; they had been the subjects of cystitis, and dependent upon the catheter for periods varying from one to ten years. In all, the cystitis was cured; in 38 (two-thirds) voluntary urination was restored, and continued during the time of observation, six months to two and a half years; in 18 this function was not recovered. Fifteen of these 56 cases were complicated with stone: excluding these, since it might be objected that the cure resulted rather from the calculus extraction than from the prostatectomy, there remain 41 cases of uncomplicated prostatectomy; of these 32 (four-fifths) recovered the power of urination, in nine this ability was not recovered.

DR. EDWIN RICKETS, of Cincinnati, O., read a paper on "The Difficulty in Diagnosing a Twisted Ovarian Pedicle in Uterine Myoma;" DR. DAVID BARROW, of Lexington, Ky., one entitled "Three Cases of Intestinal Obstruction, with Remarks," and DR. R. R. KIME, of Petersburg, Ind., one entitled "Extra-Uterine Pregnancy, with report of a case of four years and three months duration, Complicated with Enterouterine Fistula."

AFTERNOON SESSION.

DR. SEATON NORMAN, of Evansville, Ind., contributed a paper entitled

TREATMENT OF ORGANIC STRicture OF THE MALE URETHRA,

in which he said in the practice of urethral surgery the operator cannot be too emphatically impressed with the fact of the requisite tenderness and sensitiveness of the urethra, and the employment of the slightest amount of force in the introduction of an instrument should be regarded as a relic of barbaric surgery. When commencing the treatment by gradual dilatation, in sensitive patients, he always produced local anesthesia by the injection of twenty to thirty minims of a four-per-cent. solution of hydrochlorate of cocaine.

Relative to internal urethrotomy, he believes that when it is properly and thoroughly executed and special care is exercised to maintain the patency of the canal until the wound is entirely healed, that recontraction is of rare occurrence. Authority is divided in regard to the performance of internal urethrotomy in the bulbous and membranous urethra. Judging from the results obtained by Harrison, the combination of external and internal urethrotomy offers encouragement for the permanent cure of stricture. Dr. Norman has performed external urethrotomy without a guide only three times, and his results as regards the non-occurrence of contraction have been entirely satisfactory. External urethrotomy with a guide is a simple operation, can be with facility and rapidity performed, and promises more satisfactory ultimate results than internal urethrotomy performed in the deep urethra.

Of the various scales that have been proposed for urethral instruments, only the French system, in the opinion of Dr. Norman, is worthy of consideration. To have urethrotomes graduated in millimetres (and all of them with which the author is familiar are so manufactured), and the sounds corresponding to the English, or any other scale, is, in his judgment, a manifest absurdity.

DR. L. S. MCMURTRY, of Louisville, Ky., made some impromptu remarks on

THE APPLICATION OF ANTISEPTIC METHODS IN MIDWIFERY PRACTICE.

He said many medical practitioners can remember the time when they heard that the wards of certain hospitals were closed and undergoing renovation because puerperal fever had become epidemic in such institutions. The hospital to-day is the safest place in which a woman can be confined. A few years ago, led by Fordyce Barker, we were taught that puerperal fever was an entity, a distinct fever, dependent upon a separate *materies morbi*, just the same as malarial fever is an entity. To-day, we know that puerperal fever, so-called, is a septic peritonitis, just the same as when a woman becomes infected after abdominal section, or after wounds of the peritoneum from any cause, or from infection of the endometrium and through the Fallopian tubes to the peritonium. A woman after labor is a wounded woman. She has undergone certain physiological processes; she has received certain injuries in the process of labor which open the lymphatic channels, by which she may have become infected from without. There is no such thing as a woman having a peritonitis, unless she is infected from without. To prevent this infection, the vagina must be sterilized, the bed surgically clean, the examining finger clean, the nurse clean, and the atmosphere as approximately aseptic as it is possible to make it, etc.

The following papers were also read: "The Advantages of Attending Medical Societies and of Reading Medical Journals," by DR. T. B. GREENLEY, of West Point, Ky.; "Internal Urethrotomy with Cases," by DR. J. V. PREWITT, of West Point, Ky.; "Was it Relapsing Fever?" by A. D. BARR, Calamine Springs, Ark.; "Some Remarks on the Prevention of Myopia," by DR. FRANCIS DOWLING, of Cincinnati, O., etc.

Officers for 1891. — President, DR. C. H. HUGHES, St. Louis, Mo.; First Vice-president, DR. JOHN H. HOLLISTER, Chicago, Ill.; Second Vice-president, DR. S. S. THORN, Toledo, O.; Secretary, DR. E. S. McKEE, Cincinnati, O.

Place of meeting, St. Louis, Mo., October 21, 1891.

Recent Literature.

College Botany, Including Organography, Vegetable Histology, Physiology and Taxonomy; With a Brief Description of the Succession of Plants in Geologic Time, and a Glossary of Botanical Terms. Nearly six hundred illustrations. By EDSON S. BASTIN, A.M., F.R.M.S., Professor of Botany, Materin Medicis and Microscopy in the Chicago College of Pharmacy. Chicago: G. P. Engelhard & Co. 1890.

This book would be a source of instruction and pleasure to any student of botany with an elementary knowledge of the subject. It is an excellent text-book for an elementary college course, and it would be an interesting addition to the library of most physicians, although it contains but little medicinal botany. The parts of the book on histology and physiology of the higher plants are especially interesting.

Although no attempt is made to describe individual species, a moderately full, and for most students sufficient classification and description of the lower plants is given, but only a general outline of the nomenclature of Phanerogamia. A good glossary of botanical terms adds much to the usefulness of the book.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 6, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS : \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

INDEX CATALOGUE (VOLUME XI) OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE.

The eleventh annual volume of the "Index Catalogue of the Library of the Surgeon-General's Office of the United States Army" has just appeared. The present volume includes "Phaedronus" - "Régent." The prefatory note shows that it contains 9,539 author-titles representing 4,585 volumes and 8,908 pamphlets, and 14,262 subject-titles of separate books and pamphlets, and 38,080 titles of articles in periodicals.

An interesting feature of this volume is the word "physician." Under that head are included all the books, pamphlets and magazine articles which are signed "Physician" by their modest authors, and also all those articles and addresses which treat of the duties, the rights, the privileges, and all the possible attributes and belongings of the physician.

The physician, as a nameless author, attracts particular attention in the following title which stands among other titles, with the same signature, as a giant among pygmies. "Physician (A). A physical dissertation on drowning: in which submersion, commonly called drowning, is shown to be a long time consistent with the continuance of life, from a variety of unexceptionable though surprising facts, related by the most eminent and judicious authors, and confirmed by incontestable evidence; which facts are reconciled and accounted for, from the strictest laws of the animal economy. To which is subjoined the proper measures for recovery and relief; the obligations we lie under to practice them are clearly suggested and strongly enfor'd; intended for the good of mankind, by restoring life to many persons who are erroneously supposed to be irretrievably drowned. Recommended particularly to the consideration of the navy and army, who have frequent opportunities of practising the methods recommended. With an appendix, containing some methods for the recovery of those who hang themselves and of children supposed to be born dead, 80 pp., 1 pl., 12mo. London : J. Robinson. 1746."

The number of introductory and valedictory addresses catalogued, is naturally very great. It is curious to notice the similarity of titles in various languages, showing that the same ideas of the physician's duties are to be found in many lands and that the same good advice is given by the aged to the young, in different languages and in different centuries.

While enjoying the impression made by the new volume, the following paragraph appeared in one of the Boston daily papers, and seems to convey a warning to admirers of this giant Index :

"The multiplication of great dictionaries has one serious objection, it seems to me, and that is the opportunity which it affords for unskillful and ambitious writers and conversers to 'load up,' as it were, with epithets which they are incompetent to handle. A great dictionary is a superb armory for a man like Ruskin, although tempting to his besetting sin of magniloquence, but I think he hardly needed such resources as it would afford to lesser men. Choate found inspiration in the dictionary, but it lured him on to redundancy of adjectives, and I can well understand that Mr. Justice Wilde's remark, on being told that the new edition of one of the rival dictionaries had several thousand additional words, had something more than a humorous application, 'I hope Choate won't get hold of it,' said the learned judge."

It is a subject of remark on the part of certain cavaliers that the articles that make up the current medical literature have a tendency to follow a certain line in that the majority of such articles are made up of an unusual case and a more or less perfect résumé of all known literature on the subject; and the question arises whether the "Index Catalogue" does not offer facilities for the easy construction of such articles.

There can be but one answer. It certainly is easier than ever before to construct a composite article on all subjects included in the alphabet up to R. But even if there is greater facility for loose writing, the "Index Catalogue" is a "superb armory" for medical scholars; and it would be easy to mention certain scholars who have used the Index to the great advantage of the general profession.

AUTOPSIES IN AMERICA.

MOST American physicians realize the great advantages for promoting the advancement of knowledge which the medical profession of the continent of Europe have in comparison with us, in being able to procure and report a large number of autopsies. The report of a fatal case is not complete, and the statistics of a fatal disease are comparatively worthless without the certain knowledge which only an autopsy can give.

The fault, of course, lies in our laws, and the law is, undoubtedly, the expression of the will of the laity, and cannot be altered without a change in public opinion; but is not the medical profession also partly to blame? Is not the repugnance which is felt to autopsies in the community due largely to their infrequency?

In countries where post-mortems are considered almost as much a necessary part of death as the services of the undertaker, very little opposition is met with, even from the less intelligent part of the community. In some European States all bodies are removed to a dead-house within twenty-four hours of death, where the diagnosis of death is confirmed, and an autopsy done. In at least one city a law exists that if any person objects to an examination, a complete autopsy must be made.

The American physician is often indifferent or careless after his patient is dead. Except in large cities, it is difficult to undertake a post-mortem examination, and even where it would be comparatively easy, a busy doctor will often prefer to remain in doubt rather than undertake a disagreeable extra amount of work, and perhaps at the same time run the risk of offending the bereaved family. But every post-mortem that is made is so much aid in moulding public opinion, and it seems more than likely that if the medical profession as a whole should systematically request an examination whenever possible, the feeling in the community would soon change. Great assistance might be given in cities by a system which would make the details easy and inexpensive.

We already have laws demanding an autopsy in cases of suspicious death. Would it be too much to ask to have a law allowing a post-mortem on all patients who die in public institutions? This would be a great gain, for these cases have, as a rule, good ante-mortem clinical histories, and the autopsy can be held under the most favorable circumstances. The principal objections to such a law at present are, (1) a rare and indefinite semi-religious feeling connected with the resurrection of the body, in the presence of which feeling no one would want to enforce such a law; (2) the common feeling, already mentioned, of repugnance to the mutilation of the body of a relative, which is now the main stumbling-block; and (3) the fear in the public mind, of ante-mortem autopsies. But the physician realizes that the signs of death are better understood by the pathologist than by the undertaker, and the danger of a premature autopsy is much less than the danger which now exists of premature embalming, nor is the mutilation of the body materially greater. The idea which we occasionally meet among the lower classes that the officers of a hospital take a fiendish delight in dissecting dead bodies, and rather desire the death of a patient in order to get a chance, might at first keep a few cases from going to institutions, but it probably would not do so for any length of time.

It is not necessary to discuss at length the advantages to the medical profession and to the laity of frequent autopsies, or their influence on insurance and mortality statistics and on quackery. Let us hope that before long not only will the physician know that the death certificate which he signs is absolutely true, but that the laity will prefer to know of what diseases their relatives die.

OBITUARY. HENRY JACOB BIGELOW, M.D.

HENRY JACOB BIGELOW, M.D., died at his country house in Newton, Mass., on Thursday, October 30th, at the age of seventy-two.

For the last few years Dr. Bigelow has been subject to gastric disturbances and attacks of hepatic colic; and for several days before his death his stomach refused to retain food. A post-mortem examination showed the presence of gall-stones, and an inflammation of the common duct, which had extended to the smaller bile-ducts, and was attended with the formation of several small abscesses of the liver. There was also a fibrous stenosis of the pylorus and a slight consequent dilatation of the stomach. The pulmonary affection which was the cause of a temporary abandonment of his medical studies in his early manhood had left its traces at the apices of his lungs.

Dr. Henry J. Bigelow was born in Boston on March 11, 1818. He was the son of Dr. Jacob Bigelow, who left a name distinguished in the profession and by many acts of public benefit. He prepared for college at the Boston Latin School, and graduated at Harvard in the class of 1837. His medical studies, which were pursued with his father and at Harvard, were interrupted by ill health, and a consequent trip to Europe. His medical degree was taken in 1841. He immediately returned to Europe, where he spent three years in the further study of his profession, a greater part of this time being spent in Paris. After his return to Boston he was, in 1845, appointed instructor in surgery in the Tremont Street Medical School, succeeding Dr. Reynolds. This position he held until this school was united with the Medical School of Harvard University. In 1846 he was appointed surgeon to the Massachusetts General Hospital. In 1849 he was appointed Professor of Surgery, the two chairs of Surgery and Clinical Surgery, previously held respectively by Dr. J. C. Warren and Dr. George Hayward, being united.

A few months after his appointment as surgeon to the hospital, ether was first used in the hospital amphitheatre for surgical anaesthesia. Dr. Bigelow was one of the first to see the value of the discovery, and he was specially influential in extending the use of anaesthesia in surgical operations. It was chiefly through his paper on the subject that the knowledge of the wonderful discovery was made known.

Dr. Bigelow's writings have not been voluminous, but as contributions to surgical knowledge they have completely changed surgical practice in several particulars. His interest in anesthesia and anesthetics has been repeatedly shown by various articles on ether, nitrous oxide and on rhigolene, a petroleum naphtha for producing anesthesia by freezing. The famous case of Dr. Harlow's of the passage of a crowbar through the head, was made known chiefly through Dr. Bigelow's interest and study of the case. His work on "Dislocation of the Hip-Joint" has banished the old pulleys and rings for its adjustment from the operating theatre.

His litholapaxy has revolutionized the treatment of stone in the bladder and given rise to a literature that far exceeds in volume the united writings of its famous inventor.

But the mere enumeration of his writings fails to show the great influence of the man. He had a unique way of regarding all subjects that attracted his notice. The hospital with which he was connected, shows, in many places, his originality and in-

ventiveness. Acute, clear-sighted, and inventive as he was, he was capable of most close and severe study. The hard work which he bestowed upon the mechanism of the hip-joint extended over several years. His operation of litholapaxy and the instruments for its performance were the result of painstaking labor.

As a teacher he had the power of impressing himself upon his pupils, and of leaving in their minds a sentence or a few words that contained the truth he wished to convey.

He resigned his professorship in 1882, and his connection with the Massachusetts General Hospital in 1886. During the succeeding years he has led a quiet life, for the most part at his country house, where he has taken great interest in the pursuits of a country life, and in these details he has shown the same marked individuality that characterized his surgical career.

MEMORIAL. HENRY J. BIGELOW, M.D.

BOSTON, MASS., November 3, 1890.

MR. EDITOR: — At the meeting of the Faculty of the Harvard University Medical School, held Saturday, November 1st, it was voted that a copy of the following short memorial of Dr. Henry J. Bigelow, which was offered by Dr. R. H. Fitz, be sent to the *Boston Medical and Surgical Journal* for publication.

"The Medical Faculty of Harvard University desires to enter in the Records its appreciation of the eminent services rendered by the late Henry Jacob Bigelow to the Medical School, with which he was connected as Professor of Surgery and Professor of Surgery, Emeritus, for more than forty years.

"Remarkably gifted by nature, his talents were made unusually productive and useful by his intense devotion to the work of the moment, only ceasing with the successful accomplishment of the task.

"His lectures were models of condensed thought and applied knowledge, and were delivered with an aptness of dictation and a richness of illustration which made them ever memorable.

"As a member of the Faculty he was distinguished for the ripeness of his judgment, the wisdom of his conclusions, and the clearness and force of his arguments. Whether as advocate or opponent he was sure to add new light to the subjects under discussion, and was always to be recognized as a leader of men.

"His late and last communication to this Faculty showed a benevolent and beneficent interest in the continued welfare of the School."

Yours truly,
C. P. WORCESTER, M.D., Sec.

MEDICAL NOTES.

— The result of seven years' operation of the Medical Practice Acts in Minnesota has been to reduce the ratio of physicians to population from 1 to 650 to 1 to 1,250. During the last three years 205 candidates presented themselves for examination and 77 of these were rejected.

— The Russian Government has announced that at the end of five years, the decimal system of weights and measures shall be the only legal standard. Great Britain and the United States will then be the only civilized nations which use the ancient systems.

— Dr. Justus E. Gregory, of Brooklyn, recently died suddenly, from the effects of chloroform, in a drug-store. Dr. Gregory had been suffering from neuralgia in the temple, and to relieve the pain was accustomed to inhale chloroform, in the use of which drug he was considered an expert. He went into the store and saying that his eye pained him asked for the chloroform, and sat down to inhale it. A short time later he was found dead.

— The chair of Materia Medica in the Jefferson Medical College, Philadelphia, which has been filled by Dr. Robert Bartholow, was recently declared vacant at a special meeting of the Board of Trustees on the ground that Dr. Bartholow was mentally incapable of holding the position. Among the names suggested for the vacant position are those of Dr. Thomas J. Maya, Dr. S. Solis Cohen, and Dr. Samuel O. L. Potter, Professor of Practice of Medicine in Cooper Medical College, San Francisco.

— The Board of Health of Chester, Pa., have discovered a case of leprosy in that city, and have taken prompt action to have the patient properly quarantined. The unfortunate victim is a Swede, about forty years of age, who has been in this country for about nine years. He was formerly a sailor on coastwise vessels, and is supposed to have contracted the disease on board ship. The first evidence of the infection appeared nearly three years ago, when a small patch showed itself over his eye.

— The following are answers to questions in a recent Minnesota State examination:

"The physical properties of normal urine are hydrogen principally, together with the phosphates taken from the system, also urates and coloring matter such as indigoine, etc."

"An alkaloid is a residue or inferior part left after the principal part of a substance is taken away."

"Symptoms of scarlet fever — malice on the part of the child the sequelae may be death or recovery."

"In cases of death from suffocation the bronchia remain *'in situ quo'* and normal, possibly very little congested."

"The glans penis passes through the prostate gland. There is three lobes or parts of said gland."

"The histological elements found in the human body are blood, urine, saliva, gall, sinovia, and other secretions of glands and membranes."

"The histological elements found in the human body are carbon, oxygen, hydrogen, nitrogen and various gases."

— The prostration, says the *British Medical Journal*, from which the King of Holland is now suffering, is due to uremic poisoning, the result of chronic nephritis of long standing. In the opinion of his physicians, who met a few days since in consultation, the disease has so impaired his consciousness and brain power, as to make it absolutely necessary that the question of a regency should be immediately consid-

ered. This is the second attack of the kind which the king has had. His age is now seventy-four, and the result of the last consultation has been to compel his physicians to make a very serious representation on the subject. Medically, his condition holds out very little hope of recovery.

—The British Minister has transmitted to the Department of State a letter from the Governor of Sierra Leone, inclosing a report from the colonial surgeon at Freetown, Dr. D. Palmer Ross, relative to the case of the nine American missionaries at that place, of whom two were women. They were staunch believers in "faith healings," and consequently took no medicine until three had died and two were very sick with tropical fever, when pressure was brought to bear on them on the ground that they were endangering the community. In view of these facts and of the statement in the *Missionary Review* that another party of missionaries are expected, the Governor of Sierra Leone calls attention to the matter, "as this climate is not suited to those who trust alone to faith healing and ignore the means placed by Providence at their disposal for the relief of suffering humanity."

BOSTON.

—To diminish the danger to life and property from electric wires, the Common Council have passed an ordinance to appoint an inspector of wires, who shall have charge of all wires in the city.

NEW YORK.

—The annual meeting of St. John's Guild was held October 28th, when the reports showed that during the past summer the floating hospital of the Guild made 26 trips, and carried in all 26,136 children with their mothers. At the seaside hospital, which is the largest of its kind in the world, 1,543 mothers and children were cared for.

—The conviction of Joseph Wood, the negro murderer, having been affirmed by the Court of Appeals, he was sentenced October 31st to suffer the death penalty by electricity at Sing Sing prison during the week beginning December 1st.

—James F. Wall, a clerk in the Surrogate's office of Brooklyn, died at the Brooklyn City Hospital, October 30th, under the administration of ether for a surgical operation. It is said that only four drachms of ether had been used when the fatal result occurred.

Miscellany.

LEPROSY IN VENEZUELA.

THE report on leprosy in Venezuela, made to the State Department by the Consul at Maracaibo, describes at considerable length the introduction of the scourge in 1825, when a sufferer from Santa Domingo landed at Maracaibo and spread the infection. In the course of three years the evil had attained such proportions that an island about four miles distant from

the city was set apart for the isolation of incurables. There are now about one hundred and twenty-five patients on the island.

It was at first a much mooted point as to whether marriages should be permitted among the patients. It has always been well understood that a union between a sound and a diseased person would be liable to result in the propagation of diseased offspring, but it was believed that marriage between two undoubtedly lepers was sure to be fruitless; so, after a long discussion, the necessary permission was given, and a number of weddings were celebrated. For years the theory of sterility was not contradicted by experience and seemed about to be definitely settled, when two births occurred on the island, the parents in each case being lepers. Neither of the children have as yet shown symptoms of the disease, and in March of last year one of them, who had reached the age of fourteen years, having passed his whole life on the island with his leprous parents, was allowed to return to society.

Sound wives have been living with diseased husbands, some of whom have arrived at the last and most loathsome stages of the malady. Daughters have ministered to their afflicted mothers for years, and at the death of the latter have returned to the world, where they are to-day healthy mothers of healthy families.

A SIMPLE FEMALE CATHETER.

A SIMPLE female catheter is described in the *British Medical Journal* of June 23d, by Otto Kustner, consisting of a simple glass tube, open at both ends. The advantages claimed for it are that it is easy to clean and sterilize, and is so smooth that abrasion of the mucous membrane is almost impossible. A modification is suggested in the issue of October 18th, by Ralph Worrall of Sydney, New South Wales, whose catheter is made from a piece of glass tubing the size of a No. 8 male gum elastic catheter, eight inches long. One end is melted in the spirit lamp until quite round and smooth. A point one inch from the other end is also softened in the flame, and then this portion is bent down at right angles to the shaft. A catheter with this bend has an immense advantage over a straight tube. It renders the admission of air into the bladder impossible, and it prevents the last drops of urine from trickling back along the shaft.

DISINFECTION OF THE HANDS.

BALL¹ has carefully investigated the subject of disinfection of the hands, in order to establish a routine which shall be sufficiently thorough to be sure of complete sterilization even with previously infected hands, and at the same time sufficiently simple to be properly carried out by any one. His experiments show that the following method answers these requirements better than any other, and that if the details are completely carried out, all micro-organisms are removed:

(1) The finger-nails, whether long or short, are first freed from any visible dirt with a knife or scissors.

(2) The hands and nails are then scrubbed with a nail-brush for three minutes with warm water and a potassium soap.

¹ Deutsche Med. Wochenschrift, No. 7, 1890.

(3) The hands are then washed for half a minute in a three per cent. carbolic acid solution and then in a 1-2000 solution of corrosive sublimate.

(4) Finally the places under and around the nails are rubbed with iodoform gauze, previously soaked in a five per cent. solution of carbolic acid.

THE ELECTRIC LIGHT AS AN ANALGESIC.

VON STEIN of Moscow, says *La France Medical*, reports several cases of different painful affections which have been relieved as if by magic by the electric light. The apparatus which he uses consists of a small incandescent lamp about two inches long, with a reflector in the shape of a funnel, which is applied directly to the skin over the seat of pain. For the head and neck it is left in position for ten or fifteen seconds, but for other parts of the body it remains from one to five minutes, or until the patient complains of the heat. The author has obtained remarkable results in cases of intercostal neuralgia, rheumatic pains of the shoulder, lumbago and severe pain in other parts of the body. The number of applications for permanent relief differs much, sometimes one being all that is necessary.

ERYSIPelas AS A CURE FOR DIPHTHERIA.

A PAPER on this subject by Babinsky is referred to in the *Centralblatt für die Gesammte Therapie*, September, 1890. In the course of a very severe case of diphtheria of the nasal passages, there developed from the region of the nose an extensive erysipelas, with the remarkable result that all previously severe symptoms began to improve, and the patient finally got well. After seeing two similar cases which seemed to show the influence of erysipelas on diphtheria, the author inoculated a child who had scarlet fever and diphtheria with blood from an erysipelatous infection, and the child recovered. Since then he has inoculated fourteen cases of diphtheria from cultures of the coccus of erysipelas. Two of them died before the appearance of the eruption; the other twelve showed the eruption of erysipelas and recovered. It is to be noted that the infection thus artificially produced in all cases was of a benign character.

STOMACH WASHING IN VERY YOUNG CHILDREN.

In order to discover the therapeutic value of lavage of the stomach in very young children, Froitzyk (*Vratch*, Nos. 26 and 27, 1890) tabulated the results obtained in sixty-five babies of from two weeks to four months of age. A Nélaton sound was used, with a glass funnel, and the stomach washed out with a three-per cent. solution of salicylate of soda, in water which had previously been boiled. At least two washings were required to entirely stop vomiting. The treatment was well borne by the children.

The author concludes as follows:

(1) Lavage of the stomach is a valuable means of stopping the development of gastro-intestinal inflammation, especially if begun early.

(2) The most favorable results are obtained in cases of dyspepsia without fever, especially if the stomach

alone is at fault; the improvement is slower in gastro-intestinal affections, and still less marked in purely intestinal trouble.

(3) It is as useful in acute gastro-intestinal disease as in summer diarrhoea, but is not in itself sufficient, and must be aided by other therapeutic measures.

(4) Chronic forms of gastro-intestinal disturbance are improved by this treatment, but must also be supplemented by other means.

DECOMPOSITION OF CHLOROFORM BY ARTIFICIAL LIGHT.

AMONG the disadvantages of chloroform as an anesthetic has been noticed the decomposition of the vapor in the presence of artificial light, especially gas; producing irritating and noxious fumes. These have been analyzed by Kunkel¹ and found to consist principally of hydrochloric acid. Where free ventilation is not possible, he recommends the use of different fluids to neutralize the acid, either exposed in large basins or as a spray. Water in sufficient quantities is suitable for this purpose, or lime water, or solutions of soda or borax.

THE SURGICAL TREATMENT OF TUBERCULAR PERITONITIS.

THE surprising and inexplicable success which has attended the opening of the peritoneal cavity for the treatment of tubercular peritonitis, is the subject of an editorial in the *University Medical Magazine* for November. Evidence has been accumulating till it is now convincing, that even an exploratory incision is frequently followed by permanent cure of the local tubercular processes.

König (*Centralblatt für Chirurgie*, No. 35, 1890) has collected 131 cases of peritoneal tuberculosis treated by abdominal section, of which 23 were greatly improved; 84 were cured (65 per cent.); of these cases 30 (24 per cent.) exhibited no signs of intra-peritoneal tuberculosis for several years following abdominal section. In only three per cent. could death be attributed to the operation. As to the method by which these cures were obtained, examination of the cases shows that there was only one condition common to all; that is, the belly was freely opened, and a certain amount of intra-peritoneal manipulation was practised. Even the employment of anti-bacterial agents seems to be absolutely without influence, except that apparently a greater percentage of cures followed where no disinfectants were used.

A question of major importance is as to whether only certain forms of peritoneal tuberculosis can be cured by section. As is well-known, the effusion may be serous, sero-fibrinous or purulent; may be circumscribed or diffuse. The tubercles may vary in size, being miliary in one case, in another as large as a hazel-nut. The peritoneum may be smooth, roughened, thickened or covered with a pseudo-membrane. In so far as clinical studies go, it would seem that all these different forms have undergone resolution after abdominal section, and consequently that they are all curable.

Peritoneal tuberculosis is dependent upon extension of the tubercular inflammation from adjacent organs,

¹ Centralblatt für Chirurgie, No. 40, 1890.

or to direct infection by means of the bacilli circulating in the blood. Phillips found the lungs involved in ninety-two per cent. of the cases, the pleura also in fifty-six and the bowel in seventy-five. Intestinal invasion by tubercle is frequent, the serosa becoming quickly involved, but this involvement may remain strictly localized, and may undergo spontaneous resolution if the original source of infection, the intestinal lesion, cicatrizes. When, however, the peritoneal involvement comes from a large organ, and is extensive, it is as difficult to conceive the rationale of spontaneous resolution as it is to explain in what way operative procedure, except that of total ablation of the disease, can possibly be of the slightest avail. Yet the fact remains that a gratifying percentage of success follows simple opening and intra-abdominal manipulation in cases of tubercular peritonitis.

Correspondence.

SEVENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

WASHINGTON, D. C., October 27, 1890.

MR. EDITOR:—I am requested by the honorable secretaries of the Committee of Organization of the Seventh International Congress of Hygiene and Demography to call attention to the fact that this Congress will be held in London during the week beginning August 10, 1891.

The governments of all countries and municipalities, and all public health authorities, universities, colleges and societies occupied in the study of the sciences more or less immediately connected with Hygiene are invited to co-operate, and appoint delegates to represent them at the Congress. The Prince of Wales will preside.

A Committee of Organization has been formed, of which Sir Douglas Galton is chairman, and Prof. W. H. Corfield and Mr. Shirley F. Murphy are honorary secretaries. An exhibition of articles of hygienic interest will be held in connection with the Congress. The last of these Congresses was held in Vienna in 1887, and was attended by over two thousand persons, and it is expected that the London meeting will be one of great magnitude and importance.

Very respectfully,

JOHN S. BILLINGS, M.D.,

Member of the International Permanent Committee.

THE AGARICUS RODMANI NOT A POISONOUS MUSHROOM.

22 MONUMENT SQUARE, CHARLESTOWN DISTRICT, BOSTON, 24th October, 1890.

MR. EDITOR:—In the discussion which followed the reading of a paper of mine on "Mushrooms," before the Boston Society for Medical Improvement, the statement was made by Dr. Farlow that poisoning had sometimes followed the use of the common meadow mushroom, or, at least, one of its varieties, and that a fatal case had recently been reported; a statement which startled me and also many of those present, and probably deterred them from personally trying any of the common edible varieties of which I had spoken. Professor Farlow gave as his authority Prof. John Macoon, of Ottawa. I have recently obtained a copy of the *Ottawa Naturalist* for January and February, 1889, in which appeared the article by Professor Macoon. I fail to find in it the slightest evidence presented that the death reported was due to the variety mentioned (*Agaricus Rodmani*), or even that it was the one eaten. To show how easy it is to give a dog a bad name, I quote from that journal, pp. 142-143:

"During the evening the following note, by Prof. John Macoon, on "The Poisonous Properties of the Agaricus Rodmani," was read:

"During the past autumn many edible mushrooms have been collected in the vicinity of the city, some of which have had doubts thrown upon their value by an unfortunate occurrence which took place early in September.

"A lady purchased two lots of mushrooms on the market, one from the grocer, and the other from the open market. The latter lot was that from which the lady partook, and which resulted in her death.

"Later in September, Mr. Martin Benson of this city, also purchased a lot on the market, and when they were being cooked his wife noticed that they had an offensive smell, and the family refused to eat them. A few were sent to the writer, who advised Mr. Benson not to use them as they were, to say the least of it, unpleasant to both taste and smell.

"A few were dried, and then forwarded to Prof. Charles Peck, New York State Botanist, who is the highest authority on Agarics in America. He reported that the mushroom in question was related to the edible one, and that it had been found in New York State and in France. He said that in France it was popularly known under the name of *Agaricus Rodmani*, but that upon his own suspicion, but for the part he did not think it was poisonous, owing to its woody nature and unpleasant smell, he did not set much value on it. Its scientific name is *Agaricus Rodmani*, having been named after its discoverer. It differs from the common mushroom in having an unpleasant smell while being cooked, in being quite firm and not expanding nearly so much, and in the stem being quite large where it joins the cap and tapering to the point, which seems to enter the soil to some depth."

Mr. Peck, in the "Report of the Botanist for 1883" (N. Y. Sen. Doc. No. 53), page 45, says of *AGARICUS RODMANI*, Pk.:

"This species is intermediate between *A. campestris* and *A. arvensis*. . . . The flesh is quite thick and firm its thickness The stem is thick, exceeding in diameter that of the lamellae. This character, together with the solidity of the stem, indicates a disposition in the species to produce flesh rather than fruit, and may make it more desirable for cultivation than the common mushroom [the italics are mine]. . . . The species is respectfully dedicated to its discoverer [Rev. W. Rodman]. Its edible qualities are deemed equal to those of the common edible mushroom. It has been tested by Mr. G. Rodman. It is apparently a rare species, but may be more common than is supposed, for it may possibly have been heretofore confused with the common mushroom, which it much resembles in color."

The quotations given are sufficient, and do not need further comment from Yours very truly,

EDWARD JACOB FORSTER, M.D.

CONSUMPTION IN MASSACHUSETTS.

BOSTON, October 21, 1890.

MR. EDITOR:—In the matter of the prevalence of consumption, I would like to make a suggestion, and enter a plea for Massachusetts.

In the very able paper of the late Dr. W. Everett Smith upon the relations of climate to health and disease communicated to the Massachusetts Medical Society,¹ he says: "The census of 1880 gives presumptive evidence that the greatest prevalence of pneumonia is in the Southern and Southwestern States" (fol. 126).

Perfection in vital statistics is no more likely to be reached than in human nature. It is, however, generally acknowledged that those of Massachusetts approach it more nearly at present than those of any other sister State where a general registration law exists. There are several reasons why this result is more easily attained here, which it is not necessary to my purpose to mention. All comparisons of the vital statistics of Massachusetts with those of her sister States, and consequently all presumptions and sanitary inferences therefrom are absolutely valueless, (1) because general registration laws exist in but very few of the States, and (2), for the reason that where they exist they are very imperfectly administered.

In the principal cities of the country where registration exists under or in the absence of a general law, we have

¹ Relations of Climate to Health and Disease. Med. Com. Mass. Med. Soc.

no special reasons to doubt the accuracy of the returns other than those which will apply to Massachusetts; but statistics of cities will not answer the purpose of general statistics.

Presuming those Southern States having a majority of negroes in their populations to have general registration laws, the sparseness and ignorance of the populations in the country districts would, with the customs of the country, render any efficient enforcement of them impossible under ordinary conditions, even without recognizing as a factor the general indifference and absence of comprehension of the value of such laws among the better educated.

I have in my mind one Southern State which has had a registration law upon its statute book for several years. Not long since, in looking over the printed report of its Board of Health, which had been presented to the Legislature, and was a full-fledged public document, I found in one county, in which was a city of 30,000 inhabitants, *fourteen deaths reported as the total mortality for the year*; and in another county, with a city of 25,000 inhabitants, *a death-rate for the same year of twenty-four!* I contend,

therefore, that the presumption of Dr. Smith, *loc. cit.*, although it is in our favor, is without reasonable foundation if based upon statistics.

Dr. French, in his paper upon "Consumption in Massachusetts," in your issue of October 9th, states the showing of the Census, 1880 (based on valueless returns), to be that "the mortality in the United States from consumption is 12.05 per cent. of the entire mortality, or less than four-fifths as great as it was in Massachusetts alone during the years mentioned" (the italics are mine), and then asks, "Why this excess in Massachusetts?"

I reply that it is not yet proven, and cannot at present be proven, that any such excess exists, or that Massachusetts is entitled to any prominence in this dread disease over her sister States located upon our exposed Atlantic coast, from Massachusetts to Florida.

If presumptions are allowable, I shall presume that the undue prominence given Massachusetts in the mortality from consumption is entirely due to the superior accuracy of her vital statistics, and has no foundation in fact.

Very truly yours, GEORGE R. STETSON.

REPORTED MORTALITY FOR THE WEEK ENDING OCTOBER 25, 1890.

Deaths reported 2,349; under five years of age 830: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 361, consumption 298, acute lung diseases 241, diphtheria and croup 128, diarrhoeal diseases 101, typhoid fever 59, whooping-cough 23, malarial fever 20, scarlet fever 15, menes 8, cerebro-spinal meningitis 6, erysipelas 1.

From whooping-cough, New York 10, Philadelphia 5, Brooklyn 3, St. Louis, Baltimore, Boston, New Orleans and New Bedford 1 each. From malarial fever, New Orleans 9, Brooklyn 5, Baltimore 3, New York, Philadelphia and Nashville 1 each. From scarlet fever, Brooklyn 5, Philadelphia 3, New York and St. Louis 2 each, Baltimore, Lowell and Springfield 1 each. From

measles, New York 5, Brooklyn 3. From cerebro-spinal meningitis, Washington 2, New York, Brooklyn, Baltimore and Haverhill 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,559, for the week ending October 11th, the death-rate was 19.8. Deaths reported 3,688: diarrhoea 328, measles 92, diphtheria 61, scarlet fever 58, fever 51, whooping-cough 49.

The death-rates ranged from 12.4 in Derby to 32.9 in Blackpool, Bradford 25.6, Huddersfield 19.4, Hull 17.8, Leeds 22.9, Leicester 19.6, Liverpool 22.7, London 17.4, Manchester 29.0, Nottingham 17.7, Sheffield 21.1, Sunderland 22.9. In Edinburgh 17.3, Glasgow 19.2, Dublin 19.5.

The meteorological record for the week ending Oct. 25, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending	Barometer.		Thermometer.		Relative Humidity.		Direction of Wind.		Velocity of Wind.		State of Weather.*		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 25, 1890, TO OCTOBER 31, 1890.

Leave of absence for one month, to take effect about the 31st instant, is granted First Lieutenant J. D. GLENNAN, assistant surgeon. S. O. 146, Par. 1, Department of Missouri, October 23, 1890.

Leave of absence for one month, with permission to apply for an extension of fifteen days, to take effect upon the arrival of Acting Assistant Surgeon A. P. FRICK, at Fort Marcy, is granted Surgeon STEPHENS C. GOWRERY, United States Army. S. O. 112, Par. 2, Department of Arizona, Los Angeles, Cal., October 23, 1890.

By direction of the Secretary of War, the following changes in the stations or officers of the medical department are ordered: First Lieutenant CHARLES E. WOODRUFF, assistant surgeon, is relieved from duty at Fort Gibson, Cal., and will report in person to the commanding officer, Fort Missoula, Mont., for duty at that post. Lieutenant CHARLES E. WOODRUFF, assistant surgeon, Fort DeWitt, upon being so relieved, will report in person to the commanding officer, Fort Hancock, Tex., for duty at that post. S. O. 249, Par. 6, A. G. O., Washington, D. C., October 24, 1890.

By direction of the Secretary of War, the leave of absence granted Captain CHARLES B. EWING, assistant surgeon, in Special Orders 131, September 22, 1890, Department of the Missouri, is extended fourteen days. S. O. 230, A. G. O., October 25, 1890.

Leave of absence for one month, on surgeon's certificate of disability, is granted Captain GUY L. EDIX, assistant surgeon, United States Army, Fort Douglas, Utah. S. O. 80, Headquarters Department of the Platte, Omaha, Neb., October 31, 1890.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FROM OCTOBER 6, 1890, TO OCTOBER 25, 1890.

HUTTON, W. H. H., surgeon. Detail as chairman, Board of Examiners, revoked; ordered to Washington, D. C., for temporary duty. October 14, 1890.

WYMAN, WALTER, surgeon. To inspect quarantine stations. October 14, 1890.

LONG, W. H., surgeon. Detailed as chairman, Board of Examiners. October 14, 1890.

SAUTELLE, H. W., surgeon. Granted leave of absence for five days. October 13, 1890.

GASSAWAY, J. M., surgeon. Granted leave of absence for thirty days. October 11, 1890.

IRWIN, FAIRFAX, surgeon. Detailed as recorder, Board of Examiners. October 14, 1890.

AMES, R. P. M., passed assistant surgeon. Granted leave of absence for thirty days. October 14, 1890.

WHITE, J. H., passed assistant surgeon. Granted leave of absence for thirty days. October 24, 1890.

PETTUS, W. J., passed assistant surgeon. To proceed to Vineyard Haven, Mass., for temporary duty. October 9, 1890.

PERRY, T. B., assistant surgeon. Ordered to examination for promotion. October 9, 1890.

KINYOUN, J. J., assistant surgeon. Ordered to examination for promotion. October 10, 1890.

CONDICT, A. W., assistant surgeon. To proceed to Baltimore, Md., for temporary duty. October 18, 1890.

RESIGNATION.

AMES, R. P. M., passed assistant surgeon. Resignation accepted by the President, to take effect November 15, 1890. October 14, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 1, 1890.

F. B. STEPHENSON, surgeon, detached from Receiving-ship "Wabash," and wait orders.

H. M. MARTIN, surgeon, ordered to the Receiving-ship "Wabash."

LEWIS H. STONE, assistant surgeon, ordered to the U. S. S. "Pinta."

WILLIAM F. ARNOLD, assistant surgeon, detached from the U. S. S. "Pinta," and granted two months' leave.

THOMAS OWENS, surgeon, detached from the Coast Survey Steamer "Blake," and wait orders.

N. J. BLACKWOOD, assistant surgeon, ordered to the Receiving-ship "Vermont."

E. S. BOGERT, assistant surgeon, detached from the U. S. S. Receiving-ship "Vermont," and to the Coast Survey Steamer "Blake."

A. M. MOORE, surgeon, detached from the U. S. S. "Kearsarge," and to the Naval Hospital, Mare Island, Cal.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, November 18, 1890, at the Medical Library, 19 Boylston Place, at 8 o'clock P.M.

Readers: Dr. F. C. Shattuck, "A Case of Hydatids of the Liver"; Dr. S. J. Mixter, "Further Remarks on Permanent Tubage of the Oesophagus." G. G. SEARS, M.D., Secretary.

AMERICAN ACADEMY OF MEDICINE.—The annual meeting will be held at Philadelphia, Wednesday and Thursday, December 3 and 4, 1890. RICHARD J. DUNGLISON, Secretary.

GYNECOLOGICAL SOCIETY OF BOSTON.—There will be a meeting of this Society at 19 Boylston Place, on Thursday, November 13th, at 4 o'clock.

Paper: "Intra-uterine Diseases, their Diagnosis and Treatment," by Frank L. Burt, M.D. S. N. NELSON, Secretary.

OBITUARY. JUBAL CONVERSE GLEASON, M.D., M.M.S.S.

Dr. J. C. Gleason, died in Rockland, Saturday, November 1st. He was born in Hinghamton, November 7, 1818, and graduated at Andover in 1838. He practised medicine at the Berkley Medical College and at the Harvard Medical School in the class of 1867. After practising a short time in Gilberville, he removed to Rockland, where he remained for the rest of his life. In 1877 he was appointed medical examiner of the second Plymouth district, and continued in that position until his death. He was in the Massachusetts House in 1870 and 1882. In 1887, 1888 and 1889, he was a member of the Senate from the first Plymouth district. He was a Fellow of the Massachusetts Medical Society and one of its Councillors. He leaves a widow and one daughter.

Original Articles.**CASES IN WHICH THE DISEASE INDICATED BY THE SYMPTOMS WAS NOT FOUND ON POST-MORTEM EXAMINATION. WHY DOCTORS MAY BE NON-COMMITAL SOMETIMES.¹**

BY BENJAMIN E. COTTING, M.D., M.M.S.N., OF BOSTON, MASS.

CASE I. In the winter of 1884-85 a hard-working and industrious blacksmith, aged sixty-three years, consulted me for a difficulty in swallowing his food, or rather a difficulty of getting his food into his stomach after he had swallowed it. This had come on very gradually, until at the time of the consultation, he had almost abandoned solid food and was then living on liquids, or at best, on semi-solids occasionally. The food swallowed appeared to be arrested at about the lower third of the oesophagus, where it remained until most of it was rejected by retching and other similar efforts. Only a small portion, even of liquids, seemed to reach the stomach. The patient had lost much flesh and was greatly enfeebled. On examination nothing could be felt abnormal on the outside. A probang of one-half inch diameter was arrested at about the lower third of the oesophagus and could not be passed. An olive-shaped ivory probang of three-eighths of an inch in diameter by careful manipulation could be made to pass the place of the obstruction. The passing of this smaller instrument seemed to dilate the parts, and to allow the passage of food more readily for a few days. The operation required to be repeated every week or so for some time following, but by the end of spring the passing of the instrument became more and more difficult, and a large sized elastic catheter only could be passed. Through this, milk and other nutritive fluids were carried into the stomach, but to a limited amount only. Later, a good sized tube, tapering to a point and ending in a very small olive-shaped bulb, could be worked by patient manipulation through the obstruction to the stomach. Through this, by means of a funnel, considerable nutriment was, from time to time, administered.

Meanwhile, the patient became more and more emaciated and enfeebled. He had abandoned work and could walk about with great difficulty only. Another physician assisted me in the care of him and he occasionally saw other medical men.

During my summer vacational absence he consulted a prominent surgeon, an attendant of the Boston City Hospital, who, after a careful examination, told the patient that he had a cancerous stricture of the food passage, and gave him no encouragement as to his future. The patient was dreadfully agitated at the terrible name given to his disease, and at once perceptibly broke down in hope and strength. He, however, mustered up courage enough to apply to the Massachusetts General Hospital, where he was examined by several attendants who gave him, in general terms, the same diagnosis without using the terrific word which had so crushed him.

On my return, late in the autumn, I found him in a deplorable condition, with hope and strength gone, and extremely emaciated. To gratify friends and himself, I caused him to be taken to the office of one of the surgeons of the Massachusetts General Hospital who, the

patient thought in his visit there, had, in his kindness of heart, somewhat encouraged and cheered him. A letter from this surgeon to myself now before me, dated November 18, 1885, says — "Thanks for sending in the stricture of the oesophagus which has certainly contracted since I examined him last."

The object of introducing the foregoing quotation, is, to show that there was no doubt about the diagnosis in this surgeon's mind, as there had never been, so far as I know, in the minds of any of the other medical men who had examined the case. The patient lingered along, starving to death in spite of all efforts to sustain him, and died in the way usual in such cases accompanied with malignant disease.

If there ever was a case of stricture of the oesophagus capable of demonstration during life, surely this seemed to be one. The evidence was complete and not to be mistaken by any medical man. And yet there was no stricture; there was no cancer of the part; the oesophagus was normal throughout, and without a particle of disease.

On post-mortem examination, the oesophagus was found unharmed, and as above described. The cardiac and pyloric orifices were free from disease, as also the rest of the stomach, except midway along the larger curvature. At this place there was a mass of three large diagonals of cancer two to three inches long, lying diagonally across the median line. No other part of the body was found diseased.

CASE II. In the spring of 1870, a gentleman, aged fifty-five years, came into my neighborhood to pass the last days of his life, which was rapidly terminating in the last stages of reputed cancerous disease, at or near the pylorus. He had the usual symptoms of this disease and in his travels about the country had consulted various physicians who all were understood to have given such a diagnosis. The pain and the distress after taking food, and the subsequent rejection by vomiting somewhat later; the gradual emaciation and debility as well as the peculiar aspect of the skin and expression, were all present. And further, a well-marked tumefaction over the region of the pyloric orifice, with an apparent mass there, tender on manipulation, gave previous examiners little or no doubt concerning the nature of the malady.

As I had been called in merely to assist in soothing the last hours of this patient, I naturally wished to save him the discomfort of any unnecessary explorations. I, however, made examinations sufficient to convince me of the high probability of the diagnosis which had been communicated to me on my assuming charge of the case.

On the death of this patient a few weeks later, a post-mortem examination was made, by a thoroughly skilled expert in such matters, and, not only was there not found cancer or any other disease in the stomach, but a most minute and thorough examination gave no evidence whatever of anything morbid in the body, or indication of what had destroyed life in this instance.

CASE III. A gentlewoman, about seventy, a stout and well sustained person, lost her appetite without any known reason therefor. For this ailment she took at her own instance a proprietary medicine containing chiefly, so far as known, a "warming stimulant in ginger syrup"; this "warming stimulant" being apparently, besides the ginger, capsicum and alcohol. The number of bottles of this preparation, which this

¹ Read before the Norfolk District Medical Society, October 28, 1890.

good woman took in the course of a few weeks, was past belief, it amounted to many dozens. When at last the stomach rejected the "remedy" as well as everything else, I was asked to restore it to health. As I failed to do this satisfactorily, the aid of other medical men was sought for in consultation or otherwise. Most of the examiners thought that the digestive powers of the stomach had been irretrievably ruined by the preparation that had been so freely taken by the patient. Malignant disease was thought not impossible; and ulcer of the stomach was also suggested. One physician, however, stoutly maintained that the malady was a cancer of the pylorus; and was quite disgusted that the others could not fully agree with him. His array of facts and symptoms was certainly very formidable on paper, and his arguments based upon them were very strong, and almost complete. Still the history of the case, and especially its pre-professional treatment, caused others to hesitate. All agreed, however, that the end was necessarily fatal.

Owing to this difference of opinion, a post-mortem was looked forward to with considerable interest. It was made by an expert who did his work thoroughly and well. The stomach was large and flabby, but was not diseased. The mucous membrane was unbroken and hardly a spot could be found that gave any evidence whatever that there had been irritation there much less inflammation. All the other organs were in normal condition.

The immediate cause of the narration of the foregoing cases was the chance finding of the letter quoted and about the same time the accidental overhearing of an indignant damsel's remark that she "didn't see why doctors need be so non-committal ; there's no getting a positive opinion out of any of them." True enough, perhaps, for the difficulties attendant upon the making of a correct diagnosis seem to be incomprehensible to all outside of the medical profession. The public appear to think that a medical man should at once diagnose a case at "ten paces," and without touching the patient — sometimes he can do this but not often. Generally, even common cases require most careful investigation, and serious study. Nothing could have seemed clearer to the examiners than Case I above related. The probang was arrested at once by a seemingly solid obstacle, which never abated for an instant through the long progress of the disease. The apparent stricture became more and more confirmed as the case went on until the closure was nearly or quite complete. That it was cancerous seemed evident from the general condition of the patient, and from the fact that strictures of the esophagus are seldom, if ever, non-malignant. What gave rise to these deceptive symptoms, so constant and unrelenting, is more than we can fathom; and their unreality may now serve to restrain a too positive opinion in similar circumstances.

In Case II the symptoms were less tangible, but sufficiently perceptible to warrant the conclusions arrived at by the medical examiners ; and yet no results attributable to the disease indicated could be found after death.

Case III seemed to have sufficient cause for fatality, though the specific ailment admitted of more doubt than in the other cases, and no one of the attendants was fully correct in his diagnosis. In fact, the

autopsy gave no definite solution in this regard, nor can it help to positiveness in any subsequent similar case.

In view of such instances, and there are enough such for frequent reminders, it is not to be wondered at that medical men hesitate — especially if they are well posted in the vagaries of disease.

But why marvel at their reluctance to commit themselves when indications are often so misleading; for after all, other men in less difficult calling are not less non-committal even without apparent reason. If State officials when announcing the result of an election say of a candidate who has received nine-tenths of the ballots that "*he appears to be elected*," why may not a medical man when nine-tenths of the symptoms point in a certain direction, say that the patient *appears* to have the disease thus indicated. And if he so qualifies his opinions, should he not be commended rather than blamed therefor ?

COCAINE ANALGESIA; ITS EXTENDED APPLICATION IN GENERAL SURGERY, WHEN HYPODERMICALLY EMPLOYED.

BY THOMAS H. MANLEY, M.D., NEW YORK.

SINCE Dr. Karl Koller first demonstrated to the medical world, the therapeutic properties of cocaine, experimenters and physiologists have been occupied in endeavoring to discover the *modus operandi* of the drug. I find in scanning the latest literature on the subject, that authors proclaim the most discordant views, with reference to its physiological action, when administered internally or hypodermically.

One¹ says that it locally paralyzes the sensory nerves ; another,² that the paralysis or loss of sensation is secondary to an impression on the vaso-motor nerves, which, by their inhibitory action, cause stagnation in the blood-vessels interfering with the nutrition and sensibility of the sensory nerve-filaments ; while Paul Bert³ asserts, that the drug, when used hypodermically, its effects only extend as far as the tissues in which it comes directly in contact. According to Von Ploss,⁴ in order to cause death, enormous doses of the alkaloid would be required. As an instance, in confirmation of this assertion, he cites the case of a druggist who took twenty-two grains with suicidal intent. Shortly after swallowing the dose he went to sleep, but shortly awoke, with a violent headache ; which, however, in a few hours passed away, and he felt no inconvenience whatever.

On the present occasion I am concerned only with the local action of the analgesic, when injected into the tissues in solutions of various strength ; and, strange to say, I can find no American nor English contributor, who has written any systematic or extended articles on the uses of cocaine when injected into the tissues. This would seem to indicate, that as yet, very many regard the propriety of administering it hypodermically, in surgical operations, as of doubtful expediency, if even permissible, at all. This must arise either from an unreasonable prejudice, want of observation in its application, or an unpleasant experience with its administration.

¹ Wood's Therapeutics, vol i, p. 217.

² Lauder Brunton: Therapeutics.

³ Wood's Handbook of the Medical Sciences, vol. vii, p. 260.

⁴ Die Pflanzen Stoffe, p. 107.

All admit its wonderful power in the surgery of the eye and the nose and throat, in fact, in any part lined by mucous membrane; but, when we come to the great serous cavities; the muscular, vascular and cellular tissues, there is a portentous silence, which would seem to imply, that here, at least, it can serve no useful purpose.

I am convinced after an extended observation that this alkaloid ranks second to none, in safety and in general application, except in those surgical cases in which considerable time is consumed in operating. With my first trial of it, I was disappointed and disgusted, so that for more than three years after I wholly abandoned its use, and listened with incredulity when I heard any one speak of its value, as an analgesic, in hypodermic dosage.

The first case I tried it on was in Ninety-ninth Street Hospital, in the winter of 1886. My patient had had his leg so crushed, by a railroad accident, that I had to amputate close to the knee joint. In my desire to economize tissue, I found when the integuments closed over the stump, that there was scarcely enough to provide proper protection to it; hence, I decided to resect the exposed end of the tibia and spread the flaps over it.

As my patient was loath to take ether again, I advised the hypodermic administration of cocaine, which I assured him would so benumb sensation that no suffering would be felt. He groaned terribly when the hypodermic needle was introduced, so that it required three assistants to hold him. At last having emptied three syringefuls (thirty drops in each) of a four-percent solution, or nearly four grains, I took up the scalpel and made a free, oval incision along the outline of the stump, thereby dividing several of the surface veins, which were gorged with blood by the pressure of the elastic-band. He now became utterly unmanageable, and for a time his screams could be heard over considerable distance; and, to add to our dismay, he reeled over in a faint, became nearly pulseless, cold and deathly pale. After perhaps, twenty minutes, reaction set in, and in a short time, he was feeling better again. We postponed further operations till the next day, when under ether, we completed our resection of the stump. I need hardly say, that with this experience my enthusiasm for cocaine had faded out, and I felt earnestly thankful that a life was not lost through our experiment; for, I was thoroughly frightened.

It was not until last May, after having read the classical *brochure* of the distinguished French surgeon, Paul Réclus,⁴ on cocaine, that I again resorted to it in surgical operations.

Réclus's article throws a flood of light on the question. He reports seven hundred operations performed with the hypodermic injection of cocaine; among them colotomy (iliac), gastrotomy, nephrotomy, operation for typhilitis, lithotomy, perineal and suprapubic urethrotomy; for fistula in ano; cholecystotomy; for necrosis, minor amputations, hernia, reducible and strangulated; besides, plastic operations, and many others of a minor character. He claims to have made a searching examination into the literature of the subject and can learn from German, English and French sources, of but one death, which could be clearly attributed to the lethal action of the alkaloid.

He attaches great importance to the quality and freshness of the drug; and claims that many accidents,

immediate and remote, are attributable to the adulterated article, or else to stale, septic solutions. His most marvellous successes have been in anthrotomies, in tubercular disease; wherein he cocainizes the integuments, opens the joint, injects his cocaine solution, and then thoroughly drenches the articulation with a solution of mercuric-chloride or thymol.

Inflammation, he says, is no contra-indication, as it will act equally well then, as at other times, and that the engorged vessels manifest a marked diminution in volume, after its injection. In bone operations we are warned to be certain that the analgesic be deposited within the periosteum, if we would succeed.

Much importance is attached to dosage; small quantities, from ten to twelve centigrammes (from one-third of a grain to two grains) in a one per cent. solution is the maximum for each operation. The operator is directed to use a syringe with a long, very fine needle. The field of operation is to be divided by a quadrangle; along each lateral outline, the needle is to be introduced its whole length. Now, we are directed to do two things simultaneously; and to this, much importance is attached; namely, as we commence to send the piston home, we begin to withdraw the needle, timing both, so that the syringe will be drained before the needle's tip emerges from under the skin.

By sending the needle in four times, in rapid succession, and spraying the tissues, according to the plan directed, we not only paralyze a large district, but we also are free from the accidental injection of a lethal dose into a blood-vessel; for should the point of the needle enter the lumen of a vessel, as we commence its withdrawal, at the instant that the solution commences to escape, but very little will enter the vessel, and the danger is obviated of injecting considerable quantity into it.

We are told, by the same author, of its priceless value where the patient has a deep-rooted fear of ether or chloroform; when there is a weak heart, kidney disease or bronchitis; when no assistant is at hand, to give the anesthetic, as with the isolated country practitioner, or when there are no means to compensate an assistant.

After having studied M. Réclus's contribution, which reads more like a romance than a reality, I decided to test the truthfulness and value of his assertions, as soon as I resumed service in the Harlem Hospital, and cases came under my care in which I felt it would be policy to use cocaine hypodermically. It is scarcely necessary to go over in detail each separate case; but I may say that I have used it, in and out of hospital, more than fifty times since, without the slightest accident, or inconvenience, or mishap. There were three herniotomies (two of which were strangulated; one in a woman; all making splendid recoveries); one opening and draining of a hydronephrotic cyst; four fistulas in ano; two pleurotomies for empyema; one suprapubic incision into the bladder; one case of operation for cancer of the lower lip; one urethrotomy; one laparotomy for serous cysts in the broad ligament; one case of gun-shot wound of the thorax, for resection of fragments of shattered ribs; four lithotomies (perineal, and for enucleation); three of mucoid and lipomatous tumors; with some thirty or more minor operations on ambulant cases.

In my hospital service, the use of general anesthetics is now practically discarded, except in those cases requiring much time, and in capital amputation: s.

⁴ Cocaine-Anesthesia; Le Mardi Medico, Mai 12, 1890.

MANNER OF PREPARING PATIENT AND ADMINISTERING THE COCAINE SOLUTION.

After the part is scrubbed and is rendered thoroughly antiseptic, the patient is placed in a prone position, if possible, the face covered lightly by some light fabric, so as to completely close off the field of operation from vision. This is highly important, for with nervous, sensitive patients, the sight of instruments or the presence of blood will immediately induce syncope.

When I am operating on a limb, I apply the elastic constrictor, according to Dr. Corning's plan, before injecting. In other situations, after I have sprayed the deep tissues, with each injection I seize the underlying parts and knead them with the finger and thumb. In those patients who have very fine, thin, sensitive skins, before I puncture the parts with the hypodermic needle, I douche the surface with a syphon of ice-cold Vichy, which so benumbs the integuments, that the needle is not felt, nor is the cutting edge of the scalpel. I commence to operate almost immediately, after my field for operation has been sprinkled at such depth as may be required.

The rule so far has been that my patients have lain so quietly, that one seeing me operate, and not seeing the patient's head, would suppose him profoundly anesthetized; while, as a matter of fact, not a single faculty has been disturbed. From six to twelve centigrammes will so paralyze the reflexes that the effect is positive for fully a half hour or more.

Cocaine analgesia very greatly simplifies an operation. No force or violence is necessary to restrain the patient; and as Récluz well says, one of the most important and useful of all assistants is the patient himself, shifting and moving in any direction required. It reduces the number of assistants fully half, which is an item to an impecunious patient. As a matter of expense, in itself the cocaine is ten times less expensive than ether. In operating at night, we are not in constant danger of being incinerated, and we can carry enough of the hydrochlorate in our vest-pocket, without inconvenience, to do a dozen operations. It will be observed in surgical operations, which entail cutting, that the culminating action of the drug is interrupted or prevented by the escape of more or less of the solution along the line of the incision.

To attain the best results, the directions of Récluz must be carefully observed, especially with reference to the manner of introducing the needle and circumscribing the zone to be invaded.

DANGEROUS COMPLICATIONS OR SEQUELÆ ATTENDANT ON THE HYPODERMIC USE OF COCAINE.

Many well-known operators have acquired a violent dislike for the hypodermic use of cocaine, because some time in their practice it gave them a fright; hence, their imprecations against it in any form. They allege that it has given rise to such alarming symptoms, that they have come to regard it as a potent agent for harm; besides, not infrequently when one is able to go through the operation without much resistance, yet they suffer from vertigo and bodily weakness to such an extent as to require several hours rest before they are quite themselves again.

I have investigated many of these allegations, and find that the complaints mainly come from those who use the drug too timidly or injudiciously. With women, we will surely come to grief unless we exercise great

caution; for it has been observed with young girls and hysterical individuals to act with extraordinary energy on the nerve-centres, and may give rise to considerable temporary excitement. Hence, we resort to deception with these cases, for, if we do not, the effects of the imagination will more than counteract the good of the alkaloid. We must assure them that the operation will not be painful, and gain their confidence. If it can be avoided, they should not be permitted to see the instruments or know precisely when the regular steps of the operation are to begin.

The hypodermic injection of the solution may be made a very painful procedure, in itself, in the hands of one awkward or inexperienced; so that the patient determinedly abandons any further manipulation. Accordingly, under these circumstances, it is well to first benumb the integuments with an ether spray, or, what is better, by the douche of a syphon of ice-cold Vichy, before we introduce the needle. We should not inject more than from six to ten centigrammes in a woman, and see to it that every possible provision has been arranged, so that almost at once, and before the drug has been absorbed by the circulation, make the primary incision into the cocainized area; for it acts with nearly instantaneous celerity when injected into the cellular membrane; and, besides, the free incision permits of the draining off, with the blood and secretions, of any redundancy which might accumulate.

With those patients who become boisterous, and go into collapse, I was confident that, in the majority of cases, it comes of fright and painful anticipation; and not from the medicine. Every one knows how keenly alive certain individuals are to mental impressions: in this instance, to the array of instruments, basins, lotions, dressings, and to the elaborate preparations to forestall haemorrhage, etc., the very sight of which may, indeed, test the courage of the stoutest. The patient takes the chair in almost a state of syncope. The condition of the patient is not wholly free from contagion, if we are not prepared for it; and hence the operator's hand becomes unsteady. The needle is sent in; to the patient the supreme moment has arrived, and over he goes onto the floor. The rolling eyes and ghastly pallor strike terror into the hearts of the friends; and the "injected poison" (?) comes in, for their fiercest denunciation, when, as a matter of fact, it probably was in no way concerned whatever in the phenomena. Herein comes an explanation. With cocaine anaesthesia the psychical faculties are intact; hence syncope, fluttering pulse and alarming symptoms. I have observed in every one of my patients who were profoundly sceptical of the powers of the analgesic, that during the momentary interval elapsing between the injection of the solution and the incision, they become deathly pale; their breathing was rapid and shallow; and their pulse nearly uncountable; but after the edge of the scalpel entered the deep parts, and they were convinced that no pain was to be borne, those symptoms passed off, as if by magic.

CONCLUSIONS.

In presenting this summary of my experience and my views, I have drawn freely from the invaluable brochure of Récluz, to which I had to turn almost exclusively for information as to the use of cocaine in general surgery. I am particularly gratified to be able to verify, in every particular, the fidelity

and accuracy of every line in his scholarly and elaborate article.

That cocaine analgesia is one of the greatest boons ever conferred on humanity, is undeniable. There is scarcely a limit to its application; the great difficulty being to understand how it shall be administered, the conditions under which it must be proscribed, and to be on the alert for those indications in operations which warn us of its toxic properties.

How many lives are annually cut short by chloroform and ether! Even though our patients usually react well from general anesthesia, can any one question but that this saturation of the system with a pungent, volatile liquid, must work havoc with the histological elements of the glands, their secreting and tubular structure? Many times, indeed, the patient has to face two dangers; the anesthesia and the operation. I have had two patients die, promptly after division of the constriction in strangulated hernia, under ether anesthesia. I have cut two others who were in a state of collapse when the cocaine solution was injected; but they both made excellent recoveries. Hence any agent which causes a local numbing of the parts without compromising the system must be accepted with unfeigned delight and welcome.

We cannot yet assign to cocaine definitely, the position which it should occupy in surgery. Not until it has been more generally employed, and a summary can be drawn up which will cover a great many cases, treated under divers circumstances at different stages of life, is this possible. With a view of hastening this consummation, and recommending the subcutaneous injection of this invaluable alkaloid in general surgery, this rather desultory monograph is offered.

REPORT ON THE RECENT PROGRESS OF ORTHOPEDIC SURGERY.¹

BY EDWARD H. BRADFORD, M.D., AND ROBERT W. LOVETT, M.D.

KNOCK-KNEE AND BOW-LEGS.

THE recent lectures of Pye² which deal with the rates of growth in healthy and rachitic children deserve more extended notice than can be given to them here. By the use of Bowditch's tables and by further observation of his own, he formulated the normal rates of growth in normal children, and by comparison with a large number of rachitic children of the same age, he found that in the latter the rate of growth was retarded during the activity of the disease. Inasmuch as growth is most rapid in the first year, and diminishes from that time onward, it follows that the earlier the disease appears the more marked is the arrest of growth. After the disease passes off the growth of the bones becomes nearly normal again, and upon this depends the tendency to the outgrowth of the deformity. Pye divides rickets into marasmic and non-marasmic varieties, and defines in detail these two classes.

Some investigations were made by Joel E. Goldthwait,³ in a series of cases operated on at the Boston Children's Hospital, as to the ultimate result of osteotomy and osteoclasis. Of twenty-eight cases (twelve of the former and fifteen of the latter operation) the legs were found to be straight and in excellent position ex-

cept in one case of knock-knee, in which relapse had taken place. The cases operated on were on the average four years old, although some were as young as two years. In all cases at least a year and a half had elapsed after operation.

Dr. G. C. Davis,⁴ of Philadelphia, takes an extreme position in advocating the treatment of bow-legs by prolonged recumbency. With regard to ambulatory treatment he says, "If the case is a marked one it is only a waste of valuable time to put on braces and allow the child to continue walking." He would keep young children in bed with the legs bandaged together or with inside wooden splints, until the deformity is cured. Such a method is so little in accord with modern American methods that it deserves mention, and the comment that the experience of Dr. Davis with regard to ambulatory treatment is widely different from that of other American surgeons.

Dr. Humphrey⁵ lays particular stress upon restricted ossification at the epiphyseal lines as the cause of knock-knee and bow-legs. This he regards as due to the effect of undue pressure coming either upon the outer or inner condyles of the femur in children with rickets where the processes of ossification are abnormal and easily disturbed.

A series of one hundred cases of osteotomy is reported by Haggard without any mishap or difficulty. Thirty-two cases were simple bow-legs and forty-five simple knock-knee, the latter being operated on by Reeves's method. In ten other cases cuneiform osteotomy was rendered necessary by extreme curvature of the tibia.⁶ Antisepsis was most carefully followed out.

From 1879 to 1889 there were treated at the Poly-clinic of the Rigs Hospital in Christians⁷, 1,953 cases of rickets, among whom were seen fifty-seven cases of knock-knee (2.9%). This deformity was most common at the age when children begin to walk. An attempt was made to connect the deformity by the arm on which the child is carried by the mother during the nursing period.

INFANTILE AND CEREBRAL PARALYSIS.

Karewski⁸ contributes a paper on the advantage of performing arthrodesis (scraping out the joint) on joints affected by severe infantile paralysis. He advocates it especially in the shoulder, knee and ankle joints. A French article by Deschamps,⁹ deals also with the surgical treatment.

Stephen Smith¹⁰ advocates excision of the knee-joint as a remedy for the "dangle leg" resulting from infantile paralysis and reports an illustrative case.

In a very admirable paper contributed by Dr. Ashby¹¹ to the British Medical Association, he considers the pathology of the forms of paralysis occurring in the first two years of life (including spinal and cerebral forms). The classification of causes which he makes is as follows: (1) intra-uterine lesions (meningo-encephalitis); (2) meningeal hemorrhage; (3) syphilitic arteritis and softening; (4) acute cerebral parapysis; (5) acute spinal paralysis; (6) peripheral paralysis. A similar article is contributed by Dauchez.¹²

The most important contributions to the pathology and clinical history of the affection are those of Osler⁴⁴ and Sachs and Petersen⁴⁵ which are too extensive for review here.

TREATMENT OF TALIPES CALCANEUS PARALYTICUS.

Gibney⁴⁶ reports 28 cases of operative treatment by Willett's method. Seventeen gave good results; eight gave fair results; three poor results. In the latter the resulting cicatrix had stretched and the deformity had recurred.

The method used consisted of a large Y-shaped incision over the posterior aspect of the leg, at the lower fourth the end of the incision being at the os calcis, the vertical incision being about one and one-half inches long, the incision exposing the sheath of the tendon. The tendon is divided obliquely and the ends sown together. Willett advises section of portion of the tendon. Gibney sews the ends together by lapping them, making, as it were, a splice. Dr. Gibney prefers catgut to wire for sutures.

Dr. Judson prefers the mechanical treatment, thinking that the appliance which is adjusted for these cases gives a firmer means of locomotion than that offered by the operation.

Dr. H. L. Taylor reports the result of the mechanical treatment as fairly satisfactory.

ARTHRODESIS FOR PARALYTIC TALIPES.

Defontaine⁴⁷ reports, what is termed, arthrodesis, that is, cartilaginous resection; a method introduced by Albert in two cases of paralytic club-foot. The method he employs is exposure of the tibio-tarsal articulation and section of the cartilaginous surface of the tibia and of the astragalus by means of an osteotome or scissors, then the peroneal tendons can be divided and resutured or spliced.

The results reported appear to be satisfactory.

TORTICOLLIS.

An interesting case of congenital torticollis was observed by Meinhard Schmidt,⁴⁸ where the asymmetry of the face and head was clearly primary and not the result of the deformity, at the end of seven months the deformity had entirely disappeared without more active treatment than daily attempts at repositional.

Sarlet⁴⁹ reported a case of torticollis due to late syphilis in a girl seventeen years old, which was improved by specific treatment.

At a meeting of the Société de Chirurgie held last summer,⁵⁰ the question of the operative treatment of torticollis was fully discussed. While the weight of opinion seemed to favor the division of the muscle by open incision, certain surgeons (Berger and Jalaguier) held to the subcutaneous tenotomy, arguing that it was safe if done far enough above the clavicle and that the scar after open incision was often disfiguring. Verneuil, Kirmisson and Championniere, were in favor of open incision, especially in extensive cases.

Articles dealing with this question have also been written by Rédard⁵¹ and Ducurtil.⁵² Two cases have

been reported⁵³ where the deformity seemed due to defective eyesight.

A simple and apparently efficient apparatus for the retention of corrected cases of torticollis in the right position is described by Braatz.⁵⁴

FLAT-FOOT.

In writing of flat-foot, Kirmisson⁵⁵ discusses the etiology and gives an account of the methods of mechanical treatment with a detailed account of the various operations for the relief of the most obstinate cases.

Trendelenburg,⁵⁶ in severe cases of flat-foot, has done supra-malleolar osteotomy and has found it very satisfactory in correcting the deformity. The operations (four in number) were all performed upon adults.

Among operative measures, removal of the scaphoid is advocated by Davy⁵⁷ in confirmed and irreducible cases and Golding Bird,⁵⁸ on the other side, deprecates operative interference in any but the very worst cases and in very few of those, and thinks that when operative measures are undertaken there should be removed a fairly extensive wedge of bone.

Hare⁵⁹ recommends osteotomy of the astragalus and scaphoid, "mortising" the astragalus and scaphoid together on the inner side of the foot by careful chiseling.

Whitman,⁶⁰ in an extended experience has found the use of a steel sole plate carefully shaped on the cast of a corrected foot sufficient in a majority of cases, in some of the severer cases he has used rectification under an anesthetic necessary preceding the use of the plates.

Dr. Young⁶¹ gives a review of the varieties and etiology of flat-foot and advocates its treatment by the elevation of the arch by Robert's spring.

Gibney⁶² calls attention to the occasional co-existence of flat-foot and ingrowing toe-nail and relates cases where the painful symptoms were relieved by the radical cure of the ingrowing nail.

CLUB-FOOT.

Rédard⁶³ describes an appliance for correcting club-foot forcibly. It consists of a plate with arrangements to hold the tarsus firmly by means of screw-pressure. The front of the foot is moved by means of a lever, which rests against the side of the foot, and is attached to a plate which controls the sole. The apparatus is an improvement on that of Morton,⁶⁴ of Philadelphia, who has found his not sufficiently reliable, and prefers resection of the astragalus.

Shaffer⁶⁵ has devised an elaborate and efficient appliance for correction of club-foot by gradual stretching. He has found that the amount of pain is not greater than can be borne without an anesthetic, and in many instances, by daily application for a short time of this appliance, he has succeeded in correcting resistant talipes equino-varus without tenotomy.

Kirmisson, of Paris, warmly advocates Phelps' open incision in resistant club-foot.

BONE-DRILLING NEAR INFLAMED JOINTS.

Noble Smith⁶⁶ calls attention to the advantage of bone-drilling in the neighborhood of inflamed joints in cases of acute and painful joint inflammations, and relates three cases where much benefit followed the procedure. Not only in hip disease and similar inflammations has he seen benefit from it, but in cases of painful Pott's disease he has relieved spinal sensitiveness by drilling into the apices of the spinous processes.

FIXATION AND ANCHYLOSIS.

Phelps⁶⁷ has carried out some experiments in the prolonged fixation of the joints of dogs, which go to show that such fixation does not produce ankylosis. Drawings of the joints accompany the paper, and the work has been most carefully done.

ACUTE ARTHRITIS OF INFANTS.

W. R. Townsend,⁶⁸ in a consideration of the acute arthritis of infants, relates 19 personal cases, and has collected 53 other cases from literature. His conclusions are that it occurs most during the first year of life, and that it is pyemic in character. Fifty per cent. of the cases are fatal, and commonly the disease runs a rapid and destructive course. It occurs most often in the hip, knee and shoulder, and the proper treatment is early incision.

HEREDITY IN BONE TUBERCULOSIS.

Dollinger⁶⁹ concludes from a study of 250 patients affected with bone tuberculosis that tuberculosis of bone, as such, is not often inherited, but that it is most likely to occur in the descendants of persons with tuberculosis of the lungs.

HAMMER TOE.

Haslam⁷⁰ reports the dissection of a hammer toe, in which the second phalanx was flexed on the first, the third being parallel to the second. The toe could be straightened with moderate force, but sprang back with a click or "trigger action." The tendons were found normal — the lateral ligaments were thickened and resisted extension — division of one of them permitted extension.

HALLUX VALGUS.

Fowler⁷¹ reports success in the operation of partial resection of the head of the metatarsus in hallux valgus. He advises in after-treatment a digitated stocking and a shoe with an inserted portion between the great toe and its neighbor.

— A youthful Esculapius, fresh from the Melbourne University, in Australia, established himself in one of the thriving centres of the cattle industry and was called in to attend an old lady suffering from tapeworm. He attended her with great success, and forwarded an account for 10s. 6d. which his patient thought exorbitant, and demanded to know the particulars. This is the reply she got: "For delivering you of a tapeworm ten and one-half feet long — at a shilling a foot, 10s. 6d."

Clinical Department.

A CASE OF MULTIPLE NEURITIS DUE TO ARSENIC.⁷²

REPORTED BY E. G. CUTLER, M.D.,

Visiting Physician to the Massachusetts General Hospital.

The following case, sent in by Dr. Walton, entered the Massachusetts General Hospital under Dr. W. L. Richardson, and remained in his care for over three months till he was practically well. I am permitted, through the courtesy of Dr. Richardson, to report the case:

G. H. M., shoemaker, single, aged twenty-two, born and living in Natick, Mass., entered the Massachusetts General Hospital March 25, 1890, with the following history: Father and mother living, three brothers died in infancy. He had had no previous illness. There was no syphilis or alcoholic appearance or history. No evident exposure to lead or arsenic. He ascribed his trouble himself to the constant use of a treadle machine for stitching leather. About three weeks before entrance first noticed weakness of the right hand, with a feeling of numbness and prickling in the fingers. Within a few days a similar weakness of the left arm and hand and of both legs developed, and has increased slowly. Numbness, tingling, pins and needles sensation, with subjective feeling of coldness in the legs, have existed from the outset; and for ten days there has been general soreness of the arms and legs, with painful cramps of the calf muscles. No headache; no disturbance of vision; slight cough only for two or three days; appetite fair; no dyspepsia; no attacks of colic; bowels rather constipated; no urinary disturbance.

Patient was poorly nourished; the mental condition intelligent; pulse 104, regular and of fair strength. Pupils alike, and react to light and accommodation. No blue line on gums. The hand grasp was weak; the gait feeble and shuffling; the muscles of the limbs were wasted and flabby. No wrist-drop or toe-drop, but special weakness of extensors. Skin cold, circulation sluggish. Moderate tenderness of muscular masses of extremities and along nerve trunks. Sensation to touch seems everywhere normal. Knee-jerks absent. Superficial reflexes weakened. Heart, lungs and abdominal organs were negative. The urine was acid, of high color, 1022 specific gravity, no albumen, the sediment consisted of abundant urates only.

He was up and about the ward for a few days, complaining only of slight headache. Atrophy of the muscles markedly increased, and, finally, on the first of April, he was kept in bed. At this time he complained of headache and had occasional cramps in the calf muscles. The pain was moderate, and quickly relieved by small doses of phenacetin. Parasthesia in feet and hands became less marked and was not continuous. Tenderness remained the same.

April 5th, Professor E. S. Wood reported the presence of arsenic in the urine. Twenty grains of iodide of potassium was given three times a day, and he was sponged daily with salt water. The patient, who had been steadily at work for one year, said that he had to handle a dozen or more green paper labels attached to the shoes daily in his work, and he had the habit of putting these papers in his mouth. He also injured right

⁷² Read before the Boston Society for Medical Improvement, October 13, 1890.

hand, and had a sore in palm, lasting three or four weeks before entrance. Hand and tags remained wet most of time. Until the middle of April the atrophy and flaccidity of the muscles increased so that he was unable to move, though the tenderness and cramps diminished. He could move the hands a little, legs not at all. Weight one hundred and ten pounds. At the end of April the patient began to regain slight power in the leg muscles, though the feet and legs remained markedly cold at night. He was then rubbed with ice daily. The middle of May he was about the ward in a wheel chair, and steadily gaining in muscular power. The third week of May slight dorsal flexion of the feet was possible. On June 1st he began to go about on crutches; and by July, could walk with a stick. There was steady gain in weight and strength till he was discharged to the convalescent home on the 17th of July, able to walk about quite well, and go up one flight of stairs slowly, but unable to walk in the dark or where he could not see distinctly.

There was no reaction of degeneration when I first saw him, July 1st.

The patient was seen by me again within a few days. He looks quite well, and is strong enough to walk seven miles without fatigue. He can walk in the dark with as much freedom as ever. His weight is one hundred and twenty-eight pounds, which is the normal for him. There are occasional shooting pains in the muscles of the extremities; no paraesthesia; no tenderness anywhere. The cutaneous reflexes are normal. The patella reflex is just visible at times, not always.

At my request, the patient sent me two of the tags, which I pass round. Dr. C. P. Worcester, assistant in chemistry at the Harvard Medical School, kindly tested them for arsenic, and found a large quantity. I pass round the mirror which he obtained by using for his test the small fragment seen to have been cut from one corner of one tag.

CASES OF BERI-BERI OCCURRING IN THE PROVINCETOWN GRAND BANK FISHING FLEET.

BY W. S. BIRGE, M.D., PROVINCETOWN, MASS.

In the fall of 1889, when the fishing fleet from the Grand Banks arrived home, I was called upon to attend seven cases, coming from two different vessels, a description of which may prove of interest from the rarity of the disease originating as far north in this quarter of the globe as did these cases.

The prominent symptoms in each case were general oedema, shortness of breath with precordial distress, numbness of the lower extremities with a peculiar shuffling gait, showing marked inability to lift the lower limb at the knee. One case only was confined to the bed, and that was marked by an advanced stage of hydrothorax, dulness on percussion and disappearance of the respiratory murmur, the pulse was weak, irregular and very much increased in frequency, and after five days the patient died with all the symptoms of pulmonary oedema and heart failure. The other cases, after a period varying from two to six weeks, recovered. One man died on the passage home, and the history of the case, as near as I could ascertain, was similar to that just stated. In three cases there was marked enlargement of the spleen; in only one case was there any trace of albumen in the urine, and there

was a doubt if that was due to the disease in question. The urine in all was scant, high colored, and contained an excess of urates; there was no retention in any case; the temperature was normal in all; the knee-jerk in two cases was entirely lost, in all diminished; the digestive organs seemed to be but little affected; the appetite was fairly good in the majority of cases; nausea and vomiting were present in one case, but was easily controlled; the bowels in all were constipated, but no more than is usually the case in those that go to the Grand Banks fishing, resulting probably from the kind of food furnished on such voyages, and neglect in going to stool.

The prodromic period in these cases, as nearly as could be learned from the patients themselves, was characterized by general weakness and depression, and an indisposition to work; an edematous condition of the areolar tissue on the anterior part of the legs manifested itself, together with severe cramps and pains of a neuralgic character. That the disease was beri-beri there is no doubt, for the symptoms are identical with those described, proving conclusively that the bacteria or septic organism may be produced independent of any earthy or climatic influence, and in a latitude as far north as 45° or 46°.

The undoubted causes of the disease in these cases were defective nourishment; the vessels were poorly fitted for the voyage, the two previous years having been unfortunate ones peculiarly for the owners, in consequence of which the outfit was cut off in every possible way, the salt beef was of a poorer quality than usual, and the stock of fresh provisions was very meagre. The dampness and cold which is always present on the Grand Banks would undoubtedly act as a factor in developing the disease in a system impoverished and rendered anæmic from a diet of unwholesome food deficient in nitrogenous principles. The catch of fish was at irregular intervals, so that having that article in a fresh state was a rare occurrence. The majority of cases in which this disease occurred were strong, able-bodied men, in whom there were no previous traces of any constitutional disturbance.

Treatment. — Diet seems to form an important part of the treatment of this disease. A mixed diet composed of the coarsely prepared grains, as oatmeal, wheat, etc., with liberal allowance of fresh beef, in my own experience, is to be preferred. In regard to medication the treatment is rather expectant than specific. Diuretics and hydrogogue cathartics are indicated when the dropsical effusion is marked; digitalis, to stimulate and control the heart's action. Tincture of chloride of iron and iodide of potassium were also prescribed with apparent benefit.

October 27, 1890. Since writing the above and during the past week about twenty cases of the same disease have been landed here on vessels arriving from the Grand Banks, eleven cases occurring on one vessel out of a crew of thirteen; two of the cases died with the symptoms as before described within twenty-eight hours after being brought ashore. Some of the cases were sent to the United States Marine Hospital at Chelsea, and others are being treated here.

My object in writing this brief report is to call the attention of the profession to the disease and elicit from others their ideas and opinions regarding the same, for it seems to be a settled fact that each year our fleet returns from the Grand Banks there is an increase in the number of cases.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. O. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, October 13, 1890,
Dr. W. L. RICHARDSON in the chair.

DR. E. G. CUTLER reported

A CASE OF MULTIPLE NEURITIS DUE TO ARSENIC,¹
and showed

A CASE OF PSEUDO-MUSCULAR HYPERTROPHY IN AN
ADULT.

The following case was sent in to the Massachusetts General Hospital by Dr. G. L. Walton:
J. H., teamster, single, aged thirty-eight, born in Ireland and living in Lowell, Mass., gives the following history: Family history is negative. Personal history: Habits alcoholic. About eight years ago was thrown from team and struck on his head, but no serious symptoms followed, having only a stiff neck for a week. Has always been well till about five years ago, when he began to feel weak in the back and legs; he would be stiff in the morning, but get "limbered out" on working; there was also some pain on first starting in the morning. Stopped work one year ago on account of above weakness. He had pain in the thighs and legs at that time; legs and thighs have been growing steadily weaker, till now there is difficulty in walking up stairs, and he finds it necessary to drag himself up by the arms. There is numbness of the feet. He gets tired easily on walking, though he walks as well in the dark as in the light. The arms feel strong, but he feels weak from the hips down. There is no trouble with the sphincters, no girdle sensation, eats and sleeps well, no specific history.

On examination the patient is found to be well-developed and well-nourished. The pupils are normal in reaction. Chest and abdomen negative. Lower extremities, especially the vasti externi, the supra- and infra-spinatus and triceps extensor muscles and the calves, are excessively developed. The cutaneous reflexes are normal. The patellar reflex and ankle clonus are absent. Rhomberg's symptom is absent. When he stoops over he gets up into the erect position with great difficulty, and when he rises from his hands and knees he climbs upon his thighs in a very characteristic way. Examination of the urine gave a specific gravity of 1.024, no albumen or sugar, nothing abnormal on microscopic examination. The calves and other affected muscles feel quite hard to the touch, though perhaps less so than normally. There is atrophy of the glutei. The gait is rolling and slow. Lordosis is marked in the erect position, but disappears on sitting down. There is inability to cross the legs. The electrical reactions are weakened in the affected muscles.

DR. G. L. WALTON: I have nothing to add with regard to these particular cases, the important characteristics of which have been fully presented. The first case is a typical one of pseudo-muscular hypertrophy, the interesting feature of which lies in the age of the patient at its onset, he being one of the oldest patients on record with this form of muscular dystrophy. It is important to note not only the size,

consistency and contour of the muscles, but also the gait and various combined movements. The gait in this case is characteristic.

DR. WEBBER has just reminded me of a case which we have both seen, in which inspection alone would lead to this diagnosis, while the movements made it extremely improbable. This was a young lady whose calves were so entirely out of proportion to the arms and trunk as to make the contrast most striking. They were comparatively enormous, while the arms and trunk muscles were poorly developed. The shoulders were thrown so far back as to present an appearance of lordosis. Upon asking her to step upon the sofa she surprised me by doing so with great activity, and on asking her to lie down upon her back and rise to her feet, she folded her arms and rose to her feet without unfolding them, a feat which she observed the other girls at the school were unable to perform. The case could only have been one, therefore, of unusual local muscular development, amounting to a hypertrophy.

As regards the second case reported by Dr. Cutler, I think great credit is due him for discovering the source of the neuritis. I had examined the patient in my office, and made the diagnosis, without finding its origin further than to exclude alcohol and tobacco. Too much credit cannot be given Dr. Putnam for having so persistently investigated the subject of the mineral poisons; to his efforts are largely due our knowledge of the deviations from recognized types furnished by their symptomatology. It is certainly a wise precaution to look for lead and arsenic not only in all cases of neuritis, but in cases of nervous disease with obscure symptoms and unknown origin.

A case which I have just sent to the JOURNAL for publication illustrates this point. This was a gentleman whom I saw in consultation with Dr. Presbrey of Taunton. The principal symptoms were ataxic gait, very slight tenderness of the calves, loss of muscle sense in the toes, a suggestion of similar trouble in the hands and some nervous irritability, for example, sensitiveness to noise overhead. There was no bladder or rectal trouble, no pupil irregularity, no pains, no diplopia, no girdle sensation. The knee-jerk was absent. The case seemed to be one of very moderate neuritis combined with considerable functional disturbance, and he was put upon nux vomica and general treatment. At a later examination something in the history leading to the suggestion of metallic poison, the urine was first analyzed for arsenic with negative result, then for lead, of which a very large quantity was found. He was allowed only bottled waters, and was put upon iodide of potassium, the dose of which had to be reduced to a minimum, and to be discontinued at intervals; but his condition grew gradually worse both in the intervals and during the administration, until death ensued. A most exhaustive search for the source of lead by Dr. Presbrey had revealed the fact that he was in the habit of drinking large quantities of hot water from a tin-lined copper kettle. Most of the lining was gone, but analysis of water which was heated and allowed to stand in the kettle for a few hours showed traces of lead. This makes, I believe, the sixth case of reported ataxia from lead poisoning, including those reported by Dr. Putnam, but judging by the frequency of this symptom in other forms of neuritis, it is likely to be found more frequently as the knowledge of the subject becomes more general.

¹ See page 463 of the Journal.

There is no branch of neurology of more practical interest than the diagnosis and treatment of multiple neuritis. These cases are extremely liable to be mistaken for locomotor ataxia, on account of the gait, and the absence of tendon reflex. I have seen a case only recently in which the latter diagnosis was made by two physicians in Maine. The brother of the patient set out with him, determined, he said, to travel until he found some one who made a less unfavorable diagnosis. On coming to Boston, he was referred to me by Dr. M. H. Richardson, and proved a case of multiple neuritis, whether resulting from lead or not, remains to be proved by the analysis of the urine, which is being done under Dr. Webber's supervision, whom he also consulted, and who made the same diagnosis. In this case the absence of bladder symptoms and normal pupils were the chief points in eliminating locomotor ataxia, though the gait was that of marked in-co-ordination.

DR. CUTLER: Dr. Walton is mistaken in attributing the credit of the discovery of arsenic to me: it belongs to Dr. Richardson, who thought it must be that of lead, and had the urine examined.

DR. S. G. WEBBER: In the last case Dr. Walton mentioned, he did not speak of the source of the lead. The man was a sea captain who lived largely upon canned goods. He said that in almost every can that was opened there would be two or three lumps of solder. He had a fissure of the anus, and being at sea treated it himself. A part of the treatment consisted in the use of a strong solution of acetate of lead upon a swab which he passed up the rectum, and he stood nearly on his head to get as much in as he could. After about a month of that treatment he began to have the symptoms which finally resulted in almost entire loss of locomotion in the legs.

In the case of pseudo-muscular hypertrophy in the girl, Dr. Walton spared my feelings a little by not stating that I did not recognize it as simply hypertrophy. It was one of those cases that I think might lead to a mistake, and it is instructive in that regard. The calves were very large and very hard, and she stood back so that there was almost or quite lordosis. There was feebleness of the muscles of the upper part of the body and a very great wasting of the arms. She had, while having a good appetite, grown very thin. I made a hasty diagnosis, not making the tests Dr. Walton had spoken of. I understand that she is improving in strength and in flesh, so that it is probably not a case of pseudo-muscular hypertrophy.

DR. J. J. PUTNAM: These cases are of great interest and I am glad to say a few words about them. In the first place, in regard to the case of *pseudo-muscular hypertrophy*, I should like to call attention to the fact that this patient can stand on his tiptoes with great ease. The weakness in the calves is evidently very much less than one would anticipate from the weakness of the thighs. I think that point is interesting, because it certainly is true, as I believe in some of these cases that the calves of the leg are not always large and weak, but sometimes large and strong. The interesting case referred to by Drs. Walton and Webber although not a case of pseudo-muscular hypertrophy, still may be one of those cases related to it, and I think the relation of these diseases is as interesting as the diseases themselves. The investigations of the last few years have shown the way in which the different forms of muscular dystrophy (including pseudo-

hypertrophy) and typical progressive muscular atrophy shade into each other, so that Schultz, who has written one of the most valuable monographs on the subject, concluded that there is no absolutely pathognomonic sign by which we can distinguish between the different forms. Of course from the clinical standpoint, speaking broadly, there are very great differences. I think it is very extraordinary and interesting to see a condition such as this, which usually appears in the early years of life and which we are in the habit of associating with imperfect development, appearing in middle or advanced age, after the nervous or muscular tissues involved have done duty very well for a great many years. Certainly we do see that in a considerable variety of nervous affections. I will simply recall the fact that in the interesting series of eight cases of so-called hereditary locomotor ataxia occurring in one family, reported by Dr. Everett Smith a few years ago, the father, who had been perfectly well up to a late period, finally showed signs of the same disease; and the same thing is occasionally observed, though very rarely, in pseudo-muscular hypertrophy. It is extremely interesting to note the peculiar association that one sometimes sees between these constitutional trophic affections and diseases of unknown pathology, that we are in the habit of calling functional, such as exophthalmic goitre with progressive muscular atrophy and other analogous affections. It seems to me the word "functional," although convenient, is a very misleading one, as leading the mind away from these relationships.

In regard to the case of *arsenical neuritis*, this opens a very large field for discussion as well as for inquiry. The diagnosis of the case seems to be perfectly well made out and the aetiological diagnosis as well, especially in view of the fact that the patient was ataxic. Although neuritis from lead and alcohol and other causes occasionally give rise to ataxia, still this symptom has been observed far more often in cases of arsenical neuritis than in the others. Unfortunately we cannot confidently use the test of the examination of the urine as establishing the diagnosis of lead or arsenic poisoning with the same readiness that we did formerly, because the investigations that have been carried on at my suggestion in the last four or five years have shown that both lead and arsenic frequently occur in the urine of persons in apparent health. A routine examination of the urine for arsenic has been made by Dr. Worcester in nearly one hundred cases, mainly of patients at the Massachusetts General Hospital, not presenting characteristic symptoms, and in at least one in four of them arsenic was found. Nearly the same may be said with regard to lead. The urine of about thirty medical students was tested for lead, and it was found twice. In a much larger number of hospital cases, with various non-characteristic symptoms lead was found in more than ten per cent. One of the students in whose urine lead was found had been perfectly well and had an excellent family history. He had, however, become epileptic, and had attacks of a pronounced but rather a mild character. Since a prolonged course of treatment with iodide of potash he has had no further attacks, more than a year having passed.

I think the fact that Dr. Cutler's patient was poisoned in the way he speaks of may or may not have been true. It could not account for the arsenic in the majority of the cases I examined, and we are almost

compelled to fall back on the supposition that it comes in a considerable proportion of cases from wall paper or fabrics. And it seems to me the community is exposed to a very considerable danger, and one to which it ought not to be exposed. It is a danger which for the larger number is very slight, but for the smaller number very great. This patient apparently got his arsenic from green paper tags, and several instances are on record where sucking arsenical papers has caused serious symptoms and even death. One such source is the paper strips with which envelopes are enclosed.

I think it is objectionable that chemists in reporting upon the condition of wall papers, as to their being arsenical or not, are in the habit of stating that the paper is "dangerous" or "harmless" or words to that effect, as is habitually done. Although intended as an accurate statement, it is liable to mislead, because it seems to be a pre-judgment on the part of a person naturally regarded as an authority as to the amount of arsenic which is harmful or harmless, whereas in fact, this seems to me to be purely a clinical question. *A priori*, the amount of arsenic in any wall paper seems altogether too small to warrant the idea of poisoning, and yet it certainly occurs; so that it is purely a clinical and not a chemical question where the danger stops, and nothing is more striking than the fact that in some of the reported cases, recurrence of poisoning has occurred from exposure to quantities of arsenic which seemed absolutely insignificant. It would certainly be much better if chemists would give the quantitative analysis. This I believe is practically possible. I have recently talked with Professor Sanger who has studied this matter, and he told me that he and Professor Hill of Cambridge have established standard mirrors which can be used to secure quite accurate quantitative estimates.

A single instance which has come to my notice in the past year seems to me to illustrate several of these points. At the Infant Asylum in Jamaica Plain recently, a number of children were taken sick at the same time with peculiar symptoms. All of them had more or less bronchitis, some of them pneumonia, from which I think two died. At the same time several of the nurses had local irritations of the skin. My brother, who at that time was in charge of the Asylum, after looking about and finding no satisfactory cause of this singular epidemic, thought of arsenic, and investigated the paper and clothing, and found that the nurses had recently been provided with certain prints to make dresses of, and had been wearing these. On examination these prints were found to contain a considerable amount of arsenic. It so happened that the cook in my own house had been given a piece of this same stamp to make a dress, and while wearing it she complained of a curious eruption on the face and neck which I looked at and could not make much of. It finally passed away. My brother spoke of the matter to the firm where the cloth was bought. They had it analyzed and a slight trace was reported. It was again examined by Dr. Worcester, and he reports the amount as considerable. Both chemists were thoroughly competent.

In regard to the case of neuritis with ataxia, from lead, reported by Dr. Walton, although I would very readily admit the diagnosis, and have no reason to throw any doubt on it at all, still I have seen in the past few years a number of cases where the difficulty of

distinguishing between neuritis and myelitis was very great, and although, of course, the fact that a case proves fatal is not a proof against the diagnosis of neuritis, still I should consider it as rather in favor of myelitis, and it is almost impossible to distinguish between them at certain stages of the disease. Numbness beginning in the hands and feet and spreading upwards, in a subacute manner, and associated with paralysis or ataxia, with diminished or increased knee-jerk is certainly met with, not very infrequently, especially with enfeebled persons. I have examined microscopically four spinal cords and found the characteristic lesions of posterior and lateral sclerosis with diffuse myelitis. It is also a matter of considerable interest that in several of the cases that I have seen lead was found in the urine. In three or four of these it was found twice, and in one, arsenic had been found three times. Whether the symptoms were due to that cause I do not know. I had reason to think, in all the cases, that the causes were several in number and among them were conditions of imperfect development. In regard to the sea captain from Maine, it is also a matter of interest that there seems to be a peculiar liability among the seafaring profession to have neuritis develop for some reason or other, and neither lead nor arsenic is capable of explaining it. Dr. Shattuck reported quite a number of cases of neuritis which occurred on a certain vessel, and I have seen partly through the kindness of Dr. Irwin, several other cases, and have collected notes of a still larger number. Part of the cases came from two or three vessels off the Grand Banks and part of them from off Cape Cod, and the cause of the trouble could not be made out. No reason for suspecting lead or arsenic could be found.

DR. E. S. WOOD: I wish to say a few words in connection with what Dr. Putnam has said in reference to the standard by which a paper is pronounced dangerous or harmless. It is certainly a purely arbitrary one, and the limit which we, at the medical school, have established, has been ten milligrammes of arsenic to the square metre, or about one-sixth grain to the square yard. That amount was what we tried to have established as the limit in the act which we attempted to have passed by the Legislature, but which failed. The only object of making that limit was that we had known of cases of arsenical poisoning which were due to an amount of arsenic in wall-paper of about one-fifth or one-sixth of a grain to a square yard and had never known with certainty of poisoning being produced with any amount less than this, and, therefore, that we could safely say, in the vast majority of cases, that only in those cases where a patient was exceedingly susceptible to the action of arsenic could any symptom be ascribed to an arsenical wall-paper having an amount less than about one-sixth of a grain to the square yard, or what we always speak of as ten milligramme paper.

In regard to the scale of mirrors which Dr. Putnam referred to as having been worked out by Professors Hill and Sanger, it merely means that a distinction can be seen between a mirror formed of one one-hundredth milligramme of arsenic, by two, three, etc., up to ten one-hundredths milligramme; so that by comparing a mirror formed from a square decimetre of wall-paper, the amount can be approximately estimated, provided that it is not more than ten milligramme paper, and by diminishing the amount of paper, an approximate

estimation can be made. The amount which we always take for an analysis in the medical school is a square decimetre, and when the amount of arsenic in that square decimetre gives a mirror which is larger than one-tenth millegramme of arsenic we call the paper dangerous; if the mirror is smaller, then we say it contains an insignificant trace and is harmless. That limit is an arbitrary one, but I don't see how the chemist can do anything else. He cannot know the susceptibility of the patient without knowing anything about the patient, and in 999 out of 1,000 cases the physician himself does not know this; so that I think, in the vast majority of cases, it is perfectly proper to draw an arbitrary line where the limit is put as small as ten millegrammes to the square metre.

DR. PUTNAM: I think that would be perfectly true if all chemists would agree on the amount. Again, the fact of the paper being dangerous or harmless depends just as much on the degree of exposure as on the amount of arsenic in the paper. If the person is in the room a long time a paper may be dangerous, which, in the case of a person who only occupied the room for a short time, would be harmless.

NEW YORK STATE MEDICAL ASSOCIATION.

THE Seventh Annual Meeting was held at the Mott Memorial Hall, New York, October 22d, 23d, and 24th, 1890, the President, DR. JOHN G. ORTON, in the chair.

The Chairman of the Committee on Arrangements, DR. J. G. TRUAX, in his report formally welcomed the Association to its occupation of a new home and library at the Mott Memorial Hall, recently acquired for permanent use.

The Annual Report of the Secretary referred to the New York State Medical Examinations Bill, which has recently become law. He stated that every pressure, by argument and remonstrance, was brought to bear upon the Governor to withhold his signature, upon the ground that the bill had not been duly considered in the Senate, and that its clauses were unjust and one-sided. The tenor of the reply to this appeal was that the Governor must assume the bill to have been duly considered in committee and that if exception was taken to it, another bill in modification could be sent up next year.

THE PRESIDENT'S ADDRESS.

The President congratulated the Association on having at last acquired a home for its members and its library. He then considered at some length the question of educational preparation for the profession. He said that while upholding the principle that medical colleges should demand proof of adequate preliminary education from would-be medical students, he was not prepared to go so far as to say that the possession of academic degrees should be demanded as a *sine qua non* of qualification for entering upon a medical course. He did not believe that the colleges of this country were below par. There was every evidence that they were steadily raising the standard of excellence in the educational pabulum. They were really better adapted to the requirements than were those of the old country. The unfortunate phase of the situation was that the colleges had not shut their doors against inadequately prepared students. The speaker then paid unqualified

tribute to the value of medical journals, which he said had assumed a proportion and weight of character unequalled in any other literary branch of science or art. To-day, a subscription to a reliable medical journal was an investment which would repay with interest many times compounded. He advocated the establishment of local boards of sanitation, the business of which should be to formulate principles of sanitary science for the people, for publication in the secular press, which would enable them to intelligently guard against preventable disease.

PROGNOSTICS IN MEDICINE.

DR. JOHN CRONYN, of Erie County, read a paper on this subject. In the course of an extended review of points for prognosis, he touched upon the question of treatment. He thought that prognosis in cases of apoplexy could now hardly be as favorable as when blood-letting was more in vogue. Pneumonia was not as low in the mortality tables as the vaunted progress in medical science would seem to warrant.

NEW METHOD OF TREATMENT FOR RETRO-DISPLACEMENT OF THE UTERUS, WITH ADHESIONS.

DR. A. P. DUDLEY described his present method of surgical treatment for certain forms of the above condition. After review of the various methods for correcting this lesion, recently in vogue, he narrated the details of his operative procedure in a case of diseased ovaries and tube. He opened the abdomen, broke up the adhesions about the uterus, and then taking the left ovary and tube he drew them up through the abdominal incision, and saw that the fimbriated extremity was open. He then took a piece of No. 27 silver wire, slightly pointed at one end, which he gently passed through the entire length of the tube, demonstrating it as pervious. The ovary, which contained several cysts, was then tapped with a spear-pointed needle, by passing the needle directly through the organ and squeezing the water out. The sacs were then allowed to fill with fresh blood. The tube and ovary were dropped back and the right side was treated in the same manner. An assistant then placed two fingers in the vagina, and lifted the uterus as high as possible in the pelvis. The operator was thus enabled to bring the uterus close up to the abdominal incision. With a pair of delicate scissors he then denuded the peritoneum from the anterior wall of the uterus, the surface thus freshened being of an oval shape. Care was taken not to go too near the bladder. Then each round ligament was brought up and a portion of the peritoneal covering upon the inner side denuded to correspond with that upon the uterus. With continuous suture of catgut he then sewed these denuded surfaces together. The sutures were passed deep enough to secure against their cutting out before union took place. The uterus was then dropped back and the traction upon the round ligaments immediately drew the organ into a position of anteversion, the sutured surfaces lying in apposition to the posterior surface of the bladder. He did not introduce a pessary, preferring to allow the work to rest upon its merits. The advantages of this operation were three-fold: (1) It shortened the round ligaments, without sacrificing any part of them, sufficiently to hold the uterus in a position anterior to the perpendicular line of the body. (2) Denuding and firmly fastening the round ligament to the anterior surface of the uterus, thickened and

gave extra support to the latter. (3) The uterus was maintained in a normal position without fastening any of it to the anterior abdominal wall, a position which he thought Nature never intended it to occupy.

The operation the speaker claimed, presented the following advantages over hysterorrhaphy or Alexander's operation: (1) It corrected the displacements by utilizing the natural supports of the uterus without sacrificing any of them. (2) The proper diaphragmatic action of the pelvic floor was not interfered with. (3) The bladder was not imprisoned, and its proper action was undisturbed. (4) There was no chance for intestinal adhesion about the line of suture for the latter laid in apposition to the posterior surface of the bladder and adhesion taking place at this point simply elongated the utero-vesical junction. (5) In case of impregnation the uterus was free to lift in the abdominal cavity naturally. (6) The use of the catgut suture did away with the danger of the formation of sinuses by the ligature. One of his objects in performing this operation had been to save this woman's ovaries, for he had come to believe that more was taken out than should be. He had operated in the manner described four times, and he thought this was enough to demonstrate that it was possible to attack the cysts in the ovaries and still not have any trouble in the tubes and ovaries after the laparotomy.

DISCUSSION ON INTRA-CRANIAL LESIONS.

This subject was considered by various speakers under the following subdivisions:

- (1) The present means of localizing intra-cranial lesions.
- (2) The nature of the chief intra-cranial lesions (hemorrhage, abscesses, tumors), and how they can be discriminated.
- (3) The indications and contra-indications of operative interference in cases of intra-cranial lesions.
- (4) The best modes of operating in cases of intra-cranial lesions.
- (5) The immediate and also the remote results of operative treatment in cases of intra-cranial lesions.

DR. W. W. KEEN of Pennsylvania prefaced his remarks by the exhibition and description of a new Rolandic fissure meter, with radiating arm and index, built after the manner of a cystometer, and the design of Mr. Horsley of England. The indications for operative treatment in the brain lesion, he said, should be based upon careful observation of the peculiar physical characteristics, the mechanical depressions and functional disturbances.

In the course of an elaborate survey of the whole clinical aspect of the subject from an operator's point of view, the speaker emphasized his opinion that if a lesion could be located and differentiated from other conditions which might produce more or less similar phenomena, and if the general clinical indications were such as pointed to the necessity for operative treatment, then it was the duty of the competent surgeon to open the head. The head had been too long regarded as something apart and different from other portions of the body, and he would urge that it should be made to fall into line with other cavities, subject, as it was, to the same diseases and injuries. The methods of treatment might require modification in detail, but should be the same in principle.

DR. J. J. PUTNAM drew attention to the relative value of certain so-called localizing signs of cerebral

tumors, especially such tumors as laid a little outside the familiar areas of the central, temporal, and occipital zones, and only impinging upon them, so that the symptoms to which they gave rise would be liable to occur rather late in the progress of the case. There were cases which, obviously for more reasons than one, were relatively unsuited for surgical treatment. It was generally admitted as a clinical principle, that the monoplegia and localized paralyses were more valuable as localizing signs than the mono-spasm or localized convulsions. Those functions of the brain which were relatively of a highly specialized and complex character were more likely to suffer disturbance than the less highly specialized and complex, or more fundamental functions. There must be few tumor operations, in which the convolutions near the growth were not found more or less displaced, and often they were broadened to twice their natural size, or flattened to the thickness of card-board. There were cases, however, where this error was of importance, those, namely, where convolutions were excited by pressure transmitted from a considerable distance, or by oedema and anæmia. This had occurred in a case of the author's. Unilateral neuritis had been held as being significant in indicating the pressure of a tumor of the opposite side of the brain. But the reverse of this condition was true in the author's case of tumor of the middle frontal convolution so that this sign was really of very little value. No one interested in cerebral localization could have failed to notice the experiences of Scharffler and Mauk, in showing that infinite movements of the eyes and eyelids were represented in the posterior limb of the angular gyrus, and in the occipital lobes, the connecting tracts reaching the oculo-motor nuclei, not indirectly through the Rolandic area, but by direct paths.

DR. C. K. MILLS said the causes of failure in the present method of localizing intra-cranial lesions were due to a variety of circumstances, and might conveniently be arranged into several classes: (1) by giving too much weight to certain classes of symptoms, which were regarded as determinative of the site of the lesion, as for example, the so-called signal or initial symptom; (2) by considering only symptoms of late invasion, as in the case of lesions growing from latent to active areas; (3) by giving relatively too much importance to motor localizing symptoms; (4) by overlooking multiple or diffused lesions; (5) by operating for incurable cases of arrested development. The so-called signal or initial symptom while of great value, had proved sometimes a misleading light. The motor signal symptom had been made use of in a large number of cases to guide the surgeon, sometimes successfully, but the author was almost inclined to say, almost as often not so. It must be remembered that in every case of unilateral or mono-spasm, whether reflex, dural, nephritic, toxic or hysterical, the spasm really, or apparently began with an initial symptom in the limb or face. This might indicate that the beginning of the cerebral discharge occurred in the area of the cortex, which was the seat of the representation of the movements, but it would be unwise to operate with such indications. Occasionally conjugate deviation of the eyes and head had been used as a guide to operative procedure. This was one of the errors into which a thoughtless, or badly informed neurologist might sometimes be led. In making a diagnosis as to the existence of hemorrhage, we must depend more

largely upon general symptoms. What was true of tumor in this respect was still more strikingly true of abscess. A number of mistakes had been made in cases of trephining for tumor or abscess by the operator being guided too much by motor symptoms, which were really the result of the diffusion of the lesion to the motor areas. In the analysis of the symptoms with a view of deciding as to operation, too much stress was sometimes placed upon motor symptoms, particularly on more or less circumscribed spasmoid manifestations. In not a few cases of cerebral abscess, sensory or special symptoms, might decide in favor of operating, and at the same time might not properly guide to the seat of operation. All active localized symptoms of the brain, the result of mastoid or aural disease, unless it was word deafness and left-sided affections, were the result of the extension of the purulent process. Several mistakes had been made, in cases in which large lesions, either in the frontal or temporal lobe, had caused prominent motor symptoms by pressure, either upon the motor tracts in the capsule, or upon the cortical areas of these tracts. In one case of this kind the symptoms all pointed to brachial crural monoplegia, due to tumor and intercurrent hemorrhage. The autopsy showed a tumor with large hemorrhage in the right temporal lobe, and strictly confined to this lobe, but evidently causing great pressure. Several recorded failures had been the result of overlooking the pressure of multiple or diffused lesion. Operating in cases of tubercular disease of the brain vessels or membranes, had also been another source of error, and cause of failure. It was one error at least in the majority of cases to operate guided by certain localizing phenomena of the spastic and paralytic, congenital and early infantile affections. A careful review of the surgical operations guided by localization rule, in whole or part, showed that probably the greatest success during the last few years had been trephining for endo-cranial hemorrhage. Occasionally failure had resulted in traumatic cases, and for several reasons. In the first place the fact was not fully considered, that in many cases of depressed or non-depressed fractures, hemorrhages took place not only at or in direct connection with the place of injury, but also at various positions more or less remote.

DR. J. D. BRYANT in considering the question as to the present means of localizing intra-cranial lesions, limited the term lesion to abscess, hemorrhage, depressed bone and tumor of intra-cranial origin. The present means of localizing these lesions could be classified for convenience sake as topographical, physiological and instrumental. The topographical related to the connection existing between certain established landmarks, and lines of the cranium, that were found to bear a decided relationship to superficial parts of the brain, many of which parts had had definite functions assigned to them already. The physiological means related to the establishment of the site of a pathological process by studying the derivation of the function of a part from the normal, as the result of a local disease or injury. The instrumental means were largely subsidiary and their application was often more of an experimental than of a practical character. The speaker then further dealt with the question by the recitation of cases having direct bearing on the subject. Among the most important deductions were: (1) That a small and presumptively circumscribed in

jury of the brain substance at the upper end of the fissure of Rolando, might incite an advancing cerebral disintegration sufficient to involve the motor centres associated with this fissure, without causing notable constitutional symptoms. (2) That aspiration of the brain as a means of diagnosing the existence, or the situation of an abscess, was of uncertain utility, even when a fair-sized needle was used, and that the employment of the ordinary hypodermic appliances for this purpose was entirely unreliable and misleading. (3) That extensive fissure could begin at some distance from the violence causing it, and that its existence might remain unrecognized without an extended exploration. (4) That extensive and fatal vascular complications might be caused at a considerable distance from the seat of an apparently innocent injury of the scalp or skull. (5) That where paralysis, involving the motor areas of the brain, followed an apparently trivial injury of the head, an operation at the seat of the areas was indicated for the purpose of exploration alone. (6) That the removal of a compressed brain clot was not necessarily followed by improvement of the symptoms of compression, and that if the brain did not soon resume the normal relation with the skull, death would ensue as the result. In another of the cases cited, the patient had, immediately after being hit over the head with a bottle, lost the power of speaking his own name, but had been able to write it and the name of his assailant on paper. When admitted to the hospital he could not recall his own name or those of many common things. An examination of the injury had disclosed a small circumscribed compound depressed fracture of the skull, located near the lower end of the fissure of Rolando. On the following day the depression was elevated and the aphasic symptoms had all disappeared. The case had impressed the fact that circumscribed compression, due to traumatic influence, might limit its effects to one motor centre only.

DR. T. H. MANLEY spoke of lesions of the brain substance of traumatic or mechanical origin. He described the proper use and common abuses of the trephine, and protested against the unnecessary use of anesthetics in intercranial operations.

HYPNOTISM.

DR. ERNEST SCHMID in his remarks upon this subject said nobody hesitated to admit the influence of the body upon the brain. Eminent alienists maintained that no diseased state of the mind ever existed without a pathological condition of some portion of the brain. Why should we then hesitate to admit the influence of the mind upon the body. The author held that every unconscious imitation was a transfer of a brain movement communicated to another brain in such a manner that the brain which repeated this movement of the first brain, adopted it as one of its own originating, and not a repetition. On this rested the great problem of hypnotism. That the view of the contagiousness of brain movements, of physical, intellectual and moral diseases, was not a singular one, and was demonstrable amongst other things by the fact that not a few alienists had formed the belief that mental aberration might be communicated to a sound mind by example and daily intercourse with the insane. There did exist within us a secret force which constantly conformed our thoughts to our actions, and our entire inner being to our external habits. The speaker was

convinced that the true essence of hypnotism possessed kindred elements to those thoughts. It was the imparting of a brain movement to others or the creating of a new one in another, which became as the other self-originated thought. That the hypnotic state could be produced was an established fact. Like all other therapeutic measures it had its circumscribed sphere, but its usefulness was destined to become very great.

RETENTION OF URINE FROM PROSTATIC OBSTRUCTION IN ELDERLY MEN: ITS NATURE, DIAGNOSIS AND MANAGEMENT.

This paper was read by DR. J. W. S. GOULEY. The author said that to the question, what caused this impediment to urination in elderly men, a common but incomplete answer was, enlargement of the prostate. This answer was incomplete because of its failure to specify the kind of enlargement, for it was known that elongation and also uniform general enlargement of the prostate did not obstruct the urethra or vesical orifice, or impede urination. Very large prostates had been discovered after death in elderly men who had never suffered the least inconvenience in urinating, and whose bladders were in a normal condition. On the other hand, small prostates, that is, of even less bulk than natural, with only moderate increase of the lower isthmus, often sufficiently obstructed the urethro-vesical orifice as to give rise to stagnation of urine, cystitis, and even to complete retention of urine. It was then only where the prostate was unequally enlarged that it interfered with urination, and to this, even, there were exceptions, for the multiple tumors at its base sometimes caused incontinence of urine, as did other forms of prostatic enlargement which prevented the closure of the urethro-vesical orifice, and allowed the urine to flow constantly from the bladder as fast as it trickled out of the ureters. Of the several forms of unequal enlargement of the prostate which obstructed the urethro-vesical orifice the following might be named: (1) General enlargement with excessive development of the posterior third of the lower isthmus, called supra-montanal portion by Mercier, and third lobe by Haue. (2) Enlargement of the posterior third of the lower isthmus, without apparent increase in the rest of the prostate, sometimes called concentric enlargement. (3) Enlargement of one lobe which encroached upon the opposite lobe and obstructed the prostatic urethra. (4) Unequal enlargement of both lobes rendering the prostatic urethra tortuous and obstructing it. (5) Multiple intra-urethral tumors; and (6) Intra-vesical enlargement of one lobe. Such were the principal forms of prostatic enlargement that impeded urination.

These alterations of structure differed somewhat in their component elements. Of the several steps in the diagnosis of abnormal urination and retention of urine due to prostatic enlargement, chiefly the following were employed: First, the history of the patient, especially in regard to his mode of urinating. Then there would follow physical exploration. The first step in this was palpation, then percussion. The second step consisted in making digital examination of the prostate through the rectum, by which means some idea might be formed of the size and consistency of the organ. The third step consisted in ascertaining the particular kind of enlargement present. A number of exploring instruments were then presented for the inspection of the Society. In the management of

acute retention of urine, to temporize, or to rely upon the use of medicaments in any case, was to place the patient in great jeopardy. The urine should be drawn with the catheter as shown by the speaker, slowly, and a small quantity at a time. The reason for this precaution was that the too precipitate evacuation of an over-distended bladder was sometimes followed by distressing and dangerous effects, such as profuse hemorrhage from its mucous membrane, cystitis, polyuria, and so forth. The after-treatment of these cases should accord with the particular necessities of each.

DR. J. A. WYETH said that in cases of persistent cystitis, it was his practice to perform supra-pubic section. He thought this the best method for dealing with this very obstinate disease. This operation in his hands had given better results than when treated by the urethra. Not only was immediate relief obtained, but a better command of the bladder was possible. He had only been doing this operation the last two years, but in that time about thirty cases had been so treated, five of which were tumors of the prostate, good results being obtained in all. He thought that for prostatic tumors the high operation was by far the best. It was his method in removing such to use the clamp forceps, and with the fingers at the prostate, gradually to twist them off, using the actual cautery to the stump. Relief had always been prompt, and in only one case did the bladder fail to remove its contents. The speaker had found that the oil of gaultheria was the best remedy to prevent the decomposition of urine. He gave it by the mouth, four or five drops, three or four times daily. When this drug was given, the urine would not decompose. The Trendelenberg drainage-tube was the one used, and six to eight weeks was the longest it had ever been necessary to leave it *in situ*.

DR. GOULEY was in full accord with the speaker in doing supra-pubic cystotomy for the removal of prostatic tumor, but he would not do the operation for this alone, but rather incidently. He believed that in the majority of cases the bladder could best be reached through the urethra, and as for doing the operation for the purpose of cleansing and drainage, it should not be thought of. In cases of contracted bladder, from prostatic obstruction, it was the speaker's practice to use hydraulic pressure to dilate, frequently increasing the capacity of the bladder from one-half an ounce to four ounces. He did not think it necessary to give anything by the mouth for the purpose of preventing decomposition of urine, when we had the means of applying it directly in the bladder.

◆◆◆

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

At the annual meeting held October 27, 1890, the following officers were elected: President, Dr. Orlando B. Douglas; Vice-President, Dr. Arthur M. Jacobus; Secretary, Dr. Charles H. Avery; Assistant Secretary, Dr. Wm. E. Bullard; Treasurer, Dr. John S. Warren.

The report of the Board of Censors, which included an elaborate report from W. A. Purrington, Esq., counsel to the Society, showed that during the year past there had been 159 cases of illegal medical practice investigated, 29 warrants procured, and about \$1,100 collected in fines from illegal practitioners.

The report urged that the laws regarding the issuing of licenses to practice medicine be more strictly enforced.

HYGIENE IN THE PUBLIC SCHOOLS

was the subject of a special report read by DR. HENRY S. CHAPIN, of the Committee on Hygiene, in which he stated that a personal investigation by him, of which he gave a detailed report, showed that many of the class-rooms were overcrowded, badly lighted, badly ventilated, and subject to foul odors. For instance, in one of the up-town school-houses, a one-story building, which was formerly a skating-rink, he found that six of the class-rooms had no window opening on the outside air, but were lighted and ventilated by sky-lights only and the ventilation was insufficient. Three of the class-rooms were unprovided with desks. The closets were on the same floor as the class-rooms, and an offensive odor was distinctly noticed in the rear class-rooms, 960 children attended at this school, and during September 220 others were excluded from it for want of room. The following is Dr. Chapin's report of another school: "School 7, No. 60 Chrystie Street, 1,100 children. This primary school is in three buildings, one of which is an old rookery, formerly a tenement, and another is part of an old factory on Hester Street. The whole establishment is a disgrace to any civilized community. The children come from poor families and they are given the poorest and scantiest accommodations. On a bright, sunshiny day, eleven of the stuffy class-rooms were lighted by gas, which, with the poor ventilation, made the atmosphere almost unbearable. Foul air from the boys' closets finds access to the school-room through the open windows and passage-ways connecting the closets with the room above. Three back rooms on this floor have been condemned on account of the foul air and the general darkness, but the other rooms connecting with them, and in substantially the same condition, are crowded with children.

He found that the amount of air space allowed to the pupils by the regulations of the School Department is as follows: "In the three lower classes of the primary departments, seventy cubic feet to each pupil; in the three higher grades of the primary departments, eighty cubic feet; in the four lower grades of the grammar schools, ninety cubic feet, and in the four higher grades of the grammar schools, one hundred cubic feet. In marked contrast to this is the Board of Health's requirement, that four hundred to six hundred cubic feet of air space shall be allowed to each occupant of a tenement house, and that, at least, four hundred cubic feet shall be allowed to each lodger in a lodging-house.

Dr. Chapin's report was unanimously concurred in by the other members of the Committee on Hygiene, Drs. Baruch, Page, Edson and Emerson.

The Committee on Hygiene, through its Chairman, DR. BARUCH, also submitted a report on

THE GENERAL APPLICATION OF HYGIENE PRINCIPLES TO LARGE COMMUNITIES,

in which public baths were especially commended, and in which it was suggested that an improved system of such baths be established, and that the custom of taking frequent baths be developed and extended by legal regulation. The Committee thought that there could be no better way of expending public funds than in the prevention of disease by putting the facilities for taking baths within the reach of every individual, and further

more suggested that baths, especially warm shower-baths, should be attached to the public schools.

In commenting on Dr. Chapin's report, the Superintendent of Public Instruction, MR. JOHN JASPER, said: "It is impossible to make the old school buildings perfect as they stand. In 1884 the city was allowed to issue \$2,000,000 in bonds for public-school purposes. The same amount was also allowed in 1885 and in 1886. In my report for 1887, I recommended that twenty-one new school buildings be erected as soon as possible. Work has been pushed on a number of new school-houses in the last three years, and the \$6,000,000 has been nearly used up. We are doing our best with what we have."

Recent Literature.

The Latin Grammar of Pharmacy and Medicine. By D. H. ROBINSON, Ph.D. Professor of Latin Language and Literature, University of Kansas. Philadelphia: P. Blakiston, Son & Co. 1890.

This book was intended for use as a text-book of Latin in the first year of schools of pharmacy and medicine, and, as such, it is excellent. A course in which it had been carefully studied would leave a young man, with no previous training in Latin, more than able to do himself credit on as much of the language as is met with in pharmacy or medicine. The constant use, while learning the language, of most of the words which he is later to meet, will be, of course, of great advantage to him.

The book is unnecessary for those students who already have a fair knowledge of Latin grammar, as it is practically a grammar with medicinal words and phrases substituted for classical ones. It would, therefore, hardly contain all that is needed for the examination in Latin which is required for admission to many medical schools. For the medical student, at least, the work would be more complete with a chapter on the practical application of medical Latin to prescription writing, and one on the distinctive terminations denoting the chemical properties of drugs.

— By virtue of a recent decree of the czar, female physicians are given the right to practise in the empire of Russia. It is hoped that the dearth of doctors now existing in certain provinces may be thus relieved.

— The pilgrimage to Mecca was effected this year under deplorable conditions. The total number of deaths from cholera cannot be even approximately stated. The unfortunate who falls is simply abandoned, his fellow pilgrims contenting themselves with covering the body with a light layer of earth. This year 43,000 pilgrims arrived by sea, the number that returned did not exceed 23,000. Fifteen thousand were therefore left on the plains or along the route of travel. In addition, at least 10,000 arrived by caravans. The estimate of a mortality of thirty-three per cent. is undoubtedly short of the actual number. One caravan set out 25,000 strong, and numbered 900 on arrival, in consequence of a "sickness by which many people died." This seems to show that cholera was not purely of Indian origin, but existed in Arabia before the pilgrimage.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 13, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 233 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMHILL & UPHAM,
 233 WASHINGTON STREET, BOSTON, MASS.

THE RELATIVE VALUE OF PHARMACEUTICAL AND HYGIENIC THERAPEUTICS.

DOUBTLESS, with the progress of the age, more and more preponderance is given to therapeutics based on hygiene and etiology. The fact is everywhere recognized that medicines are only auxiliaries to restoration, and that they are much more efficacious where the disease is due to derangement of function, than where it is the expression of serious structural alterations. Physicians long in practice rely much less on medicines than when they were fresh from their studies and had unlimited faith in the resources of *materia medica*. The story has been told of the old physician who was called in consultation in a difficult case with a young graduate; he heard the lengthy detail of medicines prescribed, and saw the formidable array of bottles; and then, after due consideration of the case, in view of the fact that despite the varieties and quantities of remedial agents, the patient was steadily getting worse, the senior practitioner mildly suggested to his youthful *confrère*, "to put all medicines to one side and give nature a chance."

With a decline of faith in the mysterious latent potencies of drugs (much as these are still valued as helpers) comes increased confidence in the natural means of cure: air, sunshine, cold water, exercise, rest, climate, food. Modern text-books on Practice more and more emphasize these hygienic means, giving but a subordinate place to drugs, which are largely used as agents only of a symptomatic treatment.

No one would now think of treating a disease due to overwork by medicines alone, when rest and return to right habits of living are clearly indicated. How irrational to treat a patient who is suffering from insomnia by administering nothing but hypnotics night after night, when the cause is simply close application to study or to business. The patient will doubtless be for the time relieved by his nightly dose of morphine, chloral or paraldehyde, but the cause will be still the more operative for evil when the hypnotic is withdrawn; and who can tell the harm that may be done

to the individual by the formation of a habit of dependence on the somniferous agent?

How irrational to combat the symptomatic manifestations of alcoholism or tabagism by nerve-medicines, and allow the patient to continue the practice of his vice, or to stimulate a condition of exhaustion due to lack of nourishment without giving any food or attempting to get the stomach into good working order!

These illustrations might be indefinitely extended; it is not necessary for our purpose to pursue them further. Medicines have their place, though that is often but a subordinate one, in the treatment of disease. The victim of constipation will need laxatives and cathartics till, by being taught to practice a better hygiene—especially with regard to diet and exercise—he finds that he needs laxatives no longer. The victim of insomnia may temporarily be helped by a hypnotic, but he must *rely* on the reformation of some bad habit which prevents him from sleeping. The individual who has been exposed to malarious emanations and has ague may need quinine to break up his intermittent, but sequestration from the malarious climate is none the less the predominant indication. The gourmand may require an emetic or purgative to rid himself of the evils of a surfeit, but to him the "first law of cure" is abstinence. The neuralgic sufferer will demand an opiate or other analgesic for his pain, but his *recovery* will depend on other and hygienic means.

These truths are so trite that they hardly need to be stated, and yet there is danger of overlooking or disregarding them every day and every hour; besides, it is so easy to *dose* one's patients, and it sometimes requires so much judgment and tact to fathom the cause of the derangement and prescribe the right kind of hygiene!

A word must be said about "etiological therapeutics." It is undoubtedly true that medical science is steadily advancing in the line of etiology, and that much has of late years been accomplished in ascertaining disease-causes that were formerly obscure or altogether unknown. All the infectious diseases are with great probability now referred to microbes, and many of the infectious agents are now known. As far as these "contagia" or "germs" become understood, there is a predominant interest to destroy them by "antiseptics," which kill the microbe without injuring the human organism. Here, then, is a wide field for pharmaceutical experiments, and such will still have an important place in the etiological therapeutics of the future. It is true that such internal parasiticides are yet few.

At the same time there will always be the necessity for rigorous hygiene—fresh air, exercise, change of climate, etc.—to fortify the organism and render it unsusceptible to disease agents. The old adage about the "ounce of prevention" will always hold good. "Prophylaxis" will ever come first in the chapter on "Treatment."

KOCH'S CURE FOR CONSUMPTION.

SINCE the announcement by Koch at the Tenth International Medical Congress that his experiments with the tubercle bacillus were likely to result in the preparation of a substance which would arrest the farther development of the bacillus in man, the whole world has been aroused to a state of expectation which no medical subject has ever before excited. The reason is easily understood if one stops to realize the enormous number of people on the earth who would have profound personal interest in a process which held out a rational expectation of stopping consumption already established.

The great hope that he may be entirely successful, is likely to prejudice good judgment, and until Koch speaks we shall have to be cautious in giving too much credit to the reports which reach us, and which are pretty sure to be painted in glowing colors.

Any statements of Koch are worthy of the greatest consideration, but as he has for the present absolutely declined to be interviewed, and as the experiments on human subjects have been surrounded by the utmost secrecy, the medical press has, as a rule, been content to wait quietly for developments; but the lay press all over the world has been publishing rumors and interviews, from more or less trustworthy sources, of as much as can be seen outside of Koch's private laboratory. A number of patients have been treated at the Charité Hospital, and later, to secure greater secrecy, in another institution. Many are reported to have been entirely cured. As good an authority as Professor Leyden has said that the experiments have been crowned with success. Only persons known to be suffering from tuberculosis have been treated, and all have signed papers not to reveal what they have gone through. Koch has been relieved from his duty of giving lectures for the present. He has announced that he is not seeking for personal fortune, and that in good time he will publish all particulars of his process. The emperor is said to have proposed that the government build a bacteriological institute under Koch's charge giving him an annuity and a title. It is rumored that the process, if successful in curing tuberculosis, may, with modifications, be made applicable to the treatment of other diseases, notably diphtheria. A full publication is promised within three weeks, which will contain a sufficient description to make it possible for any one with a properly equipped laboratory to produce the substance.

The accounts are not all equally encouraging. Some of the European papers announce that Koch is disappointed at the results which he has obtained since the Berlin Congress.

— At a meeting of the Boston Society for Medical Improvement, held November 10th, a committee was appointed to make arrangements for a meeting memorial of the late Dr. Henry J. Bigelow; and Wednesday, November 19th has been appointed as the date,

all members of the Massachusetts Medical Society being invited. The pages of the JOURNAL continue, in the resolutions received, to emphasize the fact that by the death of Dr. Bigelow the profession of medicine has lost one of its most original and distinguished members — a man whose genius had been acknowledged at home and abroad, but whose remarkable versatility and individuality were naturally only fully understood in the community where his life was passed.

MEMORIAL. HENRY J. BIGELOW, M.D.
SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

BOSTON, November 8, 1890.

MR. EDITOR: — At a meeting of the Surgical Section of the Suffolk District Medical Society held Wednesday, November 5th, the following resolution was passed. It was also voted that a copy of this resolution be sent to Dr. William Sturgis Bigelow, and that another be given to the *Boston Medical and Surgical Journal* for publication:

"Resolved, That we feel that by the death of Dr. Henry Jacob Bigelow the surgical profession in America has lost its brightest light.

"His acute discernment and inventive genius made contributions to the surgical art which have put mankind deeply in his debt, and have won the undisguised admiration of his peers through all countries.

"We, his associates and scholars, know, too, his inspiration as a teacher, whose genius so illuminated his subject, that what might have been dry detail was endowed with interest and fixed indelibly in the memory.

"Conscious of the high gifts and genius of Dr. Bigelow, we wish to place upon our records a mark of our appreciation of what he was, and what we owe him."

Truly yours, G. H. MONKS, M.D., Secretary.

MEDICAL NOTES.

— A report issued by the Interstate Commerce Commission shows that nearly two thousand railway employés were killed by accident last year and that more than twenty thousand were injured.

— A bill has been passed at Philadelphia which enacts that no milk shall be sold in that city which shows less than twelve per cent. of cream.

— Within a few years there have been four cases of leprosy reported in Philadelphia and vicinity. The president of the Philadelphia Board of Health, has written a letter to the Supervising Surgeon of the General United States Marine Hospital Service, to ask his opinion as to the proper disposition of cases of leprosy which will from time to time be discovered in various parts of the country. A suggestion is made that the government should provide places where persons suffering from leprosy could be separated from the public, and humanely cared for and treated in such a manner as not to deprive them entirely of the comforts and enjoyments of life.

— The students at the Woman's Medical College, Philadelphia, are in a quandary. Half of them want

to abolish the regulation white silk dresses on commencement day, and wear instead the dignified gown and scholarly mortar-board. The Faculty is nearly as much disturbed in finding a solution for the all-absorbing problem as the girls are. A member of the Faculty has said that there is no predicting when the question will be settled.

— The laws recently passed in some States limiting the practice of medicine seems to have placed some curious restrictions to the practice of the most respectable physicians. It is reported that a physician regularly licensed to practice in Brooklyn, was arrested in northern New York for giving medical advice to some one whom he met. A recent law of New Jersey prohibits physicians from other States practicing their profession within its boundaries. A large number of New York physicians have thus been cut off from their practice at the various summer resorts in that State.

— The Berlin police have issued a caution to the public against so-called "dried mushrooms," which are being sold, and which very frequently contain poisonous fungi. The caution calls attention to the fact that edible mushrooms when dried remain white, while poisonous varieties acquire a bluish tint.

— Mathias Duval has studied his faculty for remembering the names of different persons, and finds that the better a face is impressed on his mind, the more likely is the person's name to be forgotten, whereas when he knows of a person by name only, he easily retains it in his memory. As his eyesight becomes weaker with age, his power of remembering names increases. Similar observations have been made by Brown-Sequard.

— According to the *Siglio Medico* a local practitioner at the village of Benimamet in Valencia (Spain) was recently the victim of a brutal outrage of a somewhat novel character. He was called to a person whom he declared to be suffering from cholera, whereupon the family obliged him by main force to swallow the remedies he had prescribed, under the impression that the spread of the disease was directly due to the doctors.

— The effect of thunder-storms in turning milk sour has lately been investigated by an Italian *savant*, Professor G. Tolomei, who finds that the passage of an electric current directly through the milk not only does not hasten, but actually delays acidulation, milk so treated not becoming sour until from the sixth to the ninth day, whereas milk not so electrified became markedly acid on the third day. The souring he attributed to ozone generated by the passage of the electricity through the air. The first observation, namely, the retardation of souring by the passage of a current through the milk — may be a point of practical importance to milk-traders.

NEW ENGLAND.

— The Massachusetts Home for Intemperate Women has recently celebrated the opening of its new build-

ing in Longwood. This very deserving institution was founded twelve years ago by Mrs. Charpiot, the present superintendent, under whose admirable care, and supported by an excellent board of trustees, it has taken charge of a large number of intemperate women, of whom fifty per cent. have been wholly reformed. The new building has been erected at a cost of about sixty thousand dollars, of which over twenty thousand still remain to be subscribed.

— The inhabitants of Marlborough, Framingham and Brockton, Mass., have taken steps towards the erection of hospitals in their cities. A city hospital will also probably soon be built at Bangor, Me.

— The year ending September 30, 1890, was a successful one in the routine work of the Maine General Hospital, and completed the sixteenth year of this charity. The number of patients admitted was 577, of whom 137 paid nothing. The hospital has suffered from lack of room, but new wards are now being constructed.

— The catalogue of a bogus medical college has fallen into the hands of a daily paper, which has attempted an investigation. It is called the Union Medical Institute, and is situated in a small Vermont town. It is not incorporated and owns no building. The Faculty seems to consist of a very mixed company, containing among others a telegraph operator, a newspaper reporter, and some doctors of doubtful title living several hundred miles away.

— A paper entitled "The First Post-Mortem Performed in New England," was read by its author, C. J. Hoadley, librarian at the capitol, before the Hartford (Conn.) Medical Society. It described the post-mortem appearances found on the body of a child eight years of age, Elizabeth Kelly by name, who died in March, 1662. The child evidently died of some acute disease, but her death was ascribed to the malignant influences of witchcraft. The accused gude wife Ayers and her husband had to fly from their home, lest they be made to suffer the penalty of the charge, which was hanging. They left behind them a child, who became the ancestor of one of the present families of Hartford.

NEW YORK.

— Giovanni Succi, who is reputed to have fasted forty days in London, has just entered upon what he announces will be a forty-five days' fast. On the evening of November 5th, he took his last meal, and after this he weighed 147½ pounds. During his fast he proposes to take all the water that he wants and to smoke occasionally. He will also take twenty or thirty drops of an anodyne mixture, when it is required, to allay pains in the stomach. He sleeps whenever he feels inclined, and at other times engages in reading, conversation and billiards, and even in such active exercises as fencing and boxing. At the time he commenced his fast his chest, abdominal and limb measurements were taken by a committee of physi-

cians consisting of Drs. G. B. Du Moise, F. H. Ingram, H. V. Wildman, Hugh Hagan and E. Gail-
lard Mason, who are to have the general supervision
of the fast, assisted by a number of students from
Bellevue Hospital Medical College. The second day
of his fast found him very nervous and excitable, but
otherwise in excellent condition. During the day he
drank fifteen ounces of water, and smoked two cigars.
At 10 A. M. his weight was 139 $\frac{1}{4}$ pounds, and at 5.15
P. M., 138 $\frac{3}{4}$ pounds. At 4 P. M. his temperature was
98.9°, pulse 78, respiration 23, tongue clear and steady
and general condition good.

— In January last the Attorney General began an action to dissolve the Woman's Hospital of Brooklyn, on the ground that Drs. Mary A. Dixon Jones and Charles H. D. Jones, with the other trustees, had obtained control of the institution for purposes other than those designated by its charter. The defendants demurred to the complaint, but a decision has now been handed down by Justice Barnard, in which he overrules the demurser and grants judgment in favor of the people; annulling the incorporation and enjoining the defendants from exercising any of the privileges thereof.

Miscellany.

CHANGES IN THE TARIFF ON DRUGS.

A TABLE of the changes made in the rates of duties on drugs, chemicals, etc., by the McKinley Tariff Bill is given in the *Druggists' Circular* for November.

The following have been taken from the free list and now pay duty: Sulphuric acid, poppy-seed oil, Italian sage. The duties have been increased on bay rum, licorice juice, prepared opium, phosphorus, sumac, sugar of milk, mercury, gelatin and some others where there has been a change from ad valorem to specific duties. The following have been added to the free list: Beeswax, crude opium (containing nine per cent, and over of morphine), chlorate of potash and spirits of turpentine. The duties have been decreased on several drugs, among them tannic acid, chloroform, ether, iodoform, iodine, magnesia, morphine, strychnine and sulphur.

The changes made in the rates of duty on drugs by the new tariff have as yet produced no great effect upon market values. Of these, the most marked is the decline in the price of opium, as the result of the remission of the duty of one dollar per pound. The tariff on morphine has been reduced fifty cents per ounce. The increase in the duty on peppermint oil effectually bars the Japanese product from this market. The rate of duty on quicksilver is increased, and the price of the article is correspondingly higher.

A rather peculiar result of the new law is manifested in the case of chloral hydrate, because of a change in the wording of the clause relating to alcoholic preparations. The new law exacts a duty of fifty per cent. on articles in the production of which alcohol is used, as well as on ordinary alcoholic preparations. Heretofore chloral hydrate was classed with unenumerated chemical preparations, and paid a duty

of twenty-five per cent. The collector of customs at New York assessed duty at the rate of fifty per cent. on a recent importation of chloral, as an article in the production of which alcohol is used.

HARDENING OF SECTIONS OF THE SPINAL CORD BY ELECTRICITY.

MINOR has discovered (*Neurologisches Centralblatt*, No. 10, 1890) that sections of the spinal cord may be hardened by soaking them for a short time in a solution of bichromate of potash and then passing through them a current of galvanic electricity for a few days. The specimen becomes well hardened on that end which is placed against the positive pole, while the negative end becomes swollen and softened. Microscopical sections from this hardened tissue are as good as can be obtained by soaking in the bichromate solution for two or three months.

CURETTING THE SOFT CHANCRE.

PETERSEN¹ has for some time treated non-syphilitic ulcers of the penis by curetting with a sharp spoon. A subcutaneous injection of cocaine makes it possible to do it thoroughly without pain. The wound thus obtained must be treated antiseptically. By this process the author finds that the length of time required for complete cicatrization is much reduced, the average number of days in three hundred cases being less than ten.

CALOMEL PLASTER FOR SYPHILIS.

A NEW method of treating syphilis by mercury is described by Quinquaud. A plaster about four inches square, containing from fifteen to twenty grains of calomel, is applied to the skin in the region of the spleen, and changed once a week. The plaster is made by mixing ten parts of calomel with three of castor oil and thirty of diachylon ointment and spreading on cloth. The author has had very good results with this treatment in cases which did not yield readily to other methods. No bad results except a slight soreness of the gums have been observed. A large and unvarying amount of mercury is kept in the circulation by this method of application.—*Wiener klin. Wochenschrift*, October 16, 1890.

INTESTINAL ANTISEPSIS IN TYPHOID FEVER.

THE following is the treatment recommended by Professor Teissier of Lyons (*Lyon Médicale*, September 7, 1890):

- (1) Morning and evening a capsule of seven grains of alpha-naphthol, with salicylate of bismuth.
- (2) Sponge once in twenty-four hours.
- (3) To restore the action of the kidneys after the mid-day sponging a rectal injection is given of one drachm of the extract of cinchona and eight to fifteen grains of the sulphate of quinine dissolved in sulphate of valerian.

¹ *Monatsschrift für prakt. Dermatol.*, September, 1890.

(4) The diet is restricted to Bordeaux wine, milk and broth.

The author states that he has employed this treatment in fifteen cases of typhoid fever, some of which were of exceptional severity, one case only dying, due to suppurative nephritis occurring at the close of the disease. In almost all of these cases complete antisepsis was realized about the fourth day of the treatment, this being recognized by the green tint of the urine. The temperature depressed progressively, the albuminuria disappeared, the spleen regained its normal volume, and the tongue became moist, and lost its furred condition.

After a regular fall of temperature there then occurred a series of marked thermic oscillations, lasting from four to eight days, the patient then passing to the stage of convalescence, a stage of the disease which was remarkably short. He further adds, that through all the duration of the treatment the typhoid aspect was wanting.—*Therapeutic Gazette*, October 15, 1890.

PEROXIDE OF HYDROGEN AS A DISINFECTANT OF WATER.

DR. ALTEHOEFER¹ after giving references to the literature of the subject, gives his own researches on the disinfective power of peroxide of hydrogen dissolved in water. He finds that the addition of one part to a thousand to ordinary drinking water, to drinking water containing sewage, or to water containing typhoid bacillus or cholera bacillus, is quite sufficient to destroy the various saprophytic and pathogenic organisms contained under these conditions, if it is obtained perfectly fresh and kept in good condition, and if it is allowed to act for a period of twenty-four hours. It is specially valuable for the disinfection of drinking water, because it does not affect the taste, does not alter the color, and in the proportion mentioned is perfectly innocuous. As regards cost, he calculates that sufficient drinking water—say ten litres—for a family may be sterilized by means of peroxide of hydrogen at a cost of about five cents per diem.—*British Medical Journal*, October 25, 1890.

MUMPS.

BORDAS² took the opportunity offered by an epidemic of mumps in a regiment to make a careful study of the disease. Metastatic orchitis was very common, especially in those cases in which the parotitis was light, and in those who left the bed too soon. The author succeeded, in each case in which it was tried, in finding and making a culture of the bacillus, already described by Dab Harrin and Capitan. The bacilli are killed by corrosive sublimate and by boracic acid, but not by iodoform. The spores are not injured by drying. The source of infection is undoubtedly the saliva, which dries on the lips and is rubbed off either by kissing or onto towels and bed-clothes, from which it reaches the mouth and through Steno's duct the parotid gland. To prevent this infection a mouth-wash of boracic acid is recommended, and thorough sterilization of towels, etc.

¹ Centralbl. f. Bakter. und Parasitenk., July 25, 1890.

² Centralblatt für Klin. Med., No. 43, 1890.

BREAKING THE OPIUM HABIT.

In a paper on this subject in *Le Bulletin Medical*, October 15, 1890, Ball points out the objections to a sudden stopping of a large amount of opium. The principal dangers are delirium tremens, mania, sudden collapse and uncontrollable sexual desire. In gradually diminishing the amount, several drugs have been recommended to supply the stimulation which the patient craves. The author has had very good results with the sulphate of sparteine. When the daily amount of morphine is reduced to a grain and a half, a small amount of sparteine is added, which is increased as the morphine is decreased until the patient gets two grains of the former a day, and none of the latter. The sparteine is kept up for some time, and then gradually discontinued. It may be given hypodermically, mixed with the morphine.

STERILITY.

A FEW months ago a French author told a story of a married pair who consulted him, as they wished to have children. They had just come from the office of a well-known Parisian physician who had advised that the wife's uterus be curedtted. A thorough examination revealed nothing wrong with the woman, but the husband's spermatic fluid was found to be entirely without spermatozoa, due to a previous double epididymitis. That the common opinion, that failure to produce children is probably due to some defect in the wife, is not justified, is shown by Lier and Asche,¹ who found that out of 227 cases of sterility 132 could be credited to the man, most of them due to previous gonorrhœa. Where the man was at fault only six per cent recovered their power of reproduction by treatment, whereas twenty-five per cent of the women subsequently became pregnant. The authors emphasize the importance of examination of the spermatic fluid in all supposed cases of sterility.

FAUCIAL AND PHARYNGEAL TENESMUS.

MR. LENNOX BROWNE proposes to apply the term "tenesmus" to the fauces and pharynx in those cases in which there is a continual inclination to void or to swallow an imaginary foreign body, accompanied by more or less cough, straining, and pain, either after or independent of functional exercise of the voice, with expectoration or welling up of small quantities of mucus, and occasionally, more especially in rising from sleep, by the discharge of small quantities of blood. Tenesmus would, in fact, not only apply to the condition now known as "globus hystericus," but would embrace all those numerous and various subjective symptoms which occur in the throat, and have not until recently been acknowledged to have other than a neurotic basis.

The causes are mainly three: (1) Hypertrophy of the lymphoid tissue at the base of the tongue and the lingual tonsil; (2) Varix of the vessels in the same situation, the two constituting a condition called by him "throat piles"; and (3) A congestion, fulness, sometimes even obvious enlargement of the thyroid gland. Functionally, the physical conditions causing

¹ Zeitschr. für Geburtshilfe und Gynäkol. xviii.

throat tenesmus are mainly due to over-use, or wrong use of the voice, and to bolting the food, but the underlying constitutional causes are many, the principal one being a general varicose diathesis, shown by the occurrence of rectal piles, varicocele, varix of lower limbs and cold feet. It is more frequent in women than men, and often appears at the menopause. In many cases there is concurrent relaxation of the uvula, removal of which fails to cure the patient unless the other conditions are recognized and concurrently treated. It is also seen in connection with, and, as was believed, as a result of nasal stenosis. Treatment consists in destruction by electric cautery of the overgrown tissue and enlarged veins, with correction of the faults of health and of local function. Occasionally the hypertrophies are of sufficient size to enable them to be removed by a snare. Astringents or iodine fail to give permanent relief in any but the mildest cases. — *Journal of Laryngology and Rhinology*, October, 1890.

STRYCHNINE AS AN ANTITETANIC VACCINE.

THE French medical journals have given a good deal of attention to the investigations of Dr. Peyraud,¹ who gives an account of some experiments carried out with soil taken from a covered-in enclosure in which wine was stored, and in which no horses had entered within the memory of the inhabitants, and which had not in any way been cultivated since the store was erected. Dust from forage when inoculated induces tetanus in fifty per cent. of the animals experimented on, but soil taken from this wine store induced tetanus in one hundred per cent., five out of every six of the animals inoculated dying. Having obtained this virulent material, Dr. Peyraud carried out a series of experiments to test his theory that strychnine, which produces many of the symptoms of tetanus, would probably act as a vaccine; he, therefore, injected a half milligramme of strychnine in solution every day for five days. Ten rabbits so vaccinated and four test rabbits were inoculated with a small portion of tissue from near the wound in an animal in which tetanus had been produced experimentally, and the wounds were carefully closed. Of the fourteen animals the four test rabbits, and three of those vaccinated, died. In a second series of experiments, seven prepared rabbits and fourteen test rabbits were inoculated with tetanic virus six days after the strychnine inoculation had been stopped; thirteen of the test animals and four of the prepared animals died.

MM. Verneuil, Trasbot, and Nocard were appointed as a committee to test the accuracy of such an important statement, but unfortunately they were unable to obtain as good results as Dr. Peyraud had recorded. They found that the soil was undoubtedly capable of producing tetanus in a certain proportion of rabbits, but in their hands this proportion was only eleven per cent. After experiments to test the preventive inoculation of strychnine, the reporters conclude that although an important fact has been demonstrated by M. Peyraud as regards the presence of the tetanus bacillus in non-cultivated and undisturbed soil, his experiments on preventive inoculation with strychnine against tetanus, are vitiated by some important fallacy, as the committee were unable to obtain the same results. — *British Medical Journal*, October 25, 1890.

THE BRAINS OF FEEBLE-MINDED CHILDREN.

CONCLUSIONS based upon a series of post-mortem examinations, including microscopic study, of one hundred brains of feeble-minded children, are given by Dr. A. W. Wilmarth, in the *Alienist and Neurologist*, October, 1890. The children were taken from all grades in the Pennsylvania Institution for Feeble-Minded Children.

A comparatively large number were cases of actual cerebral disease, in contrast with the relatively small number where imperfect development seemed the causative agent of the mental defect. With this fact, we see a corresponding improbability of a large majority of these cases ever attaining a full mental development. That a large majority of them can be greatly improved, we have daily evidence in our schools. Children inheriting inactive brains from parents below the usual average of intelligence, without history of infantile disease or epilepsy, seem the most promising of general and permanent improvement. The brain diseases of infancy, on the other hand, are peculiarly destructive, and not only leave a permanent injury to the brain, preventing its growth and development, but are liable, from the irritation they leave, to kindle the epileptic habit with its destructive effects. Realizing these facts, the physician should be more cautious in giving the customary diagnosis of "Arrested development that special training will remove," thereby arousing hopes in the minds of the parents that can only result in disappointment.

TRAUMATIC TETANUS: RECOVERY.

DR. A. W. TANCIL¹ describes a case of traumatic tetanus occurring in a colored boy, fourteen years of age, who, about the last week in July, stuck a nail into his foot. The wound healed under domestic treatment, but about one week subsequent thereto, while playing, it broke out again, which caused quite a hemorrhage, but it got well and attracted no further attention. Symptoms of tetanus first appeared on August 18th, and three days later became intense. He was then put upon bromidia, in large doses, a teaspoonful every two hours more or less, according to the symptoms. Four days later he was much better; and the bromidia was continued in full doses at lengthening intervals until September 26th, the total amount given being more than fifteen ounces.

In commenting on the case, Dr. Robert Reyburn, who saw the patient in consultation, said that it was a typical example of the more chronic variety of traumatic tetanus, and is interesting because it illustrates very well the correct method of treatment. The reflex action of the great nervous centres, and more especially the spinal cord, is so immensely exaggerated in tetanus, that the slightest noise, the exposing the patient to a current of cold air, or even a slight movement of the patient, may develop a fatal spasm either of muscles of respiration, or some other of the group of muscles which control functions necessary to life. Anæsthetics, while they for a time seem to modify and control the spasmodic contractions of the muscles, have, in his experience, never effected a cure. The only treatment that he has found to be reasonably successful is morphia given in large doses and in combination with bromide of potassium, but in order to do any good with the remedy it must be given

¹ Journal American Medical Association, July 19, 1890.

in double or triple the ordinary doses and continuously; in other words, you must keep the patient in a condition of semi-narcotism all the time, for days or weeks, if necessary.

In the treatment of the above case it was found absolutely necessary to disregard the ordinary rules of dosage and to give with a liberal hand the bromidia in quantities sufficiently large to keep the muscles relaxed. Several times during the early stages of the treatment of the case, the attempt was made to diminish the doses of the powerful agents used, but the aggravation of the trismus and the painful and powerful contractions of the muscles of the abdomen and extremities compelled a return to the larger doses. Another most important point in the management of these cases is to insist upon the most absolute rest and quiet. The patient is

to be placed in the darkest and most secluded corner of the house, away from noise and secure from the well-meant but often fatal kindness of visitors and friends.

Correspondence.

CONGRESS OF HYGIENE AND DEMOGRAPHY.

BOSTON, November 10, 1890.

MR. EDITOR:—The last meeting of the International Congress of Hygiene and Demography was in Paris, 1889. That held in Vienna, 1887, was the fifth of the series.

I write to correct the statement in Dr. J. S. Billings's communication, November 6th, page 454.

Respectfully, H. J. B.

REPORTED MORTALITY FOR THE WEEK ENDING NOVEMBER 1, 1890.

Deaths reported 2,535; under five years of age 787: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 351, consumption 347, acute lung diseases 287, diphtheria and croup 148, typhoid fever 72, diarrhoeal diseases 61, scarlet fever 26, whooping-cough 16, measles 12, malarial fever 9, cerebro-spinal meningitis 4.

From scarlet fever, Brooklyn 10, Philadelphia 7, New York 3, Chicago 2, St. Louis, Baltimore, Fall River and Salem 1 each. From whooping-cough, New York 6, Philadelphia and Brooklyn 4 each, Lowell, Lynn and Waltham 1 each. From measles, New York 7, Chicago 2, Brooklyn, Nashville and Lowell 1 each. From malarial fever, New York and Brooklyn 3 each. Baltimore 2, Fall River 1. From cerebro-spinal meningitis, New York, Chicago, Brooklyn and Washington 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,559, for the week ending October 18th, the death-rate was 20.8. Deaths reported 3,870: Acute diseases of the respiratory organs (London) 340, diarrhoea 285,

measles 121, scarlet fever 65, diphtheria 61, whooping-cough 58, fever 56.

The death-rates ranged from 12.3 in Nottingham to 28.0 in Manchester, Birmingham 16.7, Bradford 22.5, Hull 18.0, Leeds 19.1, Leicester 19.9, Liverpool 22.0, London 20.5, Norwich 20.2, Oldham 22.4, Portsmouth 15.7, Sheffield 24.9, Sunderland 23.2, In Edinburgh 19.0, Glasgow 22.0, Dublin 21.3.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,559, for the week ending October 29th, the death-rate was 20.6. Deaths reported 3,832: acute diseases of the respiratory organs (London), 417, diarrhoea 206, measles 151, scarlet fever 90, whooping-cough 54, diphtheria 46, fever 45.

The death-rates ranged from 13.3 in Huddersfield to 29.9 in Cardiff, Birkenhead 28.3, Brighton 14.8, Hull 25.4, Leeds 19.1, Leicester 15.2, Liverpool 20.6, London 19.5, Manchester 20.4, Nottingham 18.5, Sheffield 23.2, Sunderland 27.5.

In Edinburgh 17.5, Glasgow 24.4, Dublin 24.5.

The meteorological record for the week ending Nov. 1, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending	Barometer.	Thermometer.			Relative Humidity.			Direction of Wind.	Velocity of Wind.	State of Weather.*	Rainfall.			
		Daily Mean.	Maximum.	Minimum.	8.00 A. M.	8.00 P. M.	Daily Mean.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 1, 1890, TO NOVEMBER 7, 1890.

So much of paragraph 2, Special Orders 208, Adjutant General's Orders, September 5, 1890, as directs First Lieutenant NATHAN S. JARVIS, assistant surgeon, to report for duty at San Carlos, Arizona Territory, is revoked. On the expiration of his present sick leave of absence, Lieutenant Jarvis will report in person to the commanding officer, Fort Bayard, New Mexico, for duty at that station. S. O. 234, Par. 13, A. G. O., October 30, 1890.

First Lieutenant PHILIP G. WALES, assistant surgeon, is relieved from station and further duty at Fort Huachuca, Arizona Territory, and assigned to duty at San Carlos, Arizona Territory, where he is now temporary serving. S. O. 234, Par. 13, A. G. O., October 30, 1890.

Captain WILLIAM J. WAKEMAN, assistant surgeon, is relieved from duty at Fort Bidwell, Cal., to take effect on the final discontinuance of that post, and will then report in person to the commanding officer, Fort Huachuca, Arizona Territory, for duty at that station. S. O. 234, Par. 12, A. G. O., October 30, 1890.

Captain WILLIAM H. ARTHUR, assistant surgeon, is relieved from duty at Fort Bayard, N. Mex., and will report in person to the commanding officer, Fort Grant, Arizona Territory, for duty at that post, relieving First Lieutenant WILLIAM B. BAKER. Captain Arthur, on his arrival at Fort Bayard, will be relieved by Captain Arthur, will report to this city, and report for duty to the commanding officer, Washington Barracks, D. C. S. O. 234, Par. 12, A. G. O., Washington, D. C., October 30, 1890.

Leave of absence for one month is granted Lieutenant-Colonel DALLAS BACHE, surgeon, medical director, Department of the Platte. S. O. 82, Par. 6, Department of the Platte, Omaha, Neb., November 1, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 8, 1890.

J. M. EDGAR, passed assistant surgeon, ordered to the U. S. S. "San Francisco." November 10, 1890.

L. W. SPATLING, assistant surgeon, ordered to the U. S. S. "San Francisco." November 10, 1890.

CHAS. H. WHITE, medical inspector, ordered to the U. S. S. "San Francisco." November 10, 1890.

HORACE B. SCOTT, passed assistant surgeon, placed on the retired list, October 31, 1890.

RICHARD ASHBRIDGE, passed assistant surgeon, surveyed and sent to Hospital, Philadelphia, Pa.

R. M. KENNEDY, assistant surgeon, detached from Navy Yard, League Island, and ordered to U. S. Training-ship "Richmond."

L. W. ATTLEE, assistant surgeon, ordered to the Navy Yard, League Island, Pa.

OBITUARY.

THADDEUS KINGSLY DEWOLF, M.D., M.M.S.S.

Dr. T. M. DeWolf died in Chester, Mass., November 4, 1890, at the age of eighty-nine years. He has been prominent in the town of Chester for sixty years as a physician, post master and justice of the peace.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

MEETING IN MEMORY OF HENRY J. BIGELOW, M.D.

A meeting in memory of the late Dr. Henry J. Bigelow will be held in the Medical Library Building, Boylston Place, by the Boston Society for Medical Improvement, on Wednesday, November 19, 1890, at 4.30 P. M.

Members of the Massachusetts Medical Society are invited to be present.

R. H. FITZ, M.D.
E. H. BRADFORD, M.D. { Committee.
A. T. CABOT, M.D.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, November 19, at 7.45 o'clock.

Dr. G. W. GALVIN: "The Necessity of an Emergency Hospital in the Business District of Boston." Drs. Waterman, George Stedman, T. H. DeBlois, G. H. M. Rowe (Superintendent of Boston City Hospital), J. W. Pratt (Superintendent of Massachusetts General Hospital), Cheever, J. Homans, Gay, M. H. Richardson, Cabot, Burrell and others are expected to take part in the discussion.

Dr. W. F. TEMPLE: "An Unusual Case of Aneurism." Drs. G. M. Garland and Henry Jackson are expected to take part in the discussion.

E. G. CUTLER, M.D., Chairman.

E. N. BLODGETT, M.D., Sec'y., 138 Boylston St.

AMERICAN ACADEMY OF MEDICINE.—The Constitution was altered at the last annual meeting, so as to admit, in addition to those possessing the degrees of A.B. and A.M., those who can present evidence of preparatory liberal education equivalent to the same.

Dr. J. E. Emerson, Detroit, Mich., Chairman of Committee on Eligible Fellows, will forward to any applicant copies of the amended Constitution and By-Laws, list of members, and other information as to the Academy.

RICHARD J. DUNGLISON, Secretary.

814 N. 16th Street, Philadelphia, Pa.

BOOKS AND PAMPHLETS RECEIVED.

The Aladdin Oven: What It Does and How It Does It. Invented and Patented by Edward Atkinson. Sold by Kenrick Brothers, Brookline, Mass.

A Contribution to the Pathological Anatomy of Chorea, with the Report of a Case. By Charles L. Dana, M.D., New York, Visiting Physician to Bellevue Hospital.

A Study of the Anesthesia of Hysteria. By Charles L. Dana, M.D., Professor of Diseases of the Nervous System in the New York Post-Graduate Medical School. Reprint. 1890.

A Manual and Atlas of Medical Ophthalmoscopy. By W. R. Gowers, M.D., F.R.S., etc. Third edition. Edited with the assistance of Marcus Gunn, M.B., F.R.C.S., etc. Philadelphia: P. Blakiston, Son & Co. 1890.

A Practical Treatise on Impotence, Sterility and Allied Disorders of the Male Sexual Organs. By Samuel Gross, A.M., M.D., LL.D., etc. Fourth edition. Revised by F. R. Sturgis, M.D. Philadelphia: P. Blakiston, Son & Co. 1890.

Original Articles.**THE CONTINUOUS INHALATION OF OXYGEN
IN CASES OF PNEUMONIA OTHERWISE
FATAL, AND IN OTHER DISEASES.¹**

BY ALBERT N. BLODGETT, M.D., BOSTON.

It is a recognized fact that several of the most common and most fatal maladies to which the practitioner of medicine is called, are fatal on account of interference with the function of respiration. These diseases kill, by either preventing the access of a sufficient amount of respirable air to the lungs, or by diminishing the respiratory area within the lungs. This may be caused by exudation of foreign material, or from closure of the lumen of the respiratory passages through inflammation, or from other causes. It is only within the latest times, that the attention of the practitioner of medicine has been effectually called to the possibility of treating these conditions by the direct employment of oxygen, for the purpose of offering to the impaired respiratory function the means of fulfilling its mission to the animal economy, by extending to it an atmosphere containing a richer supply of this all-important element, and thus enable it to carry on its indispensable duty, though it be forced to do so by means of diminished or diseased respiratory apparatus.

The following paper is not intended to discuss this subject in an exhaustive manner, nor is it intended to enter into any examination of the ways or methods in which oxygen acts upon the tissues of the body, but its sole aim is to call the attention of the profession to the great benefit which we may secure for our patients from the use of oxygen in the treatment of disease, and, to attract the notice of those enjoying large opportunities to its use, in the hope that their undisputed authority may indorse what, to my mind, constitutes a great advance in the treatment of some of our most intractable and most fatal diseases. The subject may be appropriately introduced by the narration of the following case:

Mrs. H. W., is a lady of nervous temperament, rather strong-willed, and has been married about six months, being at the present time about thirty-seven years of age. She has always been free from serious disease. She has had many harassing scenes in her family life previous to her marriage, and to some degree since that event. Is rather unusually strong and active in general.

On February 14, 1890, late in the day, I was called in see this lady, on account of a severe cough, which had been harassing her unremittingly for some days. The patient was found lying upon the outside of the bed, and very much flushed. The following symptoms were ascertained to be present. The cough, of which I had been told, was almost constant, and each paroxysm was accompanied by pain, as expressed by groans and exclamations, the distress being referred to an area covering the location of the lower lobe of the right lung. Over this area there was dulness, increasing to flatness as the lower border of the lung was reached, the respiratory efforts were painful, and exaggerated; there was bronchial respiration over a large part of the affected area, and crepitant rales toward the upper portion of the same, with coarse, dry rales over portions of the chest adjacent. The temperature

was elevated, the restless condition of the patient not admitting a positive record of the degree of fever, but the thermometer showed 101° F., taken under the tongue. The pulse was somewhat variable, but averaged from 120 to 130 in the minute, of fair strength and volume. The face was mildly cyanosed, and the breathing though fairly free, was insufficient, the respirations being twenty-four in the minute. Two days before, there had been a chill, or rather a chilly sensation of considerable duration, which had been followed by heat and headache, which has since persisted. There was almost complete anorexia, due to nausea. The bowel had been thoroughly evacuated of its contents by domestic purgation. The skin was hot and dry, the color of the surface mildly dusky, the eyes bright and staring, the tongue dry and rough, with many superficial fissures. The teeth were moderately covered with adhesive gummy material. Herpes labialis present. The lips were dry and parched, though not fissured or cracked. There was no expectoration, though there was the constant desire to get something up, which caused, to some extent, the troublesome cough. There was constant pain in the right side, referred to a point of greatest intensity about the region of the nipple, from which it radiated in various directions, and extended around the side. There was no tenderness or other disturbance of the digestive organs, except the symptomatic phenomena above mentioned.

An anodyne mixture was given to relieve the intensity of the cough, and to aid in expectoration; and quinine, with a little wine, was ordered four times daily. Liquid diet was prescribed, and the patient was enjoined to remain quietly in bed, in the hope that the morbid process would remain confined to the portion of the lung already affected.

On the next day, February 15th, the patient was found vastly more comfortable. Cough was greatly relieved, and the night had been restful and she was much refreshed. Treatment was not changed, and the directions before given were continued.

February 16th. I was hastily summoned early in the day, and found the patient in a most alarming condition. There was great oppression in breathing, the surface was everywhere deeply cyanosed, and the respiration was hurried and difficult. The cough had again become distressing; there was a constant feeling of impending suffocation; and the patient was restless, and agitated by the apprehension of sudden dissolution. The face was of a deeply livid color, conjunctive were injected and dusky, and the tongue was heavily coated with a brownish layer of offensive character. I found that on the previous day, she had been out of bed, had attempted to arrange the room, had been sitting at the window, and had been chilled while thus engaged. During the night she had become rapidly worse, so that her condition had awakened alarm in those about her. The area of dulness was found to be more extensive, now including almost the whole of the right lung, and the lower portion of the left, the dulness on this side reaching as high as the nipple. The process in the base of the right lung seemed to be in about the same condition as before described, and there was no noticeable tendency toward resolution. Bronchial respiration was every where detected in the territory of dulness or flatness, and abundant fine crepitation was heard. Temperature was 103° F., respiration 30, pulse 120.

Milk was directed in two-ounce draughts every two

¹ Read before the Boston Society for Medical Observation, October 6, 1890.

hours, and digitalis was ordered, as the circulation was evidently but imperfectly carried on. Tincture of nux vomica in five-drop doses was ordered every four hours, in the hope that it might act to stimulate the respiratory powers. Brandy in moderate amount was also advised, and a competent nurse was obtained, to whose efficiency and care are no doubt attributable the successful issue of what was during many hours by far the most desperate condition which I have seen end in recovery. In the afternoon the temperature was 102.6° F., the pulse 120, and the respiration 35. The patient was very restless and much harassed by a short, dry cough. It was difficult to persuade her to take food. At 7 p. m., there were signs of collapse, the pulse became very weak, the respiration sighing in character, the extremities cold, and the intelligence clouded. A mustard plaster was applied to the chest with benefit, and digitalis and brandy given with a little hot milk. After an hour the signs of extreme peril were relieved to some degree, and the patient turned on the side and slept for twenty minutes. The night on the whole was quiet but not restful, the patient having several paroxysms of coughing, in each of which the surface became livid, and the signs of asphyxia again appeared.

February 17th, at 6 a. m., pulse was 134, respiration 40, temperature 99.8° . The cheeks were quite livid, but there was no evident great distress in breathing. A considerable amount of urine was withdrawn by catheter. At 11 a. m., temperature 100.8° , pulse 120, respiration 52 and somewhat labored. Mustard was again applied to the chest, with some improvement in the respiration; and the patient slept at intervals. At 6 p. m., temperature 102.4° , pulse 126, respiration 45. The patient was now showing unmistakable signs of exhaustion, and the feebleness of the heart's action was apparent. Consultation was suggested, but declined.

At this time I advised the use of oxygen gas, in the hope to increase the respiratory function by furnishing the limited lung-area with an augmented amount of oxygen, so that the condition of the circulation might be improved, and possibly the constant apprehension of asphyxia be relieved. I cannot say that I looked for any permanent good from it, but I hoped to at least gain for the patient the comfort of euthanasia. The gas employed was diluted with ten per cent. of nitrous oxide, and in this form caused no appreciable sensation of discomfort to the patient. The amount given was limited to a few gallons, the exact quantity not being ascertained, owing to a leak in the holder, but the effect was soon noticeable in the appearance of the patient, who became much more quiet, and was relieved to a great degree of the embarrassment in respiration. The face soon became less dusky, the conjunctive clearer; the intelligence of the patient was much benefited, and she expressed herself as feeling better. The oxygen was now withdrawn, and the patient fell into a gentle sleep.

February 18th, at 3 a. m., temperature 97.8° , pulse 122, respiration 52. Face was again very dusky, and patient wandering and restless. Oxygen was again administered, in the manner described above, and again the patient seemed to derive benefit from its use.

At eight o'clock the extremities were cold, the respiration labored, the mind wandering, the body was covered with a clammy sweat, the skin was relaxed, the eyes dull, and every symptom of rapidly approaching dissolu-

tion was stamped upon the case. At this time I directed the continuous employment of oxygen, as the only means of prolonging life, and averting the paroxysms of distress which recurred at intervals. The gas was conveyed from the tank in which it is supplied through a wash-bottle directly to the mouth of the patient, and a constant stream of gas was flowing through the tube all the time, so that with each of the rapid respirations the patient was obtaining a constant increased amount of oxygen. This method of administration, of which I have thus far found no account in the means of information at my command, seemed to afford considerable relief in a short time, and after watching the case for an hour, I left, giving directions to continue the gas.

At 11 o'clock the respirations were higher than at any time heretofore, being 64 in the minute, and the pulse 144; but the patient was not only conscious, but was not particularly uncomfortable, and certainly suffered no such distress as was the case with a much lower frequency of respiration, only a few hours before.

At 6 p. m., the pulse was 120, respiration 56, temperature 98.2° , and the condition of the patient was, on the whole, more satisfactory. The patient took food, and the cough had become less harassing, and there was a noticeable loosening, and the indication of approaching expectoration.

February 19th, 7 a. m., pulse 160, respiration 60, temperature 97.1° . The night was rather restless, the patient was delirious, the extremities became very cool, and were livid in color, the veins of the neck were turgid, and the appearance less favorable, but this condition improved with the morning, and she became quiet and again seemed better.

She continued in this way during the day, until the afternoon visit at 5 o'clock, when the supply of oxygen unexpectedly gave out. A new supply was at once ordered, but the patient sank rapidly, and she seemed to be dying. She passed into a state of collapse, the pulse became imperceptible, the color was more livid than at any previous time, the respirations became shallow, and were reduced to sixteen in the minute, the eyes were glazed, clammy sweat burst forth over the entire body, and every sign of immediate dissolution was present. A subcutaneous injection of pure brandy was at once given, which was followed by a temporary improvement in the pulse and respiration, but this soon subsided; a second injection of the same character was given, with a less perceptible effect, and at the time when it seemed that the patient was irrecoverably lost, the oxygen arrived. The gas was at once conveyed into the patient's mouth, and mechanical aid was given to assist the respiratory movements. For a time there was no appreciable benefit from the gas, but gradually the color of the surface improved, the respiration was less embarrassed, the patient could swallow, and the immediate symptoms were again relieved. The patient was, however, restless, the extremities were cold, and efforts to revive the temperature were only partially successful. The pulse remained at 140 most of the night, and the temperature was subnormal. The respirations fluctuated to some extent, but remained between 44 and 58 to the minute.

February 20th. At 7 a. m. the temperature was 96.8° , the pulse 120, and the respiration was irregular, on account of the violent efforts of the patient to get out of bed, etc. At noon, pulse was 134, respiration 56. Strychnia (one-sixtieth of a grain) was ordered

every four hours, in the hope to invigorate the respiratory efforts. In the afternoon the temperature was 99.2° .

February 21st. The temperature, although falling to 96.8° in the morning, recovered to 98.8° , pulse 120, and the general condition of the patient was satisfactory. She was able to sleep at intervals without the use of anodynes, and there was a gradual improvement in the strength. Enemata were employed to relieve the bowel, followed by considerable exhaustion. The respiration continued about 50 in the minute, but the condition of the patient was on the whole much more satisfactory. At night the respiration again rose to 60 in the minute, but there was no distress. There was now considerable expectoration, and later in the day the bowels and bladder were moved spontaneously for the first time during the severe phase of the illness.

February 22d. The breathing was less labored, and the patient, in this way, more comfortable than at any time during her sickness. Temperature in the morning normal, in the afternoon 100° . At 8 P. M. pulse was 100, respiration 32. The bowels acted naturally.

February 23d, 8 A. M., temperature 98.2° , pulse 94, respiration 36. Passed a fair, though not a very restful night. Began to raise large masses of tenacious matter from the lungs. At 3 P. M., the oxygen was discontinued *after continuous administration for a period of 106 hours*.

February 24th, at 7 A. M., temperature 99° , pulse 92, respiration 30. At 6 P. M., temperature 97.6° , pulse 96, respiration 35, and the patient was perspiring freely. She passed a good night, and awoke refreshed and strengthened.

February 25th, 7 P. M., temperature 98.8° , pulse 96, respiration 28.

From this time there was an uninterrupted convalescence from the pulmonary disease, though the progress was not rapid, and was delayed by neuralgic attacks in various parts of the body, which, at length, however, subsided. There was prolonged mental enfeeblement, caused perhaps by the extreme gravity of the disease, which has since gradually cleared up, so that the patient, in all respects, is, at present, apparently as well in both body and mind as before her sickness.

It will be noticed that coincident with the continuous administration of the oxygen there was a remarkable and enormous fall of the temperature. The thermometer registered on the afternoon of February 17th, 102.5° . At this time the patient sank into a state of profound collapse, and the thermometer registered at the next visit, 97.4° , a fall of 5.1° within a very short time. The condition of the patient was, during many succeeding hours one of the greatest gravity, there was little tendency to rally, and for several days the morning temperature was subnormal.

On one occasion, with subnormal temperature there was associated a pulse of 160 in the minute, and a respiration of 56. Upon two occasions during the severity of the case, the lines of temperature and pulse cross each other, that is, a rising pulse line is found associated with a declining temperature, a phenomenon which has been believed to be invariably indicative of a lethal termination of the case.

I account for these various unusual symptoms upon the ground of the extreme exhaustion of the patient, and the great prostration of all the vital processes.

I have thus, somewhat at length, detailed this case

in the hope that I might bring to my aid the experience of other and abler men in the use of the means here employed for combatting the asphyxia accompanying pneumonia, and, which I have no doubt, is equally applicable to other diseases which kill by reducing the respiratory capacity of the lungs, or by preventing the elimination of noxious products of respiration. I have been able to find very little in the literature upon this subject, and have never seen or heard of the use of oxygen in any other, than rather an experimental and dilettante manner in the treatment of disease. When I directed the continuous administration of the gas, I did so under the positive conviction that the patient was irrevocably doomed, and the best result that I looked for, was simply relief to the sensation of suffocation, and not any curative action. The record then made in my note-book, February 18th, at 8 A. M. is "in articulo mortis." At this time I had only employed the gas in the manner ordinarily directed, that is, two or three gallons at a time, several times daily. I now directed its use without cessation, and to my great surprise, the patient not only obtained the relief desired, but was enabled to carry on the function of respiration.

The amount of gas employed was not far from two hundred gallons in twenty-four hours. The dealer who supplied the gas was astonished at the amount required, and, thinking to do me a service, sent me a cautionary message, implying that no human being could possibly stand so great an amount of oxygen, on account of the dangerous degree of stimulation to the system and the increased combustion of tissue. I have no doubt that the warning might be appropriate in any ordinary or occasional use of the gas, but in this case, the temporary absence of the oxygen was followed by the most alarming symptoms, and it was only with the greatest exertion that the patient was resuscitated. I think that the recovery of the patient from the condition in which she then was, is due entirely and unquestionably to the administration of the gas. Its effect was almost as pronounced and evident as is that of a ligature in hemorrhage.

To my sorrow I have to confess that I am able to recall more than one case of pneumonia which has terminated in death, in which I cannot but think that the timely use of oxygen gas might have been conducive toward a different ending of the disease. I am inclined to think that the judicious employment of this agent will be followed by distinct amelioration of the symptoms, and reduction of the distress in all cases of impending asphyxia. If in this way the strength of the patient may be husbanded, and the blood be maintained in a state of oxidation sufficient to allow the respiratory phenomena to go on, I think that many cases will be found in which the period of greatest danger may be safely tided over, which would otherwise unquestionably be lost.

I have been able to find only very rare and unsatisfactory allusions to the use of oxygen in pneumonia, and what I have found are almost wholly without benefit in forming a conclusion as to the best manner of using this agent, and also in relation to its action. I have only found one allusion to the continuous administration of oxygen, and in this case the gas was conducted into a pail of water, placed by the side of the patient's bed, and the air of the room was fanned toward the patient. I think it may well be questioned how much benefit was derived by the patient from

this uncertain method of administration of the gas, though I believe that in this case the patient happily recovered. I had not seen the report of this case, and it is so unsatisfactory that I should hardly have been inclined to accept it as a safe guide in the use of what was to me an unknown method of administration.

I shall not at this time attempt to analyze the action of oxygen upon the organism, nor the way in which it changes the condition of the patient, but will simply express my conviction that its employment in the laboratory for physiological experiment does not at all indicate its usefulness or its action upon the organism in cases of disease. I feel that in extreme dyspnoea, or in threatened asphyxia, we have in this agent the means of obtaining in many cases a distinct relief of the suffering; and a painless if inevitable death. If more extensive experience should confirm my present conviction, we have in oxygen the means of tiding the system over periods of great exigency in the direction of suffocation; and the chances of recovery in such cases are raised from absolutely nothing, to a very considerable proportion.

In my opinion, the *first* of these propositions would be a sufficient reason for urging the use of any appropriate agent; and the *last* makes its use in proper cases imperative. It is none the less indicated, and acts in these cases in exactly the same way as in cases of poisoning from illuminating gas, in drowning (submersion), in carbon-dioxide poisoning, and in other conditions which will present themselves to the mind.

A somewhat imperfect review of the literature upon the subject of the employment of oxygen in the treatment of pneumonia has not afforded the assistance which I hoped to obtain, and I am convinced that it is not the subject of frequent administration. The "Index Medicus" has relatively few allusions to it, and the cases there recorded are either imperfect to a degree which deprives them of all value as articles of reference, or are so purely amateurish in character that no useful deductions can be made from them. Dr. Maurice Dupont² states that oxygen was first used by Dujardin-Beaumetz, and adds that the indication for oxygen inhalation is most pronounced in asphyxia. Beddoes has employed oxygen for the relief of asphyxia after submersion. Paul Bert has recommended the use of oxygen to aeronauts in making ascents into great altitudes, where the atmosphere is relatively attenuated, and the contained oxygen much rarified. The concomitant asphyxia attending these ascensions is best combatted by oxygen gas. A case is mentioned in which the asphyxia due to attenuation of the atmosphere was so sudden and so profound, that two of the three occupants of the balloon were overpowered before the necessary preparations for inhalation could be made, and only one individual survived the perilous adventure.

Crequey has reported several cases of profound suffocation from carbon-dioxide which have been promptly relieved by oxygen. "This is advantageously combined with injection of ether, or ether vapor may be mingled with oxygen gas. Inhalations of oxygen have been of vital importance in poisoning from illuminating gas, which is less amenable to treatment than is the more ordinary form of poisoning from carbon-dioxide. It has been found of great service in the treatment of persons overpowered by the unwholesome or poisonous

gases of vaults, sewers, mines, etc. The uses of oxygen apply solely to a single symptom, the dyspnoea; in cases of functional disorders of the respiratory system, or of asphyxia, in some cases acute, as in carbon-dioxide poisoning, or chronic, as in pulmonary congestion from incompetency of the cardiac valves or muscle."

Dr. J. H. Davenport³ states: "The cases in which oxygen is of benefit are conveniently divided into three classes: (1) those involving dyspnoea, which are essentially acute; acute stages of Bright's disease, heart disease, uremia, opium-poisoning, etc.; (2) those involving defective nutrition or excretion, which are chronic. Oxygen here acts as a tonic. It has in this way been found valuable in phthisis, emphysema, acute dyspepsia, anemia, etc. The amount usually employed and directed is three or four gallons daily, at considerable intervals; (3) in certain spasmoid diseases. The paper above quoted is a valuable contribution to the study of oxygen in general, but it presents no cases, and touches only to the extent above indicated upon the use of oxygen gas in the manner and for the object to which the present paper is devoted.

Dr. W. Gilman Thompson⁴ gives the following summary of uses of oxygen gas: (1) In neurotic dyspnoea; (2) when there is diminished surface for aeration of the blood; (3) diminished inflation of lungs from many causes; (4) specially beneficial in the dyspnoea of chronic Bright's disease, uremia, pneumonia, capillary bronchitis, asthma, catarrhal bronchitis, sometimes pulmonary congestion, and early stages of edema. This article has also a very carefully collected list of the published articles bearing upon the topic under discussion.

Sajous⁵ writes: "Griffith states that Dr. F. Glasgow administered oxygen internally to a patient with pneumonia, and observed decided improvement in the color of the skin, and in the general appearance."

Hilton Fagge in his concise and valuable work, does not mention oxygen in relation to pneumonia. In critical periods he recommends alcohol, ammonia, and sometimes cautious venesection.

Ertel⁶ says: "The employment of oxygen inhalations seems to me most justified scientifically in cases in which the relative pressure of the oxygen is considerably lowered, and in maladies attended with dyspnoea, in which the blood is overcharged with carbonic acid. Paul Bert was the first to demonstrate by experiments on animals as on the human subject, that in attenuation of the air down to 450 to 400 millimetres of the barometer, the symptoms of oxygen insufficiency are set up, but by the inhalation of more richly oxygenized air, a further reduction of the pressure can be borne. Under pathological conditions, arrest of the diffusion of oxygen from the lung into the blood, may give rise to a similar diminution of the pressure of the oxygen of the blood as does the lowering of the relative pressure of that gas in the atmospheric air. In such cases an increased supply of oxygen will in the same way avert the immediately threatened danger, although it exercises no direct influence upon the cause which gives rise to it. Accordingly we find indications for the use of oxygen inhalations in those diseases of the

⁶ In the article on Respiratory Therapeutics, in v. Ziemasson's

⁷ Handbook of General Therapeutics, vol. iii, p. 243.

respiratory organs which are attended with severe dyspnoea due to defective exchange of gases, and consequent accumulation of carbonic acid in the blood, such as acute exacerbations of chronic catarrh, emphysema, asthma attended with cyanosis, and dyspepsia, in which, according to the published reports [Birch-Ascheron] oxygen inhalations arrested the dyspnoic attacks, often when they had assumed a most dangerous form. Hitherto, however, there are no published records which furnish any satisfactory account of the extension of the use of oxygen inhalations (*vide Waldeburg*).⁸

In a short article by Dr. E. C. Titus⁹ the author states that "in pneumonia it should be administered continuously from three to five minutes, and as frequently as the urgency of the case demands." He also states that "it has been found by clinical experience that oxygen is less irritating and more readily absorbed when combined with a certain equivalent of nitrogen monoxide. The proportions that I have found most valuable is two parts pure oxygen and one part nitrogen monoxide. In order to obtain good results it is of the utmost importance that these gases should be absolutely pure and properly combined. Pure oxygen I believe to be too powerful an oxidizing agent when used alone, especially when there exists inflammation of the air passages." . . . "Nitrogen monoxide is valuable as a modifier of pure oxygen, and has a soothing effect upon the nervous system. It renders the oxygen with which it minglest more assimilable, and hence more promptly available in the general system."

He reports the following case: "A gentleman, aged sixty-three, of robust habit, was taken ill with double pneumonia. Recognizing the case to be of extreme gravity, because of the rapid respiration and the early development of delirium, with a rapid, feeble and irregular pulse, I immediately began the use of oxygen and nitrogen monoxide, with stimulants and other remedies. At first the inhalations were given very frequently, as often as every fifteen or twenty minutes, and for a period of from three to five minutes at a time. After using a few times, the patient became more quiet, the breathing easier and less rapid, with clearing up of the cyanosis, abatement of the delirium, and free expectoration. The remedies were continued through the night. The following forenoon the patient expressed himself better, and very much relieved by the inhalations. The inhalations were continued through the course of the disease, at either longer or shorter intervals, as the exigencies of the case demanded, and were always followed by an amelioration of the urgent symptoms."

The last-mentioned quotation is taken from an ostensible reprint of the paper referred to, published by a company in New York as an advertisement for oxygen, which is furnished by the company in large steel cylinders containing one hundred gallons. Oxygen is also offered to the profession in the quantity of one hundred gallons, contained in small wrought-iron cylinders, under enormous pressure. In my limited experience the gas from the larger cylinders has seemed to last longer, and I thought the patient seemed to obtain more benefit from its use than from that in the smaller cylinders. In both cases the oxygen is diluted with a certain amount of nitrous oxide gas.

THE SURGICAL TREATMENT OF SPASTIC PARALYSIS IN CHILDREN.

BY E. H. BRADFORD, M.D.

AMONG the so-called paralyses of children is one affection which, though well-marked in type, has, until recently, received but little attention. Spastic or cerebral paralysis in children has remained almost neglected by orthopedic surgical writers. This fact is the more surprising as the disease gives occasion to a marked awkwardness in gait, and to deformity second only to that following infantile paralysis. The explanation for this omission may be given by the fact that until recently the affection was but little understood. Fortunately this is not the case at present, and although the pathology of the disorder is as yet somewhat of a mystery yet thanks to a number of recent writers, there is no difficulty to be met in recognizing the affection and estimating its clinical history and probable course.

The disease is in no sense a true paralysis. There is in typical cases at the early stages no loss of power of the muscles, but the patient is unable to use the limb not from any lack of strength so much as an inability to control or co-ordinate muscular action. This condition of things is limited to certain groups of muscles, usually those of the lower extremities, sometimes also of the upper extremities. In some instances only one upper extremity and one lower extremity, in others simply one lower extremity is affected. In one exceptional case in the forearm of the right hand, some of the muscles of the tongue were affected, while all other muscles were normal. In many instances the disease is combined with an impairment of intelligence. Frequently, however, the intelligence is unusually good.

Where both limbs are affected, this condition is doubly trying; and when the adductor muscles are also involved, the limbs are crossed, and the gait becomes very difficult. A degeneration of the muscles takes place, and they become permanently affected. Atrophy of other muscles also occurs, and the limbs become wasted; but ordinarily, there is not, during childhood, much wasting of the muscles, and they are peculiarly firm to the touch, even when not in use. A characteristic of the affection, in contrast to infantile paralysis, is the presence of exaggerated knee reflex which is always present. The affection is supposed to be congenital, but is frequently not noticed by parents until after the child begins to walk.

In some instances a large number of the muscles of the trunk, and the extremities are involved. In one instance the bladder was affected, attacks of incontinence of urine occurring, but usually the rectum and bladder are not affected. In one instance there was an apparent paralysis of the nerves controlling the perspiration on one side of the face. The affection is usually accompanied by a certain amount of nervousness of disposition, excitability, in other instances, however, the patients are of a calm temperament. It has been said to result from some injury at the birth of the patient; but this has not been proved, and in the majority of cases, which the writer has seen, the birth was perfectly normal. In one instance, that of an idiot, a spastic condition of the muscles of the forearm appeared to be due to an injury by the pressure of forceps at birth.

Where no defect of intelligence is present, if the

children are of a nervous or excitable disposition, they are managed with difficulty. Even in the lighter cases, the children are often deprived of an ability to play about with their companions: they are prevented from forming friendships, and lose the education which comes in that way and which is of great value in developing character. Where the affection is more extensive, and locomotion becomes difficult, children prefer to remain sitting, rather than to move about actively, particularly if all their wants are supplied by parents. They, therefore, become more helpless from inactivity than they would be simply from the natural defect. Walking is labored, and the children move about as little as possible. In the severest cases, the children's state is unusually deplorable. They are practically helpless, although their general health may be good. Where this condition is accompanied by idiocy the condition is hopeless, but in those cases where the mental intelligence is really good, but has been entirely undeveloped by the circumstances accompanying growth, the state is particularly lamentable. In the other cases where the children are able to go about readily, the awkwardness of their gait makes them frequently objects of derision among their companions, and that in itself sometimes in sensitive children is an impairment to their complete growth in mental qualities.

The gait in walking is characteristic, and is seen in no other affection. The heel is not placed upon the ground, the knee is bent, and the knee is thrown to the inner side. When both limbs are affected, the gait is a peculiarly springing one as if the patient was as desirous as possible of resting on one foot as little as he could. The limbs are dragged one over the other, and the feet sometimes turn slightly in, or less frequently they may be turned out. Occasionally the patient can walk naturally for a step or two, but when excited, in play or in ordinary walking, they will twist the limbs more violently.

In the severest cases one limb crosses another so that it is with difficulty that the patient stands. Where the upper extremities are affected, the thumb is usually pressed upon the ball of the hand, and the fingers flexed. The hand turns in, and the forearm rotates inward, whenever there is any attempt to move the arm. The muscles at times may be soft, and the hands when at rest, in good shape and position. In some instances when the patient is at rest, the muscles of the lower extremities are soft to the touch, and gentle, passive and active motions are normal; but motion following nervous effort or excitement is accompanied by spasm. The pathology of this affection is not definitely understood, farther than there is reason to believe that it is due to some affection, defect or injury to parts of the motor centres or to the cortex of the brain, accompanied in many instances by degeneration of the lateral column of the spinal cord, but this portion of the subject can better be left to the researches and investigations of the neurologists.

The important subject of treatment has been considered by the neurologists, and their reports are not encouraging. Neither the administration of drugs nor electricity is of use. Massage is of doubtful benefit. The careful education of patients and muscular training carried out persistently are, however, of advantage, and some improvement is to be gained in this way, but the number of cases where such treatment is

feasible or advisable, is few, and the amount which can be gained in the severer cases is slight.

The use of appliances naturally suggests itself as a ready means of correcting the deformities assumed in spastic paralysis resulting from the defective muscles; but, a thorough attempt of this method of treatment will demonstrate that it is practically useless, — except in cases that are very unusual.

Although it is an easy matter to devise such appliances as will prevent the limbs from assuming an attitude of deformity, yet the deformity recurs whenever the appliance is taken off. Furthermore, an appliance of great strength is necessary to resist the action of the strong muscles when the patient is of any size, for that reason it will be found that an apparatus is cumbersome and prevents, rather than aids, locomotion. And it has been found that (unlike the condition of muscles found in infantile paralysis) the muscles cannot be stretched, so that the deformities become permanently corrected. Hence, the treatment by mechanical appliances will not be found of any permanent value.

Perhaps, in the future, when surgery of the brain has been more advanced, it may be possible to attack in a few of these cases, the central nerve lesion. At present, however, such a proposition is not justified. In a case reported by Dr. Bullard and by the writer, trephining was done on the motor centre of the right arm for the reason that it was manifest that there had been bone pressure on the skull, occurring in an idiot who was certainly injured at birth by the use of forceps. The operation revealed a cortical cyst in this region — but the case terminated fatally and cannot be quoted as a precedent for future operation.

The neurologists, as a rule, have not given their sanction to tenotomy in spastic paralysis and some emphatically oppose it. The objection which has been urged against the treatment by operation being that as the affection is not a contraction of the muscles, but a defect of the brain-centres, all that an operation could do would be to weaken the muscles without altering the central conditions.

Although this objection is theoretically plausible against it can be urged recent practical experience. It has been abundantly proved that tenotomy does not injure the muscles, and it cannot rightly be said to weaken the muscles. The monograph by Rupprecht would seem to be sufficient to establish this point, substantiated as it is by the experience of other surgeons. It may be said, also theoretically, that although central brain trouble exists, yet the condition of the muscles suggests that the muscles are too powerful to respond readily to the brain influence, and, that something is needed to enable the central nervous force to compel obedience of the muscles.

What tenotomy actually does in these cases on the structure of a muscle is not definitely understood. It certainly overcomes the contraction and in spasmoidically contracted muscles it would appear that it prevents the possibility of permanent spasms. Whether this is done by lengthening the muscles or by weakening, it is impossible to say, but neither tenotomy or myotomy permanently injures a muscle. Furthermore not only tenotomy but also myotomy appears to be of advantage in these cases in enabling the patient to overcome the resistant tonic spasm in certain muscles, which interferes with locomotion.

The writer does not attempt a physiological explana-

tion of the fact, but bases his opinion on his experience in fourteen cases of varying severity. In six of these, simple tenotomy of the tendo Achillis was performed. In four, tenotomy of the tendo Achillis and section of the hamstring tendons was done. In four cases myotomy of the adductors was done in addition to the section of the hamstrings and tendo Achillis.

The cases operated upon were all children and in no case had the muscles degenerated from disease to the extent that they were not powerful, and in all was the operation amply justified by the results obtained.

Where the tendo Achillis alone was to be divided, the procedure employed was the usual one of subcutaneous tenotomy followed by fixation of the foot in a position at right angles to the axis of the leg, and later by the retention of the foot by a light appliance to prevent dropping of the front of the foot, this appliance to be worn for a few months.

If the foot be overcorrected, there appears to be, in this affection, greater danger of a resulting calcaneus, than after tenotomy of the tendo Achillis, after congenital club-foot or from infantile paralysis (anterior poliomyelitis). If, however, care is used in fixing the limb, not to overcorrect, little danger of calcaneus is to be anticipated.

Although subcutaneous division has been used in one or two of the cases of section of the hamstrings and adductor muscles, I have, of late, been led to prefer open incisions (under aseptic precautions) on account of the greater precision and definition possible.

The place of incision necessarily varies whether the part which is to be divided is in the knee or the groin. In the knee, the patient is placed on the face; after the skin is thoroughly cleaned, an oblique incision is made reaching from one side of the popliteal space to the other, running across the tendons of the outer and the inner hamstring muscles. The tendons are then carefully divided by transverse or oblique incisions. The limb is then made straight and the wound closed by a suture and an aseptic dressing is applied. If the tendo Achillis has also been divided, the foot is also placed straight. Where the adductor muscles are to be divided, they are incised near their insertion at the groin. This can be done with the tenotome or an open incision. The latter I have preferred, as it enables the surgeon to carefully limit the extent of his myotomy. The patient is placed upon the back and an assistant abducts the leg as far as possible, a straight incision just below the insertion of the muscles at the pubes is made through the skin directly over the inner border of the adductor muscle, made tense by the forcible abduction of the limb, the skin incision is separated by hooks and the adductor muscle divided by a cross-cut as extensively as may seem advisable. I have usually divided the muscle more or less completely according to the amount of the spasm, which can be more readily estimated from the fact that in these cases I have found that a complete relaxation of the affected muscles does not take place, even although all the usual symptoms of complete anesthesia from ether are present in the other muscles of the body as well as in the absence of sensitiveness of the cornea. The incision through the skin can be closed by a suture and the wound allowed to heal by first intention.

Immediately after the operation the limb should be fixed in a corrected position. The patient should be kept in bed for a few days but after this the patient

may be allowed to sit in a chair. After ten days or a fortnight the splint may be removed and the patient be allowed to go about either with crutches, or with an appliance similar to what is used in infantile paralysis. Some sort of an appliance will be necessary usually for six or seven months. The muscles, at first, may be regarded weakened by the operation, but they entirely recover their power. As far as my experience goes, there is no danger of a relapse if the operation has been thoroughly done. In a few cases, where the hamstring muscles are imperfectly divided, a slight tendency to a recurrence of flexion has been noticed.

In the cases I have observed, the benefit gained by operative interference was so marked that I think it possible that something may be gained by careful myotomy of the muscles, in the upper extremity. This will require careful examination of the muscles involved and will have to be the subject for further investigation. From evidence that has already been gained, it would appear that, in this form of the affection, tenotomy or division of the muscles relieves one of the obstacles to successful use of the limbs. Where the lower extremity is involved and where, what may be termed, the obstinacy of the muscles, interferes with locomotion; where there is spasm at the tendo Achillis this can invariably be corrected, and the same is true in spasmodic contraction at the knee and in spasmodic adduction, if myotomy has been thorough, but it is a matter requiring some judgment as to how thorough a division will be needed.

I have operated on no cases of spastic paralysis where contraction of the muscles had been followed by complete fibrous degeneration, although if tenotomy is beneficial in infantile paralysis under these circumstances, it would probably be equally so in cerebral paralysis.

In the most severe case that has come to my care all the limbs were affected and a portion of the face. The mental intelligence was remarkably good. Both arms and hands were badly affected, but he was able to use his crutches by the use of the pectoral and a few of the unaffected muscles. The child could walk about on crutches, but the lower extremities were very badly distorted and locomotion much impeded. This condition was corrected by operation and the boy became enabled to walk about with crutches without being interfered with by spasmodic twitches and inco-ordination of the limbs and with the limbs in a normal position.

Where marked mental impairment exists little or no benefit is to be expected from operative treatment, and in adult cases, persistent since early childhood, but little benefit can be expected in severe cases.

TUBERCLE BACILLI.

BY HENRAGE GIBBS, M.D.,

Professor of Pathology in the University of Michigan,

AND E. L. SHURLY, M.D.,

Professor of Laryngology and Clinical Medicine in the Detroit College of Medicine.

SINCE publishing the first portion of our investigation into the etiology of phthisis we have carried our experiments on the prevention or arrest of this disease a step further; and the results, although not verified by extended observation as yet, may be of interest to the profession.

Of all the medications used so far iodoform has been the only one that has given any definite result. This drug was administered by mechanical insufflation, mixed with varying proportions of starch and magnesium carbonate. In these experiments we have first of all taken material from a case in which the physical signs showed the presence of cavities in the lungs and the sputum contained numerous tubercle bacilli. Three monkeys were inoculated at one time with the same sputum and in precisely the same manner. They were then isolated for a week before the treatment commenced, and they were always kept isolated while undergoing treatment. The mechanical arrangement is such that the amount of the drug administered is accurately measured, and the intervals are perfectly regular so that each animal received a known amount of the drug at regular periods throughout the twenty-four hours.

These three monkeys had been inoculated and kept for a week, each one was put under separate treatment. This varied in each experiment, but one of the three animals was always put under iodoform, the others getting chlorine or some other substance with which we were experimenting.

The results obtained have been very striking, and if confirmed will be immensely important. In the animals inoculated we have not been able so far to find that any of the drugs used, either by direct medication or by insufflation, had had such decided effects as iodoform. The monkeys inoculated were kept until one, sometimes two, showed decided suffering from the induced disease, and they were then all killed so as to have all the conditions identical. The average period was three months and a half. We never in these experimental investigations allow the induced disease to go on after it is evident that the animal is suffering pain; as soon as this is manifest, it is killed. We are also very careful as to the surroundings of our animals; they are kept scrupulously clean and well fed.

On examining those animals treated with iodoform, after death, we have found an abscess at the seat of inoculation, containing fluid pus; the pus contained a number of tubercle bacilli. No lesions could be seen with the naked eye, and the lungs looked and felt as if perfectly normal. Microscopical examination showed no change whatever in either lungs or spleen, but in the liver there were patches of fatty change. This was not a fatty degeneration, but a typical infiltration, and there was a marked peculiarity about it. The arrangement of the fatty cells differed from anything we have ever seen. They were not, as is generally the case in fatty infiltration, scattered through the periphery of the lobule; but whole lobules had undergone the change, and several in one place were affected, while other parts in the immediate vicinity were perfectly normal. The whole lobule was not always affected, as at the edge of the patch consisting of several lobules, the fatty change in some ended abruptly in the middle, so that where the intra-lobular vein was cut longitudinally, it was bounded on one side by normal tissue, on the other by cells transformed into fat globules. These patches of fatty infiltration were clearly discernible in the mounted section by the naked eye. In the other animals the conditions were those of so-called general tuberculosis, all the organs except the kidneys being affected. The changes were, however, the same as those found in

pulmonary phthisis, and there was no reticular formation with giant cells.

We have these monkeys inoculated with the same tubercular material showing, in all cases except those treated with iodoform, all the well-known symptoms of artificial tuberculosis, as we call it at present. That iodoform is not a germicide is well-known: it must act by forming a chemical combination with the poison of phthisis, whatever that may be, and rendering it inert. The fatty infiltration of the liver is a point that requires looking into. As it is only an infiltration, not a degeneration, it is not so important, and can probably be prevented.

Emmerich's investigations into the antagonism of the micro-organisms of anthrax and erysipelas are very interesting, as bearing somewhat on this point. He showed that the inoculation of erysipelas organisms had certainly some effect in delaying, and in some cases preventing, the action of the anthrax bacilli. Now in this case we may suppose that some chemical substance existed in the cultures of erysipelas organisms (whether formed by them or not in immaterial) which when introduced into the system united with the poison of anthrax subsequently inoculated, and rendered it inert by forming some chemical combination. The investigations of Pawlowsky on anthrax with the simultaneous injection of staphylococcus aureus or the diplococcus pneumonia, Bouchard's results with the bacillus anthracis and bacillary pyocyanus, also the investigations of Buchner, Churin, and others, prove that there is an antagonistic effect produced, which alters and in some cases presents the well-known poisonous effects of anthrax and other diseases when inoculated into susceptible animals.

We must conclude that some substance is introduced which can combine with the poison and render it inert. Whether this is produced directly by the micro-organisms, or is a metabolic change in proteid substances brought about by their action, remains to be proved. If such a substance is able to cause this change, that is to render a poisonous substance inert, it is certainly within the range of chemistry to find this out and put it in the hands of physicians, enabling them to exhibit it on the first appearance of disease. Our experiments with iodoform certainly point this way. It may not be the best form in which iodine can be given, or it may be that further investigation will enable us to find some other drug which will act without producing any deleterious change in other organs. This has yet to be proved, and we are steadily working in this direction.

The addition of various drugs to phthisical material has rendered it inert, and in some instances has not interfered with the growth of the bacilli or with their characteristic color reaction. We have not, however, yet obtained sufficiently decided results to warrant us in publishing them. We have, however, received further corroboration to the suggestion made in our papers already published on the etiology of phthisis, that there is more than one form of bacillus connected with this disease. We have been enabled to differentiate two forms in pure cultures from human phthisis, and they differ from that found in bovine tuberculosis.

The effects produced by the inoculation of the different forms also varies, and one of them gives rise to acute inflammatory changes followed by caseation and breaking down; and we consider that this is the same organism always found in those cases of acute caseous

miliary tuberculosis, where there is no formation of reticular tissue and giant cells, and in these large numbers of tubercle bacilli are always found.

The appearances presented by the growths in tubes of agar-gelatine are sufficiently characteristic to enable them to be differentiated by the naked eye.

We trust that other workers in this direction will look into the points we have indicated, and throw more light on them.

A CASE OF METASTATIC CARCINOMA OF THE CHOROID.¹

BY O. F. WADSWORTH, M.D.

SEVERAL cases of metastatic carcinoma of the choroid have been reported in the last few years, but the number is not so great as to make it inadvisable, perhaps, to report the following one.

Miss T., forty-six years of age, consulted me June 14, 1890. Three weeks before she had observed a blur before her eyes and discovered that the sight of the right eye was much impaired. She thought there had, in the interval, been little or no change. The left eye was of normal appearance in all respects; $V=1\frac{1}{2}+$. The right eye appeared normal externally; the media were perfectly clear; $V=1\frac{1}{2}+$; T. not increased. The lower portion of the retina was pushed strongly forward; the upper and upper-lateral edge of the elevated portion was sharply defined and formed a regularly curved line, the highest point of which was situated very nearly at the centre of the macula. From this point the edge curved gradually downward to either side, on the inner side curving below the disc and reaching somewhat to the nasal side of a vertical line drawn through the nasal edge of the disc; while on the temporal side it extended to about an equal distance. All the upper part of this elevated portion presented a smooth surface, and the retinal vessels ran over it, curving sharply forward at its edge, of very nearly natural size and course, and without losing their light streak, only the fine vessels running upward toward the macula being rather larger than normal. Rapid movement of the eye produced no change in the defined upper and lateral contour, nor in the level of the surface. The color of this part was rather lighter and more uniform than that of the upper half of the fundus, which was not very strongly pigmented. No vessels other than the retinal vessels could be made out. Well downward and extending to the limit of the visible field, the retina appeared to be floating; it had lost some of its transparency, its surface was uneven, its vessels dark and winding. The disc and the upper half of the fundus appeared normal.

The opinion was expressed that, in all probability, there was a solid growth within the eye, and that in that case the eye should be removed. To settle the diagnosis I proposed that a needle should be passed into the supposed tumor. The proposition was acceded to, and under cocaine a cataract needle was thrust through the sclera, eight or ten millimetres to the inner side of the cornea, and a little above the horizontal meridian and by the aid of the ophthalmoscope its point directed to the upper central part of the elevated portion. The point could be very distinctly observed and was seen to reach the surface of the growth about one millime-

tre (two-thirds disc diameter) below the centre of its upper edge, at a point where there was no visible vessel. It caused no depression of the surface, while a distinct resistance to lateral movement was felt. From the point of contact a small hemorrhage ensued, forming a bright red stripe, perhaps one millimetre wide, extending downward over the surface of the retina some five millimetres. Five minutes later this did not seem to have increased.

It was only after I had advised removal of the eye that I learned the earlier history. Sixteen months before Dr. D. W. Cheever had removed the right breast for cancer. The mammary tumor had existed for some time, was of moderate size, dense, and had puckered in the skin. There was no microscopic examination, but no doubt was felt as to its nature. She had made a good recovery and her general health had continued good. Dr. Durgin, who had seen her for a slight cough a few weeks before her visit to me, informed me that at that time there was a nodule the size of a bean in the cicatrix, which was said not to have enlarged in the two or three months since it was first noticed, and that there were no enlarged glands in the axilla. The idea of a cancerous deposit in the lung had suggested itself to him as the cause of the cough and he had thought there was slight dulness at the lower part of the right chest; but the cough was readily thrown off, and did not recur.

Consideration of the fact that the ocular tumor was a secondary one and that there were doubtless other deposits elsewhere led me to change my proposition of immediate enucleation and to advise that there would be no harm in postponing the removal of the eye until the growth should perhaps cause pain. The patient, however, after two or three days, decided for immediate removal.

I did not see her again until the time of operation, June 26th. Vision had rapidly failed after I first saw her and there was now only perception of light. The iris reacted well to light, but there was no reflex from the pupil with the ophthalmoscope. The eye was enucleated and placed in Müller's fluid.

July 14th, the eye was divided by a vertical section antero-posteriorly through the optic nerve. The vitreous was stained with blood, and a small, loose blood-clot lay in its lower part. The tumor was situated in the choroid, was light colored, moderately firm, nearly circular, with smooth surface. It measured ten by twelve millimetres, attained a thickness of three millimetres at its thickest part, and thinned gradually toward the periphery where it presented a rounded edge. Its most posterior part was at about the centre of the macula and its inner edge curved below and somewhat to the nasal side of the disc. Over fully the posterior half of the growth and over the greater part of the fundus the retina was in position; over the anterior part of the growth and forward to the ora serrata it was loosely detached.

Dr. H. F. Sears kindly made sections of the tumor. Microscopically it showed larger and smaller masses of cubical and irregularly shaped epithelial cells with areas of hyaline degeneration in alveoli formed by connective tissue stroma. It was in the choroid and in places had invaded the inner layers of the sclera. The retina was not involved.

The ophthalmoscopic appearance was very characteristic of a solid growth, and the result of the puncture with the needle left no possible doubt. Although

¹ Read before the American Ophthalmological Society, July, 1890.

the hemorrhage which immediately followed the puncture was of very small amount and a few minutes later had not increased, yet it must have recurred later and been the cause of the subsequent rapid loss of sight.

REPORT ON PROGRESS IN THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D.

MILK SUGAR AS A DIURETIC.

PROFESSOR SÉE considers milk sugar as the most reliable of all diuretics. In diseases of the heart and stomach, and also in renal or cardiac affections accompanied by dropsy, its diuretic qualities render it very serviceable. Milk in these cases, as is well-known, is of great value, not only on account of its diuretic properties, but also because it is so complete a food. Three or four quarts of milk a day may be used with advantage, but the proportion of sugar in milk is rather too small. Professor Séé has discovered, by experimenting successively with the different constituents of milk, that lactose is the active agent. The action of the other constituents of the milk, such as the water and salts, is inconsiderable, the chloride of sodium adds nothing, the salts of potassium very little, to the polyuria induced by the sugar of milk. This sugar is found in all kinds of milk, is crystalline, and quite soluble in water. About three ounces of it dissolved in two quarts of water, with complete suppression of every other liquid, as soup, tea, wine, mineral water, etc., will afford marked diuresis of all cardiac troubles, no matter what the lesion may be, though the results are less constant in arterio-sclerosis.

In twenty-five cases, abundant diuresis resulted; at least eighty ounces of urine were passed, usually one hundred or more, in the twenty-four or twenty-eight hours subsequent to beginning the treatment. As soon as the treatment was stopped the amount of urine dropped off to what it had been before the administration of the diuretic. Professor Séé, therefore, considers lactose to be, not only the most efficient diuretic, but also the least harmful. If milk is used, and two quarts only are taken, diuresis follows; if four quarts of milk, containing six and one-half ounces of sugar of milk, marked glycosuria is produced; at the same time there is considerable excretion of urea, indicating a destruction of the albuminates. With the sugar alone these disadvantages may be avoided, for three and one-quarter ounces of milk sugar in water will set up a copious diuresis, such as we cannot be sure of from even four or five quarts of milk.

The polyuria resulting from this treatment surpasses that from all other methods; the amount of urine rises rapidly to two, two and one-half, usually to three or three and one-half quarts, and even to four or four and one-half quarts on the third day. After this it remains at that point or drops to two and one-half quarts for some days. After a few days the same treatment may be employed to repeat the diuresis.

It is fair to say that while this action of lactose may be relied upon in cases of cardiac dropsy, but in those of renal origin its effects are slight. In cardiac disease it never fails unless the kidneys are diseased, and the amount of albumen is considerable. When the amount of albumen is small, the result is favorable, from which it may perhaps be inferred that there is present only a simple venous congestion.

It is suggested that the diuresis may serve as an indication of the condition of the kidneys. Various conditions may affect the diuresis; sometimes diarrhea occurs, and this diminishes the amount of urine, or the patient may have been subject to profuse sweating, which would also lessen the quantity of urine.

As a rule, the remedy is well-borne. It may be prescribed for eight or ten days, and then omitted for a few days and again renewed. If the simple solution is not well tolerated, brandy or peppermint may be added to it. All other liquids should be reduced in amount, or omitted while the treatment is pursued.

This method presents great advantages over many others and the patient may partake of any food; a meat diet if the physician so desire. Professor Séé¹ considers that the physiological action of lactose is upon the kidneys, since it does not exert any influence upon the circulation. He classes it with caffeine, as he believes that caffeine acts upon the kidneys only, and not through the circulation, as do digitalis and strophanthus. Lactose is regarded as superior to caffeine as it does not effect the brain and nervous system.

ACCIDENTS WITH COCAINE AND PRECAUTIONS.

Dr. Delboe² has published a statistical and clinical report on the accidents produced by this substance. He collected the histories published of accidents, from which he has been able to establish that up to the present time, only five deaths have occurred after the use of cocaine. This proportion would evidently go against the method if only the bare facts be accepted without interpreting them. From the various observations published, it would appear that death resulted from the enormous doses that were administered, varying from about eleven grains to double that quantity. According to Dr. Delboe, cocaine may be employed at the maximum dose of three grains, although he would not advise such a dose ordinarily, as beyond that quantity serious accidents occur.

To avoid rapidity of absorption, solutions too concentrated should never be employed. A two per cent. solution is sufficiently strong. It is not necessary in order to obtain anesthesia to push the needle into the muscles or the subcutaneous cellular tissue, but into the thickness of the dermis. In spite of all precautions accidents may occur, and for them nitrate of amyl, injections of ether and caffeine are indicated.

Dr. Isidor Gluck³ has had occasion to use cocaine frequently in diseases of the eye, ear, nose and throat, and seeing at times most alarming effects from its use, came to have a certain dread of it.

It is when used in the treatment of the nose and throat, and when used hypodermically, that cocaine produces most alarming symptoms. Though employed in strength varying from four per cent. to twenty per cent., sometimes the weakest solutions will produce the toxic effect in one susceptible. He now uses the following solution:

R Phenol	ggt. ii.
Aqua destillat	3 <i>l.</i>
Shake until solution is perfect, then add	
Cocaine hydrochlorate	grs. x.

This formula has been in use for more than a year, and since using, no toxic effects of the drug have had to be treated. It has been used in any quantity in any part of the nose or throat, without the least fear of

¹ L'Union Médicale, 1889.

² Medical Record, June 7, 1890.

³ Medical Record, June 21, 1890.

harmful consequences. Phenol is itself a local anesthetic, and is supposed to prevent absorption of the cocaine by forming a very superficial eschar, and thus its toxic action is avoided. Further, the phenol prevents the congestive reaction, prevents the decomposition of the solution, and renders it aseptic.

Professor Wolffer⁴ points out that the causes in which unpleasant results have followed the injection of cocaine, are chiefly those in which the drug has been employed about the head. It seems that it is more dangerous when injected in proximity to the brain. While one may use sixteen minimis of a five per cent. solution in all other parts of the body, for injections about the head, the same amount of a two per cent. solution is sufficient.

CASTOR OIL AS A MENSTRUUM FOR COCAINE.

To lessen the irritation caused by a cicatrix rubbing over a corneal ulcer, Dr. S. Mitchell⁵ employed a solution of cocaine in castor oil; this relieved the pain and permitted the ulcer to heal after other solutions had been tried in vain.

DANGERS OF ANTITHERMIC AND ANALGESIC ANILIDES.⁶

Among the crowd of modern drugs it is difficult to have a clear conception of their individual action and uses; when it is possible to class them according to their chemical or other relationships the group characteristics may be more readily kept in mind as a useful guide to their administration. A group of antipyretics, having aniline as a chemical basis, may be profitably considered from this standpoint. In aniline one may replace an equivalent of hydrogen by formyl or acetyl, and obtain formanilide or acetanilide; these are the simple anilides. There is further a second equivalent of hydrogen which may be replaced by an alcohol radical, methyl. In this way other compounds, methylformanilide and methylacetanilide, are obtained. It is probable that these substances partake, to some extent, of the poisonous qualities of aniline; arranged according to their poisonous doses for animals, the methylacetanilide is the most poisonous, then acetanilide and methylformanilide, and last, formanilide. Their toxic properties increase in proportion to their molecular weights.

INTRAVENOUS INJECTIONS OF SALT SOLUTION.⁷

The indications for increasing the volume of the blood, when it has been suddenly diminished, may be met at any time by every practitioner. It is, therefore, desirable that physicians should be familiar with some of the principles involved in the use of this means of reviving a patient, especially as the operation is a simple one.

It should be borne in mind that transfused blood possesses no nutritive value. Transfusion is, therefore, useless in all forms of "atrophic" anemia where the changes in the blood-supply correspond in degree to the wasting changes occurring in other tissues. The examination of the blood alone enables us to determine whether the anemia is "atrophic" in its nature or not.

Blood, rather than salt solution, may be needed where the red blood corpuscles are incapacitated, as

in carbonic oxide poisoning, where venesection should always precede the transfusion. Even then the procedure is of doubtful value. There is scarcely a single condition of the blood in which the want of red blood corpuscles is a source of urgent danger. After the greatest losses of blood in animals, a sufficient number of red corpuscles always remain in the circulation to carry on respiration, provided the circulation is maintained. In man, the loss of blood can never be so great as in animals, as syncope occurs earlier.

Blood is, therefore, not required to carry on respiration after sudden loss of blood in a patient previously healthy; nor does transfusion of blood rather than saline solution, seem to be indicated on account of its respiratory value in anemia. The immediate source of danger from sudden loss of blood is the fall in the blood-pressure to a point where the circulation cannot be maintained; the indication is, therefore, to raise the pressure within the vessels, for death will ensue unless means be taken to meet the threatened failure of the circulation. While defibrinated blood may have certain advantages over saline solutions in restoring the tone of the vaso-motor centres, these advantages are more than neutralized by other and still greater disadvantages. For example, it is difficult to obtain blood in sufficient quantity or with sufficient rapidity, as compared with the ease with which a simple saline solution can be prepared. There are dangers attending the transfusion of blood not encountered when saline solutions are used. For practical purposes all the advantages to be gained by transfusion may be equally well and more readily obtained by injecting a neutral saline such as a three-quarters per cent. solution of common salt (about one drachm to the pint).

The only pressing indication for transfusion is collapse from sudden and severe loss of blood.

With regard to its performance, two points may be noted: to use simple instruments, a glass canula with a piece of India-rubber attached and a clean syringe, and never allow the temperature of the solution to rise above that of the body. Milk, or other mixtures possessing what are supposed to be nutritive properties, are never indicated. They have no value, not possessed by an equal bulk of saline solution. [It is simpler to let the solution flow in from a glass funnel, a glass canula or a subcutaneous needle. Three feet of small, clean rubber-tubing and a funnel are all the special apparatus required.—REF.]

THE VALUE OF LARGE SUBCUTANEOUS INJECTIONS OF SALT SOLUTION.⁸

Van Murchurier, of Dresden, reports eight cases of hemorrhage, seven of them in confinement, which were successfully treated by the subcutaneous injection of a six-tenths of one per cent. salt solution. A rather large-sized hollow needle is sterilized by heating it over an alcohol flame, and the rubber tube and funnel, or irrigator, are disinfected with a five per cent. solution of carbolic acid, directly after which the apparatus is filled with salt solution. One or two pints of the solution, at a temperature of 37° C., are injected into the back, between the scapulae or near the axilla, at one or several points. The absorption and distribution of the solution are promoted by massage of the part. This method is less dangerous than transfusion, and is comparatively painless.

CARBOLIC ACID FOR FURUNCLES.

Staff-Surgeon Len,⁹ of the German army, gives the following conclusions on the treatment of furuncles:

Subcutaneous injection of dilute carbolic acid is a simple and effectual abortive treatment of furuncles. Incipient furuncles which have not yet suppurred are especially adapted to the treatment. A cure results in these cases without necrosis of the connective tissue; in the more advanced furuncles which have formed pus or are even discharging it, no deforming cicatrix follows. The proper strength of the carbolic acid is three per cent. This mode of treatment is particularly valuable in the army, because it shortens the time on the sick list (when it is necessary to put the man on at all), and he returns to duty with a better cicatrix, while many may be treated without going to the hospital. The simplicity of the apparatus required—a subcutaneous syringe and a small bottle of carbolic solution—make it possible to carry out the treatment anywhere and at any time; for example, during manoeuvres and on the march.

LEMON-JUICE IN NOSEBLEED.

In the case of rebellious epistaxis which had resisted various modes of treatment, including plugging of the anterior nares, Dr. Fauchon gave relief by the local application of lemon-juice.¹⁰ An injection of the juice was made by a glass syringe into the nostril from which the blood was escaping, with the result of immediately arresting the hemorrhage.

DISINFECTANTS FOR INTESTINAL DISCHARGES.

Professor Uffelmann¹¹ has carefully tested the disinfectants which are commonly recommended for the purpose of disinfecting fecal discharges as to their reliability to accomplish this object. His results vary to some extent from the generally accepted views on this subject, though he insists upon the importance of contact with the disinfectant for a considerable time. We can hardly hope to find even the strongest agent capable of exerting its preventive qualities within a few minutes.

RECENT HYPNOTICS AND ANALGESICS.¹²

It is difficult to estimate the relative hypnotic power of drugs, but the order of potency seems to be as follows: (1) sulphonal, (2) amylyhydrate, (3) paraldehyde, (4) urethan, (5) methylal; none of these drugs equals chloral in the certainty of its effects. It seems probable that a dose of sulphonal has, as a rule, about the same soporific action as three-fourths of its weight of chloral; and Von Mering is of the opinion that half a drachm of amylyhydrate has the same power as fifteen grains of chloral, or forty-five minimis of paraldehyde.

The time in which sleep is brought on will vary much, according to the condition of the stomach at the time of administration; but it depends, too, on the readiness with which they can be absorbed. Urethan, being soluble and non-irritating, is most rapid in its actions; a tendency to sleep is often noticed a few minutes after administration. Paraldehyde and amylyhydrate are also rapid in their effects, but sulphonal more than chloral or any other drug, is slow in producing its effects, and two or three hours

not infrequently elapse before they are apparent, though at times sleep follows in from one-half to three-quarters of an hour.

The duration of the action of these drugs depends partly on the potency of their cerebral influence, partly on the rapidity of excretion. On the latter account, the hypnotic effects of urethan most quickly pass away; and if the tendency to sleep, soon after its exhibition, be counteracted, its influence is not again observed. Methylal, too, is very quickly eliminated.

Among the unpleasant effects, excitement, instead of sleep has been known to follow the use of chloral; amylyhydrate, too, though very rarely, has produced excitement before sleep. After sulphonated patients sometimes pass a restless and excited night, occasionally there are bewilderment and restlessness, rarely delirium. Paraldehyde is practically free from this inconvenience. It may be the greater popularity of sulphonated makes us better acquainted with its effects; but none of the other hypnotics seems to produce such disturbances of the nervous system as those reported after sulphonated, though amylyhydrate occasionally causes headache, giddiness and a feeling of drunkenness. All the hypnotics probably have some direct action on the spinal cord, but the comparative influence of the newer hypnotics on spinal centres requires further investigation.

Bromide of potassium is often a satisfactory and safe remedy in many forms of insomnia; but, this failing, we are often bound to resort to some other drug. Resource to chloral hydrate is a possible cause of great evil; it is seductive, and many have received great injury from it. It seems to be well proved that the system does not get so habituated to chloral that large doses can be taken without danger, and there seems to be good reason for believing that fatal consequences at times arise from a dose which has several times been taken with impunity. We ought never at once to order chloral for simple sleeplessness, but should first order one of the newer hypnotics. In slight cases urethan in doses of from twenty to thirty grains, is often very successful. It is not disagreeable, especially when given in a sweet, slightly flavored mixture; and of all the hypnotics it is the least likely to give rise to dizziness, headache or other discomfort. It should be given immediately before the patient settles down to sleep, for it is quickly absorbed, and the slightest disturbance may prevent its good influence. Though the effect of the drug is of short duration, the sleep induced is continued naturally. If necessary the dose may be increased up to two drachms; a larger dose than this at times causes dizziness, if it does not produce a sleep.

The tastelessness of sulphonated has rendered it a favorite remedy in simple sleeplessness. Doses of from ten to fifteen grains often fail and it is necessary to raise the dose to twenty or thirty grains; larger doses are sometimes recommended, but, from doses above twenty grains, troubles affecting the nervous system are sufficiently common to render some warning to the patient with regard to their possible occurrence desirable. It should be administered finely powdered, in soup or warm milk, some hours before bedtime.

Where delirium is associated with sleeplessness, as in delirium tremens, the milder hypnotics usually fail unless given in very full doses, and urethan is of little value. The older hypnotics, chloral and bromide of potassium, are more effective remedies. In cases of

⁹ Deutsche militär-medizinische Zeitschrift. Lancet, August 17, 1889.

¹⁰ Medical Record, October 1, 1889.

¹¹ Therapeutische Monatshefte, September, 1889.

¹² British Medical Journal, November 2, 1889.

sleeplessness with delirium hyoscine is often used with much advantage, especially where great mental disturbance is accompanied by considerable excitement of the circulation. In mental diseases, chloral, in continued doses, may give rise to serious evils, and opium is a two-edged sword; bromide of potassium often fails, unless given in quantities to affect seriously the heart; urethan is too feeble; sulphonal, paraldehyde and amylyhydrate, all have their advocates, and in moderate doses seem worthy of trial. As amylyhydrate has been known to produce very serious effects when given in excessive doses, and sulphonal, in large amounts, is capable of giving rise to unpleasant nervous phenomena, it appears probable that paraldehyde is the best drug to give when hypnotics have to be administered in full doses and continuously. Dr. Clouston, after long experience, believes that in mental cases paraldehyde is the purest and least harmful hypnotic when insomnia is marked and intractable. He begins with forty minims or a drachm, and goes up to two drachms in ordinary cases, sometimes three or four. Sulphonal, he says, will not compare with it. Other observers praise sulphonal, especially if given in small and repeated doses.

A SIMPLE REMEDY FOR HICCOUGH.

After trying all the ordinary measures without avail, Dr. Loebl fell back upon a household remedy as a last resort, and ordered a teaspoonful of pulverized sugar wet with an equal volume of wine vinegar, to be taken at one dose. The hiccup stopped immediately, and didn't return for six hours, and then ceased after a second dose of the remedy.

DR. A. N. BLODGETT read a paper on

CONTINUOUS INHALATION OF OXYGEN IN CASES OF PNEUMONIA OTHERWISE FATAL.¹

DR. MINOT mentioned a case in which the inhalation of oxygen was tried as a remedy for asphyxia from carbonic acid gas, about fifty years ago, while he was a student in Harvard College, and which was, perhaps, the first instance of its therapeutic use. Two men, employed in the kitchen of the college commons in University Hall, on going to bed one cold night, lighted a pan of charcoal in their room. In the morning they were found perfectly insensible, and breathing sterotomously. It occurred to Dr. John W. Webster, then Irving Professor of Chemistry, that the inhalation of oxygen might save the lives of the patients. Accordingly, a large quantity of the gas was made in the chemical laboratory, and administered to them. The effect of the treatment could not be positively deter-

mined, since one of the men recovered, while the other died.

DR. F. C. SHATTUCK: My interest in the therapeutic use of oxygen has been awakened especially within the past year, and I am much struck by Dr. Blodgett's communication, and the valuable suggestion which it contains. It is my impression that oxygen has been used much more in New York, Philadelphia, and perhaps some other cities, than in Boston; and I had supposed the literature of the subject to be less meagre than Dr. Blodgett has found it. My personal experience with oxygen in pneumonia is limited to two cases; one seen in consultation, the other in hospital practice; both were fatal. The gas was given at intervals in doses of ten gallons or less. I think the tendency has been to wait till the case seemed pretty desperate before using the gas, and Dr. Blodgett's experience would lead one to think that far larger quantities should be used. It would appear that on the other side of the water eighty gallons daily is frequently used in cases of different kinds. Indeed, Ephraim² states, in his little monograph, that an objection has been raised against the use of such small doses as the above. "When the average daily consumption of oxygen," it is said, "is five hundred gallons, is it not absurd to expect notable results from the administration of eighty?" One obstacle which the therapeutic use of oxygen has had to encounter lies in the attitude of physiologists toward it, and the doctrine that an individual takes from the atmosphere all the oxygen which he is capable of consuming, the percentage of the gas in the ordinary atmosphere leaving a wide margin of safety. In the monograph, to which I have alluded, this question is discussed, and recent experiments are brought forward to show that the inhalation of increased quantities may be followed by increased consumption. From a scientific point of view, this is the crucial test. But that which obtains in physiological does not necessarily hold true in pathological conditions, and clinical experience would seem to show that oxygen inhalations may be of distinct value. A second obstacle is the expense of, and, oftentimes, the difficulty in obtaining the gas; at ten cents a gallon, the former is considerable. Last winter, following a suggestion of DaCosta, I used the gas in a case of pernicious anaemia, and in another of leukemia. The former patient was steadily going down hill until the oxygen was begun — ten gallons two or three times a day. From that moment improvement set in, and was very marked. The blood was restored almost to its normal condition as far as the count went; and the complexion, from lemon yellow, became ruddy. The gas was omitted, the patient relapsed, and failed again to improve, though the gas was resumed and in larger quantities. In the case of leukemia no benefit followed several weeks' trial.

In conclusion I should like to emphasize the fact that this hint of Dr. Blodgett's of the continuous administration of the gas, in just such cases as he reports, is likely to be of great value.

DR. GREEN: I should like to ask in reference to alimentation during the continuous use of the gas.

DR. BLODGETT: The alimentation was continued as much as possible. The patient became able to take and retain food to a greater degree than before, so that that function seemed to be invigorated and increased in its activity by the use of the gas.

¹ Berliner Klinik, 1890.

² See page 481 of the Journal.

DR. VAUGHAN: I should like to speak of a recent case in which I used oxygen, and I am very glad to have this precedent for a bolder and continuous use of it. The case was not exactly a parallel one, as the seriousness of the case came more from pre-existing cardiac asthenia, than from the amount of lung involved, although the right lung was entirely consolidated. The action of the heart and the respiration were very rapid and uneven from the beginning. It was an unpromising case from the start, beginning with vomiting and grave nervous disturbance. As the case progressed, symptoms of asphyxia and marked cyanosis set in, and as a forlorn hope I resorted to oxygen. I used it in the intermittent way,—three to five minutes every half-hour at first and with evidently very good effect. The cyanosis was diminished and the breathing improved very much. About the sixth day, however, cyanosis and dyspnoea increased, and the patient began to sink rapidly. Coarse bronchial râles appeared on the other side and in the trachea, with clammy sweat and rapid, thready pulse,—all the signs of impending dissolution. We pushed the oxygen a good deal more strongly, although not continuously, with the result of tiding the patient over the crisis. The cyanosis and bronchial râles disappeared, and hope began to come back. The respirations diminished in frequency, the pulse came down almost within bounds of safety, and we began to have hope of recovery; but the next night the patient was attacked with pain on the other side, apparently pleuritic; in a few hours we got pneumonic signs, and in eighteen hours the patient died from simply lack of strength to live. The effect of the oxygen in this case was evidently good, and when we pushed it harder it met the serious crisis apparently, and tided the patient over. I think if the heart had been stronger we could have saved the patient.

DR. H. F. VICKERY: I should like to mention that a few days ago Dr. Gannett showed me a patient who he believed owed his recovery from pneumonia to the use of oxygen. I did not see the case until it was convalescent. Dr. Gannett was firmly of the belief that oxygen saved the man's life.

With regard to the use of oxygen where there has been poisoning by illuminating gas or carbon monoxide in any form, there is one difficulty *a priori* which does not exist in the case of mere diminution of the aerating surface of the lung. As I understand it each red blood corpuscle has the carbon monoxide combined in itself, and does not take up oxygen readily even if it is presented to it; so from a *priori* standpoint I can see why it may fail in its use there more often than in pneumonia. In fact, in thinking about the treatment of those cases it is very difficult to know of anything that ought to do good except stimulation and the infusion of some other person's blood into the circulation, the removal of some of the poisoned blood and the injection of blood, to which there are also objections.

DR. MARION: Some four years ago I had a desperate case of pneumonia in which I am sure that the use of oxygen was of great benefit to the patient, and I think I should use it again under similar circumstances. Although in that case the patient died, yet she was very much relieved by the oxygen.

DR. IRWIN: I have had the opportunity of using oxygen inhalation at the Marine Hospital four times during the last two and a half years. The subjects

were all sailors, and each case was one of double pneumonia. The last one was particularly unpromising inasmuch as there was alcoholism and jaundice present in addition. I am satisfied that all four of these cases owed their recovery to the use of the gas. They were all apparently dying of asphyxia and in a desperate condition. The method of using the gas was rather crude, and perhaps it would be well to mention it. The gas was made in an iron retort, and caught in an old rubber bag, and while one bag was being used another was filled; it was given continuously I think in most of the cases, probably twenty-four hours. The crudeness of the preparation was shown from the fact that there was a good deal of chlorine present which caused some irritation, and yet not enough to interfere with the efficacy of the treatment. I am satisfied that it is an excellent remedy in such cases.

DR. ROWE: I am sorry that some one of the visiting physicians of the City Hospital is not present to state the results obtained there. I know that oxygen is used there to a considerable extent. I believe that oxygen is used in a routine method in nearly all the desperate cases of pneumonia. The recovery of some of these cases has been attributed to the use of oxygen. I also know that there have been some fatal cases. My impression is that the matter is being observed and that the hospital records will contribute a large number of cases to show the result of oxygen treatment. I may say in this connection that it is almost invariably used in cases of gas-poisoning if the person is seriously ill and fails to mend after the first treatment. In regard to the kind of gas that is used, the New York canisters were so large and heavy that that fact of itself came near defeating the use of oxygen. The nurses could not handle it. Where it had to be carried from one ward to another it was very cumbersome, but in the small canisters which can be readily carried about I think the house staff were much more encouraged to use it. As to the quantities, I cannot speak with accuracy, but I think the routine treatment in cases of pneumonia, is to use three gallons every fifteen minutes.

DR. BLODGETT: I presented this paper not as a finished treatise on this subject, but in order to induce those who know more about the use of oxygen than I do to give me, and possibly others, the benefit of their experience, and I am much gratified at the result. As far as the kind of gas is concerned I do not know anything about that. I used both the varieties mentioned by Dr. Rowe simply because one source of supply became exhausted. It is my impression that the larger cylinders are more economical and last longer than the smaller ones. In cases of severe pneumonia I cannot see the efficacy of giving a small amount of oxygen for certainly four or five or six or ten gallons could not be considered a large amount, and then allowing a considerable interval to elapse before a repetition of the gas. It would seem to me to be like a stimulation, which must be followed by a depression, and the change from temporary stimulation to depression, I should fancy would be more severe at each recurrence; and for that reason I am inclined to consider the continuous administering of oxygen in quantities adapted to the emergency as having a marked advantage over its intermittent administration in even larger quantities. The fact that it worked so very pleasantly without any disagreeable after-effects in the case reported,

has certainly made me feel bold to use it in the same way again. I wish to speak of one other thing. Allusion has been made to the laboratory uses of oxygen and the deductions of physiologists from that standpoint. I am satisfied that laboratory experiments in this respect do not furnish reliable guide for the employment of oxygen in pathological conditions. I think it very likely that the effect produced by the administration of oxygen to a perfectly healthy subject might be entirely different from what I observed in its administration under circumstances in which the respiratory area of the lung was so seriously diminished. In a great many cases of this character, death occurs simply from *lack of oxygenation*, and is accompanied by all the features and signs which indicate that condition. I did not expect recovery in this case, yet I should more confidently expect it in another case of similar character and gravity, if there was no other serious pathological condition than the simple occlusion of lung-tissue. If that condition has not gone too far and is essentially free from serious complications, I cannot see why the administration of oxygen cannot be confidently adopted as the method which offers the best results with which I am acquainted. The pneumonic condition under ordinary circumstances is self-limited, and will clear itself in a pretty clearly defined time, and if we can only tide the patient over this critical period, we may, it seems to me, confidently hope for cure in many patients who otherwise must inevitably die, by that, I mean many of those cases in which the diminution of oxygen becomes so great that all the appearances of asphyxia are produced, and in which the patient dies from that cause and not from anything else.

I do not know the exact composition of the oxygen supplied by the trade, but all the gas I have used was said to be diluted with nitrous oxide in the proportion of about ten per cent.

DR. SHATTUCK: I think so much has been said about the treatment of poisoning from illuminating gas, that we ought to remember the brilliant results reported in these cases from the use of nitro-glycerine. If you can cure them with nitro-glycerine it is certainly easier and less expensive. I have read some remarkable reports this last year, although I have no personal experience in the matter.

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED Meeting, October 20, 1890, the President, GEORGE T. HARRISON, M.D., in the chair.

DR. L. DUNCAN BULKLEY read a paper entitled,

CLINICAL NOTES ON LICHEN PLANUS.

He quoted the description of this disease given by Erasmus Wilson, who was the first to call attention to it, in which he points out that the flatness of the summit of the papules in lichen planus is altogether different from anything that is met with in other affections of the skin, and that the flatness is rendered more conspicuous by the summit of the papule being occupied by a thin, horny, semi-transparent lamina of cuticle, depressed on the surface, and marked in the centre by the aperture of a follicle, which represents a sort of *hilum*. "It is to this peculiarity of figure," he says, "that the word *planus* is especially applicable, and this has guided our use of the term."

This eruption, Dr. Bulkley affirmed, was rather an easy one to diagnose; if these peculiarities were borne well in mind, for it was a peculiar fact that, as far as he had observed the disease, there were always primary lesions to be discovered somewhere (generally at the edge of the eruption), however old or altered it might be in character; and these primary lesions would always present the flat summit, with the depression in the centre. The location of the eruption, or its seat of predilection, was also rather peculiar or characteristic. It is pretty constantly met with about the wrist, and a few or many papules develop on the back of the hands. The next most frequent locality is on the lower legs, especially on the anterior aspect, and it commonly comes on the body only after there has been a considerable development on the extremities.

There was still another remarkable characteristic of the eruption, namely, that the papules or patches generally leave behind them a pigmentation much greater than would be ordinarily expected from such lesions; and this staining was measurably proportionate to the duration of the eruption or of the individual portions of it. Whether of longer or shorter duration, it was always a recognizable feature. While in certain instances the suffering occasioned by the eruption was excessive, in the main the disease was not characterized by much itching; the single papules appearing from time to time often passing unnoticed until seen.

Lichen planus was one of the rarer diseases of the skin. In Dr. Bulkley's experience, among some 8,500 cases of skin disease in his clinics at the New York Hospital, there occurred just forty cases of it; giving a percentage of .46. Among something over 7,000 skin cases in private practice of which he had records, there occurred forty-three cases of lichen planus, giving a percentage of a trifle over .60. The relatively somewhat larger proportion in private practice he thought was probably accounted for largely by the greater attention which would be paid to such an eruption among the wealthier classes, where the disfigurement would call for relief, even if the itching were not troublesome. The combined statistics of the two classes of cases of lichen planus gave a percentage of .53 in all cases of skin disease. The eruption affected males and females in almost the same proportion, and it was, furthermore, one of adult, or rather middle life, fifty-six of the eighty-three cases, or nearly seventy per cent., occurring between the ages of thirty-five and fifty-five years. There was but a single patient under twenty years of age.

Lichen planus had, so far as he knew, no tendency whatever to spontaneous recovery. Having given a table showing the duration of the disease in his cases in private practice, he said that the disease was also rebellious to treatment, as was shown by an additional table exhibiting the length of time during which forty-two patients were under observation and treatment. The prognosis, therefore, although good as to an ultimate cure, if proper treatment were faithfully carried out, should always be a guarded one in regard to the duration of the eruption.

The diagnosis of ordinary cases, he said, should not be very difficult if due regard were paid to the peculiar and almost pathognomonic features of the eruption mentioned. The only eruptions which should ever be mistaken for lichen planus were: a newly developing psoriasis punctata, papular eczema, lichen simplex,

scabies, erythema papulatum, and a papular syphilid. Some time ago Jonathan Hutchinson had described this eruption under the name of lichen psoriasis, and the mistake of confounding lichen planus with psoriasis was the more justifiable because, as he had pointed out, the lesions of the latter, when they are just developing, present minute punctate spots, with a shiny summit, like those of lichen planus. In this connection Dr. Bulkley described a case of his own in which the eruption was diagnosticated by the family physician as psoriasis punctata, and which was of special interest as making the fifth case that he had seen in which the eruption had developed largely on the glans penis. In commenting on it he said that in a guttate psoriasis which might affect almost the same extent of surface in the forearms, we would have the newly formed papules covered with a silvery, easily detached scale; the color also would be more livid, and they would not be so decidedly flat and depressed in the centre. Moreover, in this particular case, the diagnosis from psoriasis could be made with certainty by the clinical history, since no psoriasis could remain, as this had, for three months in the same condition; it being well-known that the papules of psoriasis, which may begin very small, invariably enlarge quite rapidly, so that in this time they would somewhere have presented typical lesions of the disease.

In both papular eczema and lichen simplex the papules were more acutely inflammatory, were always acuminate, and were flattened down so as to present the appearance characteristic of lichen planus. Moreover, these eruptions were more violently itchy from the first, than the latter. The scattered papules of scabies sometimes seen on the forearms and about the elbows and abdomen might suggest lichen planus; but they resembled those of eczema more in character, and the diagnostic marks of scabies elsewhere, should establish the diagnosis. A newly developing papular syphilid sometimes resembled lichen planus; but the eruption was more general from the first, while lichen planus came out slowly, being commonly localized in one place for some time before appearing elsewhere. Furthermore, the papules of the syphilitic eruption were never as flat and shiny as those of lichen planus; nor had they central indentation, while the scale which soon formed on their summit was very characteristic. The general and other signs of syphilis would also commonly serve to prevent error. The papules of erythema papulatum were, as a rule, much larger, more elevated and rounded in the summit, and had not the peculiar purplish-pink lustre generally observed on the papules of lichen planus. Moreover, the lesions of erythema papulatum commonly come out very quickly, presented much more inflammatory characters, and subsided much more quickly than those of lichen planus.

The subject of the relations between lichen planus and the lichen ruber of Hebra, or rather, the question of the identity of the two, was an important one, both as affecting prognosis and treatment; and he expressed his agreement with the conclusions published some time ago by Dr. A. R. Robinson; believing that the two eruptions were neither two forms of the same disease, nor different stages of the same eruption, but radically distinct affections.

Dr. Bulkley then went on to make some comments on the general features of lichen planus, as they had presented themselves to him, especially in private

practice. He had been constantly impressed with the observation of the far greater severity and obstinacy of the eruption in women than in men. In several of his female cases he had found it necessary to make use of internal quieting remedies in order to secure any rest at night, so great was the suffering occasioned by it. He had also been struck by the fact that in most of the cases in females in private practice, and especially where the disease was severe, the patient had been accustomed to the very great use or abuse of water on the skin, in the way of cold daily general ablutions; so that of late he had inquired into the fact, and seldom failed to find this to be the case. As this was a more common custom among females than males, in this country, at least, he had been led to believe that it is one element of causation to be taken into account; and in a number of cases in males he had found the same habit to prevail.

In regard to treatment he said that, inasmuch as we know very little as to the real causation of the disease, it was very difficult to give an intelligent explanation as to the lines to be pursued. The eruption, however, we know, was of a congestive and inflammatory nature, and it appeared to be due to a sub-oxidation process closely akin to that found in eczema and other inflammatory diseases of the skin. Practically he had found that a line of treatment in accordance with this hypothesis would yield the best results, and, indeed, when faithfully carried out, was commonly very satisfactory. The alkalies, in large doses, not only served to mitigate the sufferings of the patient, but arrested the further development of the eruption. Acetate of potash, in combination with nux vomica and a bitter infusion, taken after meals, had served him about the best. He had also found very useful an empiric sort of a prescription of Boeck, of Norway, consisting of from ten to twenty grains of chlorate of potash dissolved in considerable water, directly after each meal; followed in half an hour by twenty drops of dilute nitric acid well diluted. After a cooling course of some such a more tonic treatment was often required, and there was nothing better than sulphate of iron with sulphate of magnesia and sulphuric acid, in what is known among dermatologists as Startin's mixture. Arsenic he thought of very little use in this eruption. Indeed, in the more acute stages it even seemed to aggravate it.

Locally something could be done by proper measures both in the way of relieving the general suffering and checking the disease. Among the applications mentioned were calamine and zinc lotions, carbolic acid and glycerine, and a ten per cent. solution of ichthyol. Carbolized vaseline served admirably in certain cases. Unna had claimed to cure his cases by local measures entirely, and the main remedy that he used was bichloride of mercury. Dr. Bulkley was sceptical about cures being effected by this agent alone, but in many cases it acted well, in the proportion of two or three grains to the ounce of zinc or diachylon ointment. A good combination was the following:

R. Acid. carbolic	gr. xx.
Hydarg. bichlor.	gr. ii-v.
Ung. diachylon	3 <i>l.</i>

As to bathing, plain water baths were injurious rather than beneficial, but medicated baths were of considerable service, such agents as starch, bicarbonate of soda and borax being called for in this connection.

No special diet was of any service whatever in this disease.

DR. A. R. ROBINSON said he differed in one or two points from Dr. Bulkley. Thus, as to the case of diagnosis. In well-marked, classical cases the diagnosis certainly was easy enough; but there were other cases in which the diagnosis could only be made after a considerable number of consultations. He had frequently seen the best dermatologists and syphilographers puzzled, and it was only by continued watching and a careful study of the anatomical, pathological features that a proper conclusion could be arrived at in such cases. He thought we would not make much progress in the treatment of lichen planus until we knew more about the etiology of the affection. Personally he believed it to be a parasitic disease, and in the treatment he preferred the use of salicylic acid to Unna's bichloride method. The prognosis, as Dr. Bulkley very properly stated, must be guarded.

DR. OBERNDORFER said he had had considerable experience with this disease, and, like Dr. Robinson, he was convinced that it was sometimes extremely difficult to make a differential diagnosis. He referred to one case which closely resembled ichthyosis and another presenting the appearances of herpes zoster, and laid special stress upon the waxy appearance of the papules in lichen planus as a valuable sign. He thought it rather a bold statement of Dr. Bulkley's that all dermatologists were now agreed that lichen planus and the acuminate form of lichen were entirely different affections. He believed that they were, in fact, often different stages of the same disease. As to the treatment, he had seen cases cured by Unna's ointment, with the addition of sufficient carbolic acid to relieve the itching, and he had also seen other cases rapidly cured under the use of arsenic alone.

DR. BULKLEY said the fact that in certain cases, like the one referred to by Dr. Oberndorfer, the lesion was situated in the position of herpes zoster would argue very strongly against the parasitic origin of the disease, since the eruption appeared along the line of the intercostal nerves. He believed that in certain instances a cure could be effected by local measures alone, but he could by no means agree that this was any argument for the parasitic origin of the disease; because it was well-known that remedies applied locally often had an effect upon the nerves beneath. As he had stated in the paper he had never had any success with the use of arsenic in this affection, but possibly he had not given it a sufficient trial, although he certainly was not afraid of this remedy. Dr. Oberndorfer was mistaken in supposing that he had stated that all observers now thought lichen planus and lichen ruber to be different diseases. At the recent Congress in Berlin both sides were presented, and he was among those who argued against the identity of the two.

(To be continued.)

— The Prince of Wales, on one of his visits through the wards of a hospital, stopped to ask a patient in bed number three if he had anything to complain of. "Nothing, your Highness," said the patient, "except that I should like to be in bed number one." "Why?" asked the prince, "Because," answered the man, "the surgeon every morning on his rounds sticks his finger first into a wound in number one's leg, then into the rectum of number two, and then down my throat, I should like it much better if I were number one."

KOCH'S TREATMENT FOR TUBERCULOSIS.

THE public has now had an opportunity to acquaint itself with all that can be positively affirmed up to the present time as to the treatment for tuberculosis which Dr. Robert Koch, of Berlin, has for some time been known to be perfecting, and in regard to which so many vague rumors have of late been in circulation. A translation of Koch's own communication on the subject to the *Deutsche Medicinische Wochenschrift* (November 14, 1890) has been accessible to every one in the columns of the daily press, as well as in those of the *Philadelphia Medical News* and the *British Medical Journal*.

The communication exhibits Koch's characteristic caution and scientific spirit, but confirms an impression we had previously entertained, that the coincidence of the meeting of the International Medical Congress in Berlin, this last summer, forced Koch's hand, as it were, and led him to an earlier public announcement of his work than he otherwise would have wished to indulge in; and this first step has again naturally forced him to a second, which, under the circumstances, can hardly be called premature, but is, undoubtedly, an earlier and more public commitment than he himself would have preferred.

Probably no other name than Koch's, not even excepting Pasteur's, would carry so much conviction to the sceptical mind in regard to a question of the kind under consideration, and his affirmative statements must be allowed to weigh heavily against *a priori* reasoning, against previous knowledge and experience. Moreover, if one recalls Koch's own stringent animadversions upon Pasteur in the past for the latter's earlier and hasty conclusions as to discoveries concerning anthrax and hydrophobia, there should be a feeling of additional security in that he himself would continue to bear in mind the great temptations to such errors.

As regards the origin and preparation of the remedy, no statement is yet made, as the research is not yet concluded. We are simply told that the remedy is a

brownish, transparent liquid, which does not require special care to prevent decomposition, but the dilutions necessary for use are liable to undergo decomposition if prepared with distilled water. The place chosen for the injection, after several trials of other places, was the skin of the back between the shoulder-blades and the lumbar region, because here the injection led to the least local reaction, and was almost painless. A new proof for the experimenter of the all-important law, that experiment on animals is not conclusive, is the fact that the human patient proved extraordinarily more sensitive than the guinea-pig; calculated by body-weight, one-fifteen-thousandth part of the quantity which has no appreciable effect on the guinea-pig acts powerfully on the human being.

Neither the healthy human being nor those affected with other diseases than tuberculosis react to the injection, or, if at all, only to a very slight degree. If this is confirmed by further experience, it may, of course, prove a valuable aid to differential diagnosis, especially in cases in which neither physical examination nor the presence of bacilli can be appealed to. In the tuberculous the general reaction begins four or five hours after the injection and lasts twelve or fifteen hours; it is accompanied by fever, pain in the limbs, coughing, great fatigue, often sickness and vomiting.

The action of the remedy can be best observed in external tuberculous affections, and especially in lupus; in these a speedy cure is said to be effected in recent and slight cases, a slow improvement in severe cases. Let us not forget, however, how short a time has elapsed since these experiments were begun.

Patients with decided pulmonary tuberculosis are reported as more sensitive to the treatment than those with surgical tuberculous affections. The action of the remedy in cases of phthisis generally showed itself as follows: Cough and expectoration were generally increased a little after the first injection, then grew less and less, and in the most favorable cases entirely disappeared. The expectoration also lost its purulent character and became mucous. As a rule, the number of bacilli decreased only when the expectoration began to present a mucous appearance. They then entirely disappeared, but were again observed occasionally until expectoration completely ceased. Simultaneously the night-sweats ceased, the patients' appearance improved, and they increased in weight within from four to six weeks.

Patients under treatment for the first stage of phthisis were freed from every symptom of disease and might be pronounced cured; patients with cavities not yet too highly developed improved considerably and were *almost* cured, and only in those whose lungs contained many large cavities could no improvement be proved. Objectively, even in these cases the expectoration decreased and the subjective condition improved. These experiences have led Koch to suppose that phthisis in the beginning can be cured with certainty by this remedy. This statement requires limitation, he admits, in so far as at present no conclusive

experiences can possibly be brought forward to prove whether the cure is lasting.

The treatment, it is thought, will probably be quite simple in the beginning of phthisis and in simple surgical cases, and this would make early diagnosis all the more incumbent. At the same time, Koch himself, we are glad to note, takes occasion to utter an earnest warning against a conventional and indiscriminate application of the remedy in all cases of tuberculosis. He recommends the practice of the treatment in hospitals and sanitaria, and is still impressed with the importance of surrounding the patient with all the safeguards of medical supervision and all the adjuvants of a suitable hygiene.

It seems that the remedy does not directly attack the bacillus itself, but destroys the tissue in which the bacillus has taken up its abode and this necrosed tissue must subsequently, in some way, be eliminated or removed. It should be distinctly understood that there is no pretense that tissues which have been destroyed can be reconstructed.

The attitude of the profession towards this question should be one of candid and intelligent expectancy. The demonstrator of the bacteriological laboratory of the Harvard Medical School, Dr. Harold Ernst, is now on his way to Berlin, as are representatives of similar departments in other schools elsewhere, and the JOURNAL will shortly be in a position to give its readers reliable and interesting details as to the results attending a further experience with and investigation of Koch's discovery. Until such are at hand it is enough that we should prepare ourselves soberly for the possible acclamation of the greatest advance in medical therapeutics of modern times—a far more grateful ceremony than the veiling of a scientific idol.

THE PATHOLOGY OF THE BLOOD.

At the recent meeting of the Italian Society of Internal Medicine (Third Congress) held in Rome, October 20-23, 1890, the subject of the "Pathology of the Blood" was under discussion.

DE RENZI, the referee, affirmed that the pathology of the blood is so vast as to include almost all diseases, even the functional nervous affections, in which, as is known, alterations of the blood have also been noticed. At the present time, the most salient fact of hematology is the presence of microbes in the blood of infectious diseases.

In the normal state, the blood contains no microbes, although it may contain certain chemical ferment, as, for instance, peptones which have been considered as the result of the biological activity of microbes. In certain particular conditions, when, for example, there is a fall of temperature by inanition, a person healthy in all other respects may present microbes in the blood. Prolonged fasting seems, then, to enfeeble phagocytosis, and Canalis has succeeded in inoculating animals subjected to inanition with diseases to which in the normal state they are refractory.

The micro-parasites, which have the property of developing and of living in the blood, are such as the bacteria of charbon and the spirilla of recurrent fever. We must add, also, the plasmodia of malaria, which are not, properly speaking, microbes, but haematozoa.

The bacilli of tuberculosis, of lepra, of diphtheria, and of tetanus, as well as the staphylococci and streptococci, are not ordinarily found in the blood, but they may penetrate thither in certain special conditions.

During the death agony blood also contains bacteria.

Modern researches tend to demonstrate that the blood possesses very pronounced microbicidic properties, which certain authorities attribute to the serum. From his own experiments, and those of Pane, he thought it proved that the anthracoid virus is enfeebled in contact with the blood, but he himself attributes this sterilizing influence of the blood to the atmospheric oxygen. He emphasizes the fact that, in order to undergo rapid development, the microbes demand a special receptivity of the organism, and that they are disseminated throughout the latter, not by the way of the blood, but rather by capillarity; or, to use another expression, by a sort of impregnation of the tissues (?). At the present time, the pathology of the blood presents many obscure questions, but great progress has been made, both from the point of view of diagnosis (instance the spirilla of recurrent fever, the plasmodia of malaria), and that of treatment (instance the intravenous injections of quinine in malaria).

MARAGLIANO, the co-referee, asked whether there exist diseases of the blood properly so-called, or are these diseases rather the consequence of a trouble in the functions of the hematopoietic organs? Most authorities incline to the latter hypothesis, and do not admit a morbidity proper to the corpuscles. In his opinion, the red corpuscle, when once it has entered the circulation, preserves no longer any relation with the hematopoietic organs. From a physiological point of view, it possesses a certain independence, even when transfused into the veins of another animal, the blood corpuscle may live for several days an independent life in its new environment. But from the moment that you allow to the red corpuscle such a physiological individuality, why deny it all pathological individuality? Why not admit the existence of a real pathology of the blood?

He (Maragliano) had observed alterations of the red globule characteristic of its slow death. These alterations are first intra-globular; they manifest themselves by a decoloration, which begins in the centre, then ramifies and extends to the totality of the globule, giving rise to the formation of microcytes and poikilocytes. In the normal state, the red globule is *acidophilic*, but, in the course of its necrobiosis metamorphoses, it becomes *basophilic*.

The hemoglobin being the product of the biological activity of the protoplasm of the red corpuscle, it is easy to understand the intimate connection which exists between the decolorations and the alterations of the form of the globule.

The alterations, which are observed in the corpuscles when removed from the current of the circulation, are also met with in certain diseases. He has noticed in all forms of anæmia the existence of a globular necrobiosis in different degrees. Moreover, there is an infectious disease localized, so to speak, in the corpuscles. This is malaria, in which we find the most marked alterations of the red corpuscles, and which should not be identified with the parasite of malaria itself, whose presence in no way excludes the supervention of these intra-globular alterations.

In his researches on the action of normal and pathological serum on the corpuscles, he has found that sound, red corpuscles are destroyed when placed in a serum pathologically altered, while, on the contrary, corpuscles invaded by microbes tend to revive and take on a more healthy aspect in normal serum.

These experiments show that pathological alterations of the blood-serum, under the influence of disturbances of the nutrition, may have for their consequence the microbicosis of the corpuscles. They explain also why the appearance of anæmia is so often preceded by digestive troubles, and why atrophy of the mucous membrane of the stomach is so frequently found in the autopsies of anæmic subjects. The alterations of the blood-serum and of the corpuscles may also be produced by nervous influences, as happens in anæmia consecutive to violent emotions.

Blood-serum when pathologically altered, appears also to have a deleterious action on the leucocytes.

In the discussion which follows, FILETTI remarked that the plasmodia of malaria, when they have been stained, offer a very characteristic nucleus, which enabled one clearly to distinguish the parasite from the intra-globular alterations of the red corpuscles.

MYA insisted on the diagnostic importance of the secondary leucocytosis observed in cancer of the stomach and which often precedes the physical signs of the affection.

CATELLO has found that in acute pneumonia the microbicidic action of blood-serum is very pronounced, while it is considerably diminished in diabetes.

ROVIGHI has found that the microbicidic action of human blood varies according to the microbes. It is, for instance, considerable with respect to the bacilli of typhoid fever, and less in respect to the staphylococcus aureus. It diminishes in dyscrastic states with destruction of the red corpuscles, and varies according to temperature, being destroyed by very high or very low temperature.

In response to the question how he accounted for the microbicidic action of blood-serum, Maragliano replied that he had to confess his ignorance.

In an interesting paper on the physico-chemical alterations of the blood in certain acute infectious diseases, SCIOLLA, of Genoa, said that he had invariably found the density of the blood to diminish during the febrile process, and to rapidly augment when convalescence was established. The albuminoid elements of the blood diminish in pneumonia, typhoid fever, ma-

larial fever, and chloro-anæmia. In pneumonia the extractives increase during the acute stage, while in typhoid fever these substances diminish progressively during the entire febrile period, and even during a part of the convalescence.

Doubtless what most impresses one when reading such discussions as the above is the admission by authorities, the most competent to speak on these matters, that the pathology of the blood is still a vast *terra incognita*.

THE MEDICAL EXAMINER VS. THE CORONER.

THE system of medical examiners which we enjoy in Massachusetts is so satisfactory, and works so easily and quietly, that we are apt to forget the old days of the coroner and his bungling system, until our attention is called to him from communities where he has not yet been abolished. To any one who, in any capacity, is brought in contact with cases of sudden death in this State, the immense advantages of the medical examiner system are self-evident. As far back as 1881 the New York Medical Society, after listening to an exhaustive paper on the subject by Clark Bell, Esq., passed a resolution advising legislation in that State similar to the law then recently passed in Massachusetts. Mr. Bell has recently read his paper again, and it appears in the *Medico-Legal Journal* for September, 1890, and his argument is as timely now as then, in fact it now has the advantage that the Massachusetts law, having been in operation nearly ten years longer, has passed beyond the stage of an experiment.

MEDICAL NOTES.

—The French steamer *La Normandie* which arrived in New York on Monday had small-pox on board. Over four hundred steerage passengers were detained at quarantine.

—The New York Academy of Medicine will formally open its new building on Forty-third Street on November 20th. Dr. A. L. Loomis will give an address of welcome, Dr. E. L. Keyes will deliver the anniversary address, and Dr. Abraham Jacobi will speak about the library. Many invitations have been sent out. The building cost a quarter of a million and is free from indebtedness. The library, which is free to the public, contains over fifty thousand volumes.

—Dr. E. C. Spitzka read a paper before the Medico-Legal Society on Electrocution, in which he expressed a personal preference for the guillotine, but also his opinion that electricity was practically serviceable. His recommendations as to methods agree in general with those contained in the report of Dr. C. F. Macdonald to the State.

—The trustees of the Johns Hopkins Hospital recently tendered a reception to the members of the various local committees of the Women's Fund for the Medical School. Prominent women from all parts of

the country were present. The sum of \$100,000 has already been subscribed, and will be invested until it has accumulated to \$500,000, when the school for women will be opened.

BOSTON AND NEW ENGLAND.

—Governor Brackett has nominated Henry W. Dudley, M.D., of Abington, to be medical examiner for the second Plymouth district, vice Dr. J. C. Gleason, deceased.

—There is a common impression that the Boston Provident Association and the Associated Charities are one and the same society, whereas they are quite distinct, each having its own constitution, rules of management, officers, visitors, collectors, and methods, quite independent of the other. The error of considering them identical is fruitful of no little misunderstanding and vexation, sometimes causing delay in giving needed relief.

—Dr. Hosea N. Quinby has been appointed superintendent of the State Lunatic Asylum at Bloomsbury near Worcester, in place of Dr. John G. Park, resigned.

—Dr. Harold Ernst sailed for Berlin Wednesday, November 19th, in order to investigate Koch's new method for the treatment of tuberculosis.

Miscellany.

PHOSPHORUS NECROSIS.

A COMPLETE study of phosphorus necrosis is given in a paper by Heeckel,¹ who has had an especial advantage to observe the disease in the surgical clinic at Jena, where there have been fifty-six cases within a few years.

The most common cause is a prolonged breathing of fumes of phosphorus by employees of match factories. It begins as a purely local affection, due to the local action of the phosphorus on the jaws, especially in the presence of carious teeth. Several patients, after being entirely cured of this local necrosis have worked for years at the same trade without any symptoms. Although the author has become convinced that the process never originates from the constitutional effects of phosphorus poison, he admits that a great tendency to fracture of bones is met with in persons exposed to the fumes.

The process begins as an ossifying periostitis, more often of the lower jaw, soon involves the bone in the inflammatory process, which finally necroses. The destruction tends to spread, and produces constitutional disturbance by suppuration. The average duration of the disease, if left to itself, is about three years. Seventy-nine per cent. of untreated necrosis of the lower jaw resulted in the loss of the whole jaw-bone. On the upper jaw the process is generally not so extensive but is much more fatal.

The death-rate of all untreated cases was forty-five per cent. The best treatment is early resection of as much of the jaw as is diseased. The danger of exten-

¹ Archiv. für Klin. Chirurg., Bd. xxxix, p. 555.

sion of the process after resection, mentioned by earlier authors, was not met with. The mortality of the cases operated on was much less, and the duration of the disease much shortened.

TREATMENT OF ERYSPIELAS.

DR. ULRICH,¹ a Danish military surgeon, having had eighty-nine cases of eryspelas of the face in young soldiers, has published in a comparative table the results of the three different methods of treatment which he adopted, namely, the application of ice compresses, painting with pine tar, and painting with a solution of ichthyl in its own weight of ether and double its weight of flexible collodion. Thirty-three cases were treated by the first method; in twenty of these the eryspelas spread considerably, in four slightly, and in nine not at all. Twenty-seven cases were treated with tar; in fourteen of these there was much spreading, in one a little, and in twelve none. Twenty-nine cases were treated with ichthyl; in these the spreading was considerable in eight cases, slight in six, and in fifteen there was none. The mean duration of the disease under the ichthyl treatment was 6.88 days, while under the ice and tar methods it was 8.33 and 9.3 days respectively. The relapses, too, were decidedly less numerous under ichthyl than under either of the other plans. Dr. Ulrich suggests that still better results might be looked for if the ichthyl were painted not merely over the affected parts, but over a considerable portion of the surrounding skin.

LAPAROTOMY UNDER COCAINE.

A WOMAN, aged forty, says the *British Medical Journal*, November 1, 1890, was admitted to the Cumberland Infirmary. She had for some years suffered from a tumor in the right side of the abdomen. Her abdomen became distended and very tender; she vomited frequently; her loss of strength increased day by day. Her condition seemed so extreme that she might not recover from a general anesthetic, so Dr. Maclarens proposed to try if the operation could be done with cocaine. A twenty per cent. solution was used, and of this twelve minimis were injected. Two punctures were made, and the solution injected drop by drop along a line two inches, just under the skin, except for the last two drops, which were injected into the deeper tissues. Five minutes were allowed to elapse, and an incision was then made two inches above and parallel to Poupart's ligament. There was no difficulty in doing the operation; the patient never moved. The peritoneum was studded with malignant nodules; a mass of malignant tissue (omentum) adhered to the abdominal wall. The bowel was not distended, and it was evident that nothing could be done, so the wound was sewn up. The patient died four days after, the course of her illness being uninfluenced for good or evil by the operation. What the patient felt during the operation was very trifling. When questioned she said that it was nothing compared to her sufferings during the previous few days, that it was not greater than she had suffered in her confinements, which had been easy ones, and that what she felt most was the

stitching. The introduction of the finger and the passage of a glass tube in various directions to allow fluid to escape were quite painless. At Dr. Maclarens' request she turned herself on her side to allow the fluid to gravitate to the opening, and afterwards said she felt it running out, and thought it was blood. She was a very thin woman, which no doubt made the use of the cocaine more efficacious and the operation easy. Post-mortem examination showed much malignant disease of the peritoneum and omentum, and a distended gall bladder containing numerous stones, one impacted in the duct. The condition of the wound was perfect.

CHINESE MEDICAL PRACTICE AND PRACTITIONERS.

AN interesting and amusing paper on this subject by Dr. Joseph C. Thomson appears in the *China Medical Missionary Journal* for September, 1890.

There are practically no medical schools in China, and nothing to prevent any one from advertising himself as the eminent Dr. Blank; but the doctor by famous descent, is the most respected. In the Chow dynasty the public was warned against rashly swallowing the prescriptions of any physician whose family had not been in the medical profession for three generations. If the patient be an important person the diagnosis, prognosis and treatment must be written down; and if the doctor has made a mistake, he must answer for it in court. As no dissecting is allowed, there is no knowledge of anatomy. Nevertheless, acupuncture is a favorite therapeutic procedure. Long needles are run into the body in all directions, and driven home with a mallet. The Chinese *materia medica* is well-known to contain many curious things. A few prescriptions are given. A mixture of cinnabar, saltpetre, horse and turtle urine applied to a tooth will remove it. For a sore eye, put one-half of a chicken over the eye, and eat the other half. When a child grinds its teeth during sleep, the mother should buy a pig's tail, cook it ready for the next time, when she should slap the tail on the face several times, after which he must eat it. For cholera—a god-like recipe—take an earthen spoon, rub it with tea-oil, rub the spine of the sick person with it till small black spots appear, pierce them with a needle to the bone, then apply a burning lamp-wick; for an adult the following, one cup salt heated in an iron spoon mixed with ginger-juice, boy's urine and cold water.

In matters connected with pregnancy and child-birth Chinese ideas are especially curious. A pregnant woman must not eat turtles, chickens or ducks. She must not see a rabbit or a house which is being repaired. The child is supposed to act according to its own pleasure as to speedy or tardy coming into the world. "A good and filial child leaves the mother's womb in the time in which a man rubs his two fingers together," while an obstinate demon may require days, or even years before it is brought forth. A famous physician of old, afterwards deified on account of his diagnostic skill, was once called to attend one of the empresses in a case of difficult labor, which had baffled the court physicians. By means of a rope of considerable length (he was not permitted to see her) attached to the imperial wrist, he pronounced it, from the pulse indication, a case of the fetus grasping the heart of the mother, and recommended acupuncture,

¹ The Lancet, November 1, 1890.

which caused the child to loose its hold, and so the empress was quickly delivered. The Chinese midwife is very active, and does a great deal of harm. She is governed by a large number of rules, such as, "an arm presenting, the midwife may pinch it or put salt on it, to cause it to be drawn back, or it may be pulled off in time." To guard against cross-birth the woman must eat the ashes of the husband's hair. To wean a child, paint the mother's breasts with India ink, and the child when he sees it will be afraid, and so refuse the breast.

The unfortunate condition of medicine in China can perhaps best be appreciated by quoting a few proverbs. "If the medicine does not cause dizziness, you will not recover from your sickness." "Out of ten men eleven have the itch." "Pock-marks are marks of beauty." "Nine of every ten have fistula." "The ordinary physician kills men." "The good medicine is bitter." "In a dangerous illness call in three doctors."

Correspondence.

[From a Special Correspondent.]

LETTER FROM ITALY.

TURIN, October, 1890.

THE UNIVERSITY OF BOLOGNA.

EVEN in Italy's darkest days, when any intellectual life was very nearly dead, the old University of Bologna kept alive a little interest in medical science, and held a little of the reputation it had when Galvani within its walls demonstrated the contraction of the frog's muscles to the electric current. At the present day, when Italy has shown that she is not only once again a great nation, but is able also to make again no mean contribution to the knowledge of the world in medicine, as well as in other branches of knowledge, the old university, now entering upon its ninth century, is still true to its old motto "Bono docet." In its faculty to-day is Carducci, one of the chief poets and men of letters in the kingdom, whose ode to Piedmont has just appeared as a tribute to the twentieth anniversary of the taking of Rome; and, true to the old custom of the Middle Ages, in vogue before Harvard existed or was vexed by questions of co-education, it has, as lecturer on pathology, a young woman whose scientific attainments are said to be supplemented by marked beauty, although unlike a professor of the old days, Novella d'Andrea, she does not lecture from behind a curtain.

THE HOSPITAL OF BOLOGNA.

I visited Bologna, however, during the vacation, so that I had no opportunity to see the University in operation or to attend any lectures, but through the kindness of Dr. Biondi, professor of surgery, who had just returned from the Congress at Berlin, I was enabled to visit the chief general hospital of the city, the Ospedale San Orsolo, of which Dr. Murri, professor of clinical medicine, is the director. The hospital lies just without the city walls, with a beautiful outlook over a broad sweep of open country to the hills that surround the city. It is a large, two-story building, or group of buildings, covered with the familiar buff stucco and adorned with numerous open porticos. Printed on a poster which was on the outer wall by the entrance, was a sonnet inscribed by a grateful patient to one of the surgeons who had recently done a successful nephrectomy — a method of showing gratitude not common with us. On the corridors within I noted, among other memorial tablets, one to Valsalva, once connected with the hospital. The hospital has about two hundred patients, but only half of it is used. For three or four months in the summer the wards of the lower story are used, while the upper

story undergoes a thorough renovation. The rest of the year the wards in the upper story are in use, the physicians considering that the ground floor is too much exposed to cold and dampness. The hospital is thus practically a double one. Hard-finished walls and floors of Venetian cement set thick with small pebbles, afford no lurking-place for the microbe. The beds were the familiar iron bedsteads, with woven wire bottoms and good mattresses on top. Wide windows gave plenty of light, and the ventilation was excellent, while gardens and porticos gave the patients plenty of opportunity for out-door recreation. In all minor details the hospital seemed fully up to date, although I saw there nothing absolutely new in the methods employed. Among other interesting cases I may mention one of a boy whose brain had been penetrated by a bull's horn, which entered and extensively lacerated the right frontal lobe. The fragments of bone had been replaced, and with the exception of a slight hernia cerebri, the boy was doing well, and the only symptom observed was that for a month he constantly demanded food, even immediately after his meals.

I will speak later of some of the Italian asylums I visited. Of the other general hospitals I saw but little; although I was interested in visiting the hospital in Florence, with mediæval frescos adorning its entrance, and with two very long, very high, and quite narrow wards crossing each other at right angles, much like the ground plan of the churches, a part of the original hospital founded in 1288, by Folco Portinari, father of Dante's Beatrice.

CRIMINAL ANTHROPOLOGY.

Turin is of interest as being the centre for the study of criminal anthropology, in which new branch of science Italy is the leader. "If you are curious to know the criminal thoroughly, the innate and incorrigible criminal," writes Tarde, a recent French writer on the subject, "read the last edition of Lombroso's 'L'Uomo delinquente,'" of which the fourth edition, in two huge volumes, has recently appeared. The literature of this new science has already attained formidable dimensions, and many other Italians, Tenchini, Garofalo, *etc.*, and others, have published important works; an international congress has held several meetings, and the *Archivio di Psichiatria e Scienze Penali*, edited by Lombroso, is now in its eleventh year. Of late, interest in the subject has spread, and within the last year or two it has obtained a footing in English journals, the *American Journal of Psychology* having devoted a department to it. Through the kindness of Professor Lombroso, I was permitted to visit his laboratory and to examine there his collections relating to *l'uomo delinquente* and to accompany him to the prison to see the criminal himself. The University of Turin is unique in having a criminal clinic, for Professor Lombroso summons to his lectures discharged criminals, and illustrates to his classes the types of the criminal. In the brief space of this letter I cannot begin to condense the two huge volumes of Lombroso's work, but in his laboratory may be seen many objects illustrating the criminal: photographs of the criminal of all types, brigands, assassins and thieves, skulls showing the types of degeneration presented by the criminal, specimens of criminal handiwork, including rough but curious sketches made on the earthen water-jugs which they have in their cells, and, finally, many drawings of the tattooings of criminals, to which Lombroso devotes a long chapter, and — tell it not at Tewksbury — certain portions of skin showing actual tattooings. At the prison, of which Lombroso is the physician, all the new arrivals are inspected, and various anthropological details are noted, the color of the hair and eyes, facial asymmetry, the character of the lower jaw, the ears, the shape of the head, the length of the arms, genitals, etc. Unfortunately, I omitted to ask whether any system of elaborate measurement, like that employed in Paris by Berthillon, and recently introduced into our State Prison, was in vogue. After this inspection of the new arrivals the usual visit to the sick prisoners was made, and I again had the opportunity to note some of the more striking physical peculiarities of the criminal, as a

specimen of degenerate man. Dr. Ottolenghi, one of Professor Lombroso's assistants, under Lombroso's advice, has been making an elaborate study of the visual field, especially in female criminals, and has found very curious sector-like defects and limitations therein. To one who has lived among the inmates of a large prison and has had the opportunity to watch the criminals day by day, and to grow familiar with the criminal type of face, it is easy to accept Lombroso's teachings, and to see in the criminal only another type of physical and psychical degeneration, not wholly different from other forms of degeneration as seen in the epileptic or the paranoiac.

PELLAGRA.

Of the curious disease, pellagra, peculiar to Italy, I saw little, as it is more prevalent in the spring, and is less common in the cities. In the preface to his "L'Uomo Delinquente," Lombroso remarks that the protracted and thorough study which he gave to this subject met with much greater opposition and much less renown than his necessarily incomplete and less satisfactory work upon the

criminal. After many years of research he established what is now generally accepted, that the disease is due to poisoning from diseased maize, and he succeeded in isolating a substance which produced symptoms of pellagra when given to animals. In its onset it is characterized by nausea, vomiting, intestinal catarrh, fever, malaise, and a curious erythema most marked on the backs of the hands. Later it produces various nervous symptoms, peripheral neuritis, pareses, mental disturbances, and symptoms of disease of the cord. I saw various cases of pellagra insanity — a form of mild melancholia which is often curable in a few months; and I also saw several specimens of the spinal cord from cases of pellagra, showing combined sclerosis of the posterior and lateral columns. Judging from Italian works on nervous diseases it is a factor in the etiology of about as many different forms of nervous disease as syphilis or alcohol. Certain interesting studies on the muscular strength of patients with pellagra made with the apparatus of Mosso at the asylum in Turin show that there is a marked loss of strength, and especially of the power of combined effort.

P. C. K.

REPORTED MORTALITY FOR THE WEEK ENDING NOVEMBER 8, 1890.

CITIES.	Estimated Population for 1890.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from

Deaths reported 2,239; under five years of age 696: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 335, consumption 295, acute lung diseases 260, diphtheria and croup 122, typhoid fever 64, diarrhoeal diseases 60, scarlet fever 28, whooping-cough 22, malarial fever 15, measles 15, cerebro-spinal meningitis 8, erysipelas 4, puerperal fever 1.

From scarlet fever New York 1, Brooklyn 8, Philadelphia 6, St. Louis 1, Lowell and Gloucester 1 each. From whooping-cough, New York 10, Brooklyn 4, Philadelphia 3, Washington 3, St. Louis, Charleston and Salem 1 each. From malarial fever, New York and Baltimore 5 each, Brooklyn 4, Philadelphia 1. From measles, New York 15, Brooklyn and St. Louis 1 each. From cerebro-spinal meningitis, New York 4, Brooklyn, Salem,

Haverhill and Gloucester 1 each. From erysipelas, New York 2, Brooklyn and St. Louis 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,059, for the week ending November 1st, the death-rate was 22.1. Deaths reported 4,118: Acute diseases of the respiratory organs (London) 450, measles 159, diarrhoea 143, scarlet fever 76, fever 58, diphtheria 45, whooping-cough 43.

The death-rates ranged from 14.5 in Derby to 31.7 in Manchester, Blackburn 27.4, Bradford 19.3, Hull 19.0, Leeds 20.9, Leicester 19.9, Liverpool 23.7, London 21.4, Nottingham 16.4, Preston 31.7, Sheffield 24.1, Sunderland 17.6.

In Edinburgh 20.2, Glasgow 24.0, Dublin 25.3.

The meteorological record for the week ending Nov. 8, in Boston, was as follows, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Week ending	Barom- eter.	Thermometer.			Relative Humidity.			Direction of Wind.			Velocity of Wind.			State of Weather.*		Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 8, 1890, TO NOVEMBER 14, 1890.

By direction of the Acting Secretary of War, leave of absence for fourteen days is granted Captain WILLIAM D. CROSEY, assistant surgeon, United States Army. S. O. 259, Par. 2, A. G. O., Washington, November 5, 1890.

Captain LOUIS A. LAGARDE, assistant surgeon, United States Army, detailed as member of board of officers in connection with the World's Columbian Exposition, and will report by letter to Major CLIFTON COMLY, Ordnance Department, member of the board of control and management of the government exhibit to represent the War Department. S. O. 260, Par. 1, A. G. O., Washington, November 6, 1890.

By direction of the Secretary of War, Colonel BASIL NORRIS, surgeon, and Major GEORGE M. STEINBERG, surgeon, are appointed members of a Board of Officers, appointed to meet, at the call of the senior officer thereof, in San Francisco, Cal., to examine such officers of the Corps of Engineers as may be ordered before it, with a view of determining their fitness for promotion, as contemplated by the act of Congress, approved October 1, 1890. S. O. 261, Par. 5, A. G. O., Washington, November 7, 1890.

By direction of the Secretary of War, Lieutenant-Colonel CHARLES T. ALEXANDER, surgeon, and Major JOHNSON V. D. MIDDLETON, surgeon, are appointed members of a Board of Officers, appointed to meet, at the call of the senior officer thereat at the rooms of the Board of Engineers, Army Building, New York City, examining such officers of the Corps of Engineers as may be ordered before it, with a view to determining their fitness for promotion, as contemplated by the act of Congress, approved October 1, 1890. S. O. 261, Par. 4, A. G. O., Washington, D. C., November 7, 1890.

By direction of the Secretary of War, the extension of leave granted Major STEPHEN G. COWDREY, surgeon, in Special Orders No. 112, October 24, 1890, Department of Arizona, is extended fifteen days. S. O. 263, Headquarters of the Army, A. G. O., Washington, November 10, 1890.

By direction of the Secretary of War, the extension of leave of absence, on account of sickness, granted Major HENRY McELDERNEY, surgeon, in Special Orders No. 214, September 12, 1890, from this office, is further extended two months, on surgeon's certificate of disability. S. O. 263, Par. 28, A. G. O., November 10, 1890.

OBITUARY. RICHARD J. LEVIS, M.D.

Dr. R. J. Lewis died suddenly at his home, in Pennsylvania, on November 12th, aged sixty-three years.
Dr. Lewis graduated from the Jefferson Medical College, and in 1859 went to Philadelphia to study at the Philadelphia Hospital. During the rebellion he was a surgeon in two military hospitals in that city, and over 1,800 cases of amputation came under his care. He was afterwards surgeon to the Wills Hospital, and in 1867 was clinical lecturer on ophthalmic and aural surgery in Jefferson College. In 1871 he became surgeon to the Pennsylvania Hospital, continuing to fill that position until 1885, when he was made surgeon of the Philadelphia Polyclinic and College for Graduates. He was also surgeon to the Jefferson Medical College Hospital, to which he was elected in 1877, up to June, 1887, when he retired from active practice. He served as president of the Medical Society of the State of Pennsylvania in 1885. He was a prolific writer, and as a lecturer was clear and concise.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 15, 1890.

THOMAS OWENS, surgeon, ordered to the Museum of Hygiene, at Washington, D. C.

H. M. MARTIN, surgeon, detached from the Receiving-ship "Wabash," and ordered before Retiring Board.

P. M. RIXEY, surgeon, continued in charge of Naval Dispensary, at Washington, D. C., until November 20, 1891.

E. H. GREEN, passed assistant surgeon, promoted to surgeon, November 10, 1890.

HOWARD SMITH, surgeon, placed on the retired list, November 10, 1890.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.

At the annual meeting of the Washington Obstetrical and Gynecological Society the following officers were elected for the ensuing term: W. W. Johnston, M.D., President; D. W. Prentiss, M.D., H. L. E. Johnson, M.D., Vice-Presidents; H. B. Deale, M.D., Recording Secretary; Geo. Byrd Harrison, M.D., Treasurer; G. Wythe Cook, M.D., Corresponding Secretary.

A PRIZE ESSAY.

Dr. J. G. Orton, Ex-President of the New York State Medical Association, has offered a prize of \$100 for the best short popular essay on some subject connected with practical sanitation, under the following conditions:

(1) Competition to be open to all.

(2) Essays to be forwarded to the Secretary of the Association, Dr. E. D. Ferguson, Troy, N. Y., not later than August 1, 1891, accompanied by the name of the author under separate seal.

(3) Examination and award to be made by a committee appointed by the Council of the Association.

(4) The winning essay will be read at the next annual meeting of the Association and, if approved by the Council, to be offered for publication in the secular press, and issued in tract form, or otherwise, for general circulation.

(5) Authors of essays, unsuccessful as far as the prize is concerned, but found worthy of special commendation, to receive intimation as to a proper disposition to be made of them.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, November 24, 1890, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Papers: Dr. J. C. Warren, "The Parasitic Origin of Cancer"; Dr. C. B. Porter, "The Removal of the Appendix during a Remission in Cases of Recurrent Attacks of Appendicitis."

G. G. SEARS, M.D., Secretary.

BOOKS AND PAMPHLETS RECEIVED.

The Rotary Element in Lateral Curvature of the Spine. By A. B. Judson, M.D., New York. Reprint. 1890.

Seventh Biennial Report of the Board of Trustees of the State Charitable Institutions of the State of Kansas. 1890.

Henry J. Bigelow, M.D., LL.D.**THE MEMORIAL MEETING OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.**

A SPECIAL MEETING of the Society was held in the hall of the Medical Library Association on Wednesday, November 19, 1890. The meeting was opened by the President, Dr. W. L. RICHARDSON, who called Dr. R. M. HODGES to the chair.

Addresses were made by Dr. R. M. Hodges, Dr. O. W. Holmes, Henry Lee, Esq., Prof. D. W. Cheever, M.D., and Dr. Hasket Derby. Letters were sent by Prof. R. H. Fitz, M.D., and Dr. A. T. Cabot.

Dr. R. M. HODGES, on taking the chair, spoke as follows:

The death of Professor Henry Jacob Bigelow removes from this community a distinguished and familiar presence, which for more than forty years has enhanced the prestige of the City of Boston, and added a lustre to her institutions of education, benevolence and art.

The stirring and industrious professional life, which has ended so gradually and serenely, began with all the excitement of sudden and assured success. Two years after the completion of his medical studies in Europe, Dr. Bigelow was made Visiting Surgeon of the Massachusetts General Hospital, and three years later was appointed Professor of Surgery in Harvard University. Fresh from the inspiration of the then novel instruction of Sir James Paget, Dr. Bigelow rose far above the plane of his predecessors as an instructor in scientific surgery, not merely as the result of his aptness in imparting knowledge, but because, in this part of the world, he was one of the first pioneers—if not absolute leader—in the study of surgical pathology, as well as one of the earliest and profoundest delvers in the mines of elaborate microscopy.

His unequivocal success as a teacher was accentuated by his graphic modes of expression, his felicitous illustrations, his clear perception of essential realities, his self-reliant audacity and indifference to conventional rules, the peculiarity of his abundant humor, and his skill in black-board drawing. His remarkable manual dexterity was attractive to physicians as well as pupils; but his impromptu lectures in the ward, the accident-room, and the amphitheatre, his definitive rules of procedure in cases of common injury, his lucid explication of diagnostic points, and his reiterated exposition of every detail embodying a principle, illustrated his rare capacity for conveying information and indelibly impressing it on the minds of listeners. It may almost be said that these passing lessons have been of more value to surgeons in this vicinity than even his unrivalled demonstrations of the anatomy of dislocations of the hip-joint and fractures of the neck of the thigh-bone, or the most brilliant exhibition of his far-famed operation of litholapaxy.

His career as a surgeon began simultaneously with the discovery of anaesthesia by sulphuric ether. Quick to perceive the magnitude of this discovery, to appreciate its comprehensive value, and foresee its merciful possibilities; unhesitating when his seniors were timid or jealous. Dr. Bigelow, though then only twenty-seven years of age, took a most decisive and energetic part in securing its adoption into use. If he was bold in that crucial period, his boldness was the sublime courage of wisdom. If he trod the way fearlessly,

and (as it seemed to some of his elders) too impiously, this was because he knew his ground as no other man knew it at that time; and few, even among those who administer or who realize its consolation at the present day, are aware that without his determination, not only would the introduction of ether have been slow instead of immediate, but that the primary honor of introducing the great discovery would probably have been diverted from the Massachusetts General Hospital, and from the City of Boston, to some more progressive institution and a more enlightened community.

From its very inception, Dr. Bigelow was an influential and devoted trustee of the Museum of Fine Arts, and his versatile accomplishments have repeatedly lent their aid to its successful administration. He was such an adept in all pursuits engaging the attention of quick-witted men, that it has never been a surprise to find the search-light of his ready brain flashing in some unexpected quarter. Whatever his varied taste led him to take up—whether an unsettled question of surgery, the structure of agates, the habits of a bird or an animal, the intricacies of locks, picture cleaning, photography, or codes of ethics,—was pursued with confident enthusiasm, consummate thoroughness, and an exceptional capacity for assimilating knowledge.

His clear conceptions of efficient executive administration, and his suggestive ingenuity, contributed to the smoothness as well as the simplicity of the service in the hospital which he served with so much assiduity and with such distinction, during two generations. His fertile mechanical skill promoted the economy of its management by many now indispensable appliances in constant use; and a large number of invaluable instruments of his devising or improvement enrich the exceptionally complete armamentarium of its operating theatre, which was his own generous gift to the hospital.

Whatever Dr. Bigelow wrote, was the embodiment of his own competent opinions,—never a compendium of other men's ideas, or of work which had already been achieved elsewhere. When he spoke at medical assemblies no self-laudatory allusions or exaggeration overcolored either his impromptu talk, or his carefully prepared communications. He possessed the resources of a keen and untiring debater; and nowhere else were his force of character, his imperturbable self-possession, his courage in supporting the convictions of his independent, resolute and far-seeing judgment, more admirably shown than in debate.

In court he was an explicit and easily understood witness; and among the striking episodes of his early professional experience, was his connection with certain memorable medico-legal trials, and the acumen of some of his correct deductions from evidence.

No mystification or pretension sullied Dr. Bigelow's work in any department of his profession. No suffering invalid ever found him rough, or thought him brusque. A scrupulous consideration for pain led him to deprecate emphatically, and with recurrent persistence, all unnecessary manipulation of patients, and to advocate earnestly the use of narcotics for euthanasia.

His tenderness towards children was always noticeable; while his gentleness with dumb animals found its complete expression in a strenuous opposition to repetitive, unavailing, or incompetent vivisection.

Powerful attributes such as have been enumerated, even when accompanied by so many attractive feat-

ures, could scarcely fail to array themselves in an occasional attitude of trenchant antagonism. A chivalrous loyalty to one's own opinions is seldom appreciated at its true value by those whose way of belief is dissentient. And yet, in 1882, the President of Harvard University, in announcing to the Board of Overseers Dr. Bigelow's resignation of the Professorship of Surgery, generously declared that "it was an event of grave interest for the Medical School and the whole University." He then went on to say:¹

"A discoverer and inventor of world-wide reputation — a brilliant surgical operator, a clear and forcible lecturer, a keen debater, and a natural leader of men by force of activity, ingenuity and originality — Dr. Bigelow was from the beginning to the end of his connection with the Medical School a very influential member of the Faculty. His energy and sagacity contributed to the rapid growth of the School between 1858 and 1870. During the discussions of 1870-1871 in the Medical Faculty and the Governing Boards — discussions which resulted in important changes of the general plan and policy of the school — his part was that of a strenuous, uncompromising and indefatigable opponent of the new projects; but the caution and moderation which his opposition induced the majority of the Medical Faculty to practise, doubtless made the measures they finally recommended to the Governing Boards all the wiser and, therefore, the surer to succeed. Dr. Bigelow continued to labor in the School with unabated interest and vigor for ten years after the adoption of the plans which he had opposed. In recognition of his eminent services to the University and the public, Dr. Bigelow was chosen, in May last, Emeritus Professor of Surgery, and the degree of Doctor of Laws was conferred upon him at the last Commencement."

Everywhere Dr. Bigelow was a genial and most interesting companion. His hospital students invariably felt the magnetism of his picturesque person and manner. They were captivated by his observant power, his marked originality, his stores of learning, and, above all, by his kindly interest in their physical as well as their educational welfare. His great attractiveness, however, to those who knew him best, lay in the activity and clearness of his intellectual faculties, their pliant subservience to his every purpose, and the wide field of thought which his busy mind embraced.

There is an immense satisfaction in recalling the practical side of Dr. Bigelow's character; and no one can look back upon his efforts to simplify surgery, — his successful abolition of the "pulleys," the beneficent revolution he wrought in the treatment of calculus, and his part in compelling the immediate and unhesitating adoption of anesthesia by ether, — without a feeling of complacency and pride. But, in honoring the memory of so exceptional a man, the fact which compels our notice is, that, among his diverse qualities, the most conspicuous were his superior wisdom and his creative genius, — that, above all his other attributes, these have won him recognition throughout the civilized world, and have made the name of Henry Jacob Bigelow more familiar than that of any other surgeon of recent times.

It was one of the privileges of Dr. Bigelow's life, which he always spoke of with animated delight, to

have been the pupil, the friend, and the colleague, in hospital and in medical school, of DR. OLIVER WENDELL HOLMES. I know their intimate association was one of mutual pleasure, and that no one can speak with better knowledge of Dr. Bigelow than Dr. Holmes, who will now address you.

REMARKS OF DR. O. W. HOLMES.

It belongs to the members of the medical profession who have specially devoted themselves to surgery to tell the story of the achievements of one whom all have recognized, and who will be long remembered, as a great master in that branch of the healing art. The name of Henry Jacob Bigelow is identified with two most important innovations in mechanical surgery. It is indissolubly associated with that inventive discovery which has robbed disease of much of its terror, and emancipated womanhood from the legendary curse which has been supposed to perpetuate the wrath of an offended Deity. The story of these triumphs will be told in full by those to whom the record of his life will be committed. A few recollections are all I have to add to your memorial tributes, but they may, perhaps, shed some side lights on the strongly marked character of our late associate, who was for fifty years my friend, and for a large portion of that time my colleague in the Medical School of our University.

He was a medical student when I first made his acquaintance. He was pursuing his studies in Paris just previous to his taking the degree of Doctor of Medicine in 1841. I had occasion to write to him concerning the existing condition of homeopathy, in which I was interested as an abnormal outgrowth from the medical organism. The zeal with which he entered into the question, the pains he took to learn the most important facts concerning the subject, the intelligence he showed in looking up those facts which would be most useful, and the promptness with which it was all done, convinced me that he was a young man assured of future distinction. I became more nearly acquainted with him at Hanover, where I was for two years Professor of Anatomy and Physiology in Dartmouth College. He had threatening symptoms of disease while he was living in the hotel where I was staying. He was perfectly cool about the matter, and never lost that natural cheerfulness which often all through his life, ran into gaiety.

If I could, without spoiling the metre, change one word in the line in which Horace describes Achilles, I should be tempted to adopt it, with a large and generous rendering, to the characteristics of this hero of surgery:

"*Impiger, jucundus, inexorabilis, acer,*" —

strenuous, good-natured, inexorable to the claims of nature to keep her secrets from his knowledge, keen in detecting them under their disguises. Of all these words, I like best that hard-sounding expression "inexorable." That is what the successful student of science must be; for nature will cheat him if she can, with her fallacies; she will bully him if she can, with her alleged impossibilities. These were the qualities illustrated by Sir Humphrey Davy in that admirable series of analyses which I well remember as described in a lecture of Professor Cooke; the same which we see, perhaps, more wonderfully displayed by Pasteur and Koch in their bacteriological researches. Those who remember Dr. Bigelow's untiring, un-

¹ President Eliot's Annual Report, 1881-82.

relenting, keen-scented pursuit of the truth he was after—the best method of reducing a dislocation of the femur, or of removing a calculus—will recognize these characteristics. No man knew better than he how “to labor and to wait.” I have seen him day after day, at work with his casts, repeating his experiments, “inexorable” until his work was done, done thoroughly, done once for all, and done with. He showed the same sagacity, method and perseverance in studying the cavernous arrangement in the mucous membrane of the nares; and again in discovering the true original of the portrait long believed to be that of Ambroise Paré. He exhausted his subject,—and not till then it was given to the world; and he was ready in due time for his next practical problem. And in the intervals of his work, when his mind was not on it, when he had no plan maturing, no project nursing, never was a livelier companion than this relentless inquisitor of nature. He would, for the time, forget all about the Y-ligament, or the last *écraseur*, and be the Henry Bigelow whom his old playmates remembered.

Dr. Bigelow, as an operator, is better known to many of you than to me, who hardly ever saw him operate excepting once, when he used the knife on my own person, and did not see him then, because I was under the full influence of ether. To prevent any misapprehension, I will say that the trouble was a slight one, nothing graver than this: there was a little too much of me in one place on one of my arms, in the form of a small fatty tumor which he removed. This was more than twenty years ago, and all that is left of it is a linear cicatrix,—Henry J. Bigelow, his mark. That he was perfectly cool in greater operations, I have always understood. That he was most skilful with his hands I knew, but I do not know enough of his manual adroitness to compare him with his contemporaries, as a rapid and dexterous operator.

Dr. Bigelow sometimes paid me the compliment of asking my opinion of, and my criticism upon, an essay or a lecture he was about to read or publish. On an evening of December, 1846, he called upon me with a paper which he proposed reading the next evening at the regular meeting of the American Academy of Arts and Sciences. He began by telling me that a great discovery had just been made and practically demonstrated in the operating theatre of the Massachusetts General Hospital. He proceeded to read the paper, which was the first formal presentation to the world, of the successful use of artificially produced anesthesia in a capital operation. He had the sagacity to see the far-reaching prospects of the new discovery, the courage as well as the shrewdness to support the claims of the adventurous dentist's startling, at first almost incredible, announcement. Every possible effort was made to dislodge the infant anesthesia from its cradle in the Massachusetts Hospital, but there remains the fact that all over the wide world, patients were shrinking under the surgeon's knife and saw,—operator and victim alike ignorant of the relief in store for them at the very time when Dr. Bigelow was unfolding in my library the first paper ever written on the subject, and saying to me as he did so, that within a fortnight the news of the discovery would be all over Europe. From the first, Dr. Bigelow was the steady, unflinching advocate of ether, as the safest of the anesthetics, and his views, though not universally accepted, have had a very wide and lasting influence.

To have been largely instrumental in making the

inestimable gift of anesthesia to mankind, to have corrected the teachings and reformed the treatment of Sir Astley Cooper in the most formidable of dislocations, to have won from Sir Henry Thompson a frank acknowledgment of the superiority of his American rival's treatment of one of the most distressing maladies,—all this makes up a professional record almost, if not quite, without a parallel in the history of American surgery. If the highest claim is questioned, I can only think of the name of McDowell, and possibly one other, as disputing it, and I must leave the question to the experts who are competent to decide it.

Dr. Bigelow was not a man of erudition. He read men and women as many scholars read books. He took life at first hand, and not filtered through alphabets. He was not ashamed of his want of book-learning, and would ask questions on matters with which he was unacquainted, with the simplicity of a child. But he would get what he wanted out of a book as dexterously, as neatly, as quickly as a rodent will get the meat of a nut out of its shell. I remember an address of his delivered some thirty years ago, in which he insisted very justly and philosophically on the importance of imagination to the man of science. I think it was in that address, which I ought to have by me to refer to, that he handled his rapidly acquired knowledge of the great authors he cited, so like an adept in book-lore, that one might have thought he was born in an alcove and cradled on a bookshelf. He got what he wanted out of his authority, and the next day the volume he had eviscerated would be kicking about his floor in the midst of the pamphlets and instruments and all sorts of learned litter which was commonly to be found variegating the pattern of his carpet. This power of finding what he wanted in the midst of rubbish he did not want, was hereditary. I remember Dr. James Jackson's saying to me that if there was a grain of wheat in a bushel of chaff, Dr. Jacob Bigelow would find it quicker than any man he ever knew.

Dr. Henry Bigelow's active mind found various employment outside of his profession. At one time he had a fancy for raising pigeons, and kept a columbarium at the top of his house in Chauncy Place. He did not like doing things by halves, so he sent and obtained the prize pigeons from one of the great London shows. He was very fond of pictures, and would rub the dust from an old canvas with his wet finger, and go into ecstasies over a bright bit of pigment, though he was reported to be color-blind, about which statement I never remembered to ask him. His last fancy was the beautiful one of creating a fine country place in a spot which he had selected in the town of Newton. There I last saw him, not really well, but not complaining, planting the young trees under the shade of which he was not to sit, looking with delight on the far-off mountains which bounded his landscape; and then I hoped I might see him, if a few more years were left me, enjoying a serene old age in the consciousness of having done noble service in the cause of science and for the good of his fellow-men. But the trees are still growing, Monadnock and Wachusett are looking down upon the home he created, and he is gone.

Most of you are familiar with his fine, manly figure, his intellectual head, a dome which the insolent Schopenhauer would have allowed might well be the seat of lofty endowment; with his pleasant features and his agreeable voice and manner. He was not especially

fluent in speech, but could put what he wanted to express into as few words—I was going to say, as his father could, but that is a great deal to claim for any man, even if that man was his own son. He had no great facility in writing, but what he wrote was solid with his thought. When he was deeply in earnest, he had a particular movement by which I could always tell that the powerful brain was at work, as well as I knew that the steam was up in the boiler of an engine when I saw the working beam in motion. Some of you must remember that flexing and extending of the right forearm—that always meant some work going on in that capacious and vigorous mental engine-room.

Dr. Bigelow remains with us in memory as a striking picture, a master in his calling, a man to be admired by the many, and to whom the few who were admitted to his intimacy were sincerely attached. I trust that some fitting record of one whom, now that he is gone, it is not flattery to call illustrious, will be added to our American Medical Biography, of which it will form one of the noblest chapters.

DR. HODGES: Dr. Bigelow was emphatically a Bostonian. He was companion from boyhood until his life's end of Mr. HENRY LEE, who will find it a grateful task to recount some of the impressions left by his versatile friend as they grew up and lived together for many years in the City to which both were so much attached.

REMARKS OF MR. HENRY LEE.

If Dr. Bigelow were alive, he and I might furnish entertainment for you by provoking reminiscences from each other, and dwelling humorously upon each other's peculiarities and misadventures; but now that his voice is hushed, I am in danger of drawing a one-sided sketch when not corrected by his criticisms. Even if I succeed in setting before you fairly the image of my old playfellow, it will be but the image of the boy, in whom were latent the traits and talents which in mature life "marked him extraordinary, not in the roll of common men."

When I was just turned of three years, my father moved from a pleasant old garden house, which stood, where now frowns the portico of the Tremont House, to one of those cosey little courts which were favorite retreats for families living on intimate terms with each other and a little aloof from the great world. On one side of Bedford Place, for so was the court named, was the house and garden of my uncle, Judge Jackson; then August, though only forty-five years old. On the other side all six houses were owned and occupied by our family and near of kin. Close by, in Summer Street, in the houses belonging to the First Church, dwelt my cousin George Cabot and Henry Bigelow.

From that time until we separated for college, we formed an inseparable trio, to the great complacency of George's mother and aunt; for he was a very handsome boy—with red cheeks, brown eyes and hair, and a goodly figure—and we two pale, slender, white-haired boys set him off to advantage. We played together not only the usual recurring games, but also a few tricks of our own inventing, the remembrance of which amuses me more than the narrative would entertain you.

While in our walks into the country for birds or flowers, or at plain carpenter's work, I could beat

Bigelow; on the other hand, swimming, or dancing, or at the gymnasium—wherever agility was needed—he was immeasurably my superior.

During our college life we roomed off the same entry in Hollis two years, and he inherited my room at my graduation. Circumstances—we were both busily occupied; then he voyaged for health, I for business—separated us for a few years; then we came together again in Paris, and afterwards, until marriage and business engrossments parted us.

You want to know what traits I observed in these years of youth and boyhood. In the first place, he had a pleasant temper, or I should not have clung to him all these years. I say clung to him, for, while we clung to each other, I was rather more dependent than he, and that may have been true of all his companionships. Then, he was a most entertaining companion, not only because of his keen observation of men and things, but also, as well, because of his eccentricities—his intermittent activity and repose; his relentless, exhaustive unravelling of some tangled skein; or eager pursuit and abrupt abandonment of one hobby after another; his absorption in all he was doing, and consequent absent-mindedness; his intense curiosity about matters, some intrinsically interesting, some uninteresting; his secretiveness, or to say the least, excessive wariness. These traits combined, to make the doctor, as I early named him, a source of constant amusement to me and all his associates. We two were friends upon the principle of "like likes unlike." We were complementary to each other; I saw the outside, he the inside; I was an observer of persons, he of things. He was quite unobservant of his surroundings; took little notice of scenery or of wayfarers. While he studied the movements of a clock at a shop window, I, incapable of that achievement, had memorized the passers-by. So we jogged along, each refreshed by the other's differences.

When I was a young man, all our physicians were general practitioners; now, you are all specialists. As I gaze around, I behold the faces of those who have exercised their skill on my eyes, my nose, my ears, my skin, my stomach. Well! this is evolution; you are all by nature, as well as by profession, specialists; and my old friend and playmate was eminently a specialist—morally and mentally a specialist. He was like a man looking through a spy-glass, who sees all within the field of vision more clearly than his neighbors not so provided, so that he was able to discover and analyze details invisible to them; and the world has profited and will continue to profit by his discernment and analysis. He was like a locomotive which surpasses other vehicles in power and speed, but is confined to its track. One cannot look for inconsistent advantages; you cannot expect a man with a glass to see what is without his field of vision, unless he and his spy-glass are both afflicted with diverging strabismus. The locomotive will haul you and your goods far and fast, but only while it keeps on its track; it is no respecter of objects thereon, either animate or inanimate; strollers must heed the warning, "look out for the engine."

"Time is short and art is long"; and the man who, by concentrating his mind upon some intricate problem achieves its solution, and thereby saves his fellowmen through all time from suffering hitherto unrelieved, must be ranked high, not only in the list of great discoverers, but also in the ranks of benefactors of man.

kind. Had he not been so occupied, he might have adorned society; he might have taken an active part in public enterprises and charities of the time; he might have been more mindful of the joys and sorrows of those among whom he had been born and bred; more surrounded by friends; and when called away, he might have been missed from more circles, but he could not, in all probability, have invented and transmitted these great alleviations to his fellowmen.

Connected with this brilliancy of intellect, this shrewd discovery of the one grain of wheat in the bushel of chaff, this successful solution of mechanical difficulties which had baffled all previous essayers — connected with, and no doubt consequent upon these evidences of superiority, and consequent also upon his isolation — there came to him a natural enough presumption of superiority in other fields which he had never traversed, and where others had been hard at work, urged by motives which did not appeal to his nature. Here, beyond his rightful domain, he displayed both presumption and incredulity, — incredulity as to the possibility of mainsprings which were not to be found in his machinery; and presumption of superiority, in all directions, based upon his acknowledged superiority in many directions. This was natural error of judgment; but it was an error, sometimes of great consequence. This is why I said that, with all his genius, with all his accomplishments, he was morally and mentally a specialist.

There were two lovable traits which endeared Dr. Bigelow to all his patients, simple and gentle, — his untiring devotion and his reluctance to give pain. On this latter point I can add my testimony to that of more suffering martyrs.

I accepted this invitation very reluctantly, anticipating what I now realize, how imperfect, and therefore, how unfair, would be my sketch of my old friend. To me, up to our last meeting, he was always the old bosom crony of my boyhood and early manhood, reviving remembrances of the joys and griefs, the work and play, the frolics and rogueries and escapades of those days, which, while we talked, came back to us as vividly as yesterday.

I close with a few words which, as President of the Association of Alumni, I had put together as a fitting introduction of Dr. Bigelow, who had been made Emeritus Professor of Surgery in the Harvard Medical School. As the doctor declined to appear, they were never spoken.

"Old Dr. James Jackson, long the Nestor of his profession in Massachusetts, speaking of one of his pupils, then risen to eminence as a physician, botanist and technologist, described him as one who would find a grain of wheat in a bushel of chaff."

"While we do not here inherit titles, we do inherit talents from our fathers, and the son of this remarkable father has risen to great eminence as a surgeon and a professor, as might have been safely predicted by any of his schoolboy and college comrades, whatever profession he had selected. This eminence has been recognized by his Alma Mater this day.

"Yet there is reason to fear that our Emeritus Professor of Surgery has, by his two great operations upon the stone and upon the hip-joint, incurred the anathema of our great Shakespeare, who thus imprudently such meddlers:

"Blest be the man that spares these stones,
And cursed be he that moves my bones."

DR. HODGES: For thirty-three years Dr. Bigelow was Professor of Surgery in the Medical School of Harvard University. This long service must have left its indelible impress. The walls even of the room in which he lectured must bear some *transmittendum*. No one can tell us better of the inspiration of this contagious teaching which still lingers about the chair of surgery than its present incumbent, PROF. DAVID W. CHEEVER.

REMARKS OF PROF. D. W. CHEEVER.

This remarkable man was of Latin, rather than Anglo-Saxon type. The logic of the French, the will of the Roman, the subtlety of the Italian, were united in an intelligence, which leaped to conclusions with the accuracy of genius.

As a surgeon, in method he was a pupil of the French school. To ingenuity he added dexterity; and to dexterity, grace. He was alert, cool, practised; whenever he appeared on the operating arena it was as a central figure. Precise in touch, supple in movements, he added the polish of the finished artist to the *nonchalance* of the experienced operator. To see him operate was to recognize a master.

He was a discoverer and an inventor. He discovered the mechanism of the ilio-femoral ligament; and he utilized its fibres in reducing dislocations. He discovered the tolerance of the bladder; and he invented the lithotrites and evacuators, which this tolerance of nature patiently endured.

He was a promoter of a new discovery in anaesthesia, and the champion of its discoverer.

Though eminently persistent and thorough in details which he regarded as essential, he was impatient of anything which seemed to him needless routine; and he fortunately lived at a time when he was spared the intolerable slowness of antiseptic surgery.

His active mind often devised new mechanical combinations for unexpected cases.

He would have excelled as a leader in government, or diplomacy.

He was long in service as a professor. A terse, clear and epigrammatic teacher, he possessed peculiar powers in extracting the wheat from the chaff of learning.

He was conservative; he refused to be moved by the times; he was opposed at first to changes in medical education, because he believed that the average community required only an average doctor, and that the average doctor needed only an average knowledge; while the exceptional man would acquire higher knowledge of himself.

Expert in surgical pathology, dominant in the field of operation, and clear and logical in diagnosis, his death is a loss to surgery. His genius must always command our admiration, as his discoveries modify our art.

DR. HODGES: Of the many hundreds of students who have sat at Dr. Bigelow's feet, none remember him more vividly or gratefully than his hospital house-officers. The charm of the relationship has never been forgotten. DR. HASKET DERBY, his house-surgeon in 1858-59, still holds the memory of that year in happy remembrance for its association with Dr. Bigelow.

REMARKS OF DR. HASKET DERBY.

You have listened to the words of the associates, the colleagues, and the intimate friends of Dr. Bigelow.

It is my privilege to speak as one of his pupils, his assistants, and last but not least, as one of the recipients of his singular and unmerited kindness. With his commanding talent as a surgeon, and his ability as a teacher, all present are familiar. But there was a side to his character comparatively unknown to the world at large, and fully appreciated only by those younger members of the profession whose good fortune it had been to find in him not only a wise and honored instructor, but an ever interested and sympathizing friend.

No one who has passed a year at the Massachusetts General Hospital as Dr. Bigelow's house-surgeon, can ever fail to recognize the effect of the time thus spent on his subsequent career. His subtle influence on his students was felt the more for being exerted so insensibly. He was the one surgeon who apparently devolved on his assistant the responsibility of everything connected with the patient except the choice and performance of the operation. The head of a young man might well be turned by the confidence that seemed to be placed in his ability. But all that went on was keenly, if silently observed; and the tyro whose diligence was found to slacken, or whose conceit led him to suppose that he might vary ever so slightly from the proper path, would unexpectedly discover his mistake. The lesson thus given was never forgotten. But the diligent and faithful student had nothing to fear. His unavoidable shortcomings would be forgiven, and his earnest efforts rewarded with the bright smile or the single word that, from such a master, was worth many a set speech of dull laudation. Yet the faculties had to be ever on the alert and the senses always sharpened. At the old Medical College the professor of those days took the long, straight flight of stairs leading to the upper lecture-room in single instalments, and ascended with grave deliberation. Dr. Bigelow, always hastening from the hospital to his class, cleared three steps at a bound, and his assistant well knew that he, too, was not to dally on the way. He had need of all his strength, mental as well as physical, to follow the master he served.

The hospital term completed, the year that makes an impression on the education and character of the student never to be effaced, and the examination for the degree passed, the relation of teacher and pupil, of surgeon and assistant terminated, and the young physician hastened to complete his studies at the great European universities and cliniques. After a lapse of several years, and having perhaps in the meantime sought to prepare himself for the practice of some special department of medicine, he would return to America and endeavor to establish himself in his native city. Who has not realized the depression felt at the outset of his career, consequent on the change from the bustle and activity of the schools, from the days and nights spent in absorbing study, from the unrivalled opportunities for observation and investigation, to the deadly quiet of the first office and the weary wait for patients. Happy the man who goes through this ordeal unscathed, happier still he for whom it is shortened, or even abrogated, by the intervention of a friend like Dr. Bigelow, who would follow with unfailing interest his former student on his first settlement at home, unobtrusively tender advice, the golden fruit of his own experience, offer opportunities so rare and seemingly so natural that their carefully hidden source would scarcely be inquired into,

and send case after case from his own clientele, month after month and year after year, until the beginner found himself suddenly transported from the bottom to the top of the ladder, and in possession of a practice, the amount and material of which, he could hardly have dreamed of acquiring after years of patient waiting. No allusion would ever be made as to the source of this success, no gratitude claimed and no thanks allowed. This is what Dr. Bigelow did for students who, after an absence of years, might hardly dare to hope themselves remembered by their honored master. The kindness that prompted it was a hidden trait in his character, and one of which only the few that best knew him were fully aware.

It seems but the other day, although now more than thirty years have gone by, since he came forward in the old room of this Society in Temple Place, and uttered his official eulogy on Dr. John C. Warren, then just deceased. I remember well the words with which he closed, alluding as he did to the passing away of such men, ripe in years and honors, "their works do follow them." It shall not, in his own case, be the fault of those whom he so disinterestedly befriended and assisted, that these works are not known of men.

The following resolutions were reported by Dr. R. M. HODGES, and adopted by the Society :

Resolved, That the Boston Society for Medical Improvement desires to record its sense of the loss sustained in the death of its most distinguished member, HENRY JACOB BIGELOW. Possessed of unusual surgical perception, quick insight, great technical skill and dexterity, clearness and directness as a teacher and writer, he added to these the qualities of leadership, an unusual intelligence, and an indomitable persistency in whatever investigations he undertook. His achievements have won for him a place among the foremost surgeons of his time, and his works have benefited humanity.

Resolved, That a copy of this record be sent to the family of Dr. Bigelow and to the *Boston Medical Journal*.

Adjourned.

BIGELOW AS A SURGEON.

BY A. T. CABOT, M.D.

EMERSON says, "Intellect lies behind genius, which is intellect constructive." And rarely has an intellect so constructive as that of Henry Jacob Bigelow applied itself to the problems of surgery.

He did not devote himself to the enlarging of fields already occupied, and partly tilled by predecessors, but rather to the work of a pioneer, opening up unsuspected ways into regions not explored.

His mind, thoroughly intellectual, had a wonderful power of insight; and when it applied itself to the investigation of a subject, it was rare that its search after truth was in vain. No more striking illustration of this could be found than in his work on the hip. Until he turned his attention to the study of hip dislocations it was only known that the most powerful traction, in what seemed to be the right direction, often failed to draw the bone into place, while occasionally manipulations by rotating and pulling the limb in a more or less aimless way accomplished a reduction with a comparatively slight exercise of force. It remained for him to penetrate the mechanical mysteries of this joint, to discover the action of the Y-ligament

in shaping the deformity, and to show how this band of fibres which had so often frustrated the most violent efforts of the surgeon, could, when rightly understood, be made to assist in the reduction, and to guide the bone back into the socket. The subject remains where he left it.

It should not be supposed, however, that this great intelligence supplied the place of work; for Dr. Bigelow was an indefatigable worker, and, when pursuing an investigation in which he was interested, he never spared himself, and left no corner unexplored. If the thing sought was a perfect lithotrite, he was ready to spend days in the workshop watching every detail as it went through the maker's hands, and accepting nothing as finished until he could detect no possibility of further improvement.

Those who were familiar with his back office could form some idea of the work that he put into the perfection of the "Simplified Evacuator" from the piles of rejected models that covered the floors and tables. Every detail of his litholapaxy apparatus was thus carefully elaborated, and tested as to its working capacity at every stage in its development, and to one looking on it might truly seem that "genius is an infinite capacity for taking pains."

While undoubtedly it will be his work on the hip and litholapaxy which will be longest remembered in connection with his name, we should not forget his share in helping on the cause of surgical anesthesia: "The greatest single step forward in the history of medicine." He not only aided and abetted Morton in his experiments with ether inhalation, but his papers on the subject gave it at once a firm footing in surgical practice, and hastened its adoption throughout the world. His own well-known dislike of giving pain must have often caused him to look back upon his share in annulling surgical suffering with peculiar pleasure.

Besides these signal achievements which place the name of Henry Jacob Bigelow in the roster of the great in surgery, there were many other contributions that he made, which, though of less importance, would have been sufficient to make the reputation of a lesser man.

His discovery of the erectile character of portions of the nasal mucous membrane, his operations for extrophy of the bladder, and for ununited fractures, are evidences of his acute observation and constant interest in all branches of surgery, and the best operating chair, the best autopsy table, and the best urethral dilator now in use, all attest his mechanical ingenuity.

As a lecturer he was very clear in statement and happy in illustration. He placed the subject under discussion vividly before his hearers, and showed remarkable judgment in forbearing to cloud the clear outlines of its important features with too much detail.

The impress of Dr. Bigelow's teaching is still widely felt throughout this community, and many a man to-day dealing with surgical difficulties is helped safely through by the recollection of some aphorism of his old Professor, in which the pith of the subject was served up in a form so compact that its very dryness made it attractive and easily preserved in the memory.

Who, of his old scholars who has an injury of the elbow to treat, does not remember that he must go through the motions of reducing a backward dislocation of the joint, and must put the arm on an internal

angular splint in every case except when he can clearly make out an uncomplicated fracture of the olecranon, and in how many cases of imperfect diagnosis have stiff joints been saved by the remembrance and practice of that rule.

To those who came in close contact with him as his house-surgeons, he may have sometimes seemed exacting, for he usually had several investigations in hand, and when interested in the pursuit of facts he spared others as little as himself. This was compensated for, however, by the advantages they had in personal instruction. He taught them surgical principles, and often left them to apply these to the patients; but if an assistant became slack, or a case was not going well, the fact never escaped his keen eye, and a few words on the duties of internes, or a practical talk on the application of surgical principles to that particular case was the result. Under this practice the men learned surgery and self-reliance, and the patients did well.

To the sick he was kind and sympathetic, not patient to listen to useless tales of woe, but keenly alive to present suffering.

He early found that his strength was not great, and that he must husband his resources; and he sacrificed much of his private practice to the urgent need for time to devote to his teaching and original researches.

He was a brilliant operator, bold and keen, full of expedient, going direct to the object sought with no fumbling of mind or hand. To see him do a litholapaxy was a liberal education in that branch of surgery.

Such is a brief outline of some of the characteristics of that leader that we have lost. Quality, not quantity, he strove after in the work he gave to the world; and for that quality will it endure.

HENRY JACOB BIGELOW, M.D.

A TRIBUTE OF RESPECT INSPIRED BY AFFECTION, ADMIRATION AND OBLIGATION.

BY REGINALD H. FITZ, M.D.

THE brilliant achievements of the late Henry Jacob Bigelow in the art of surgery may obscure in the minds of many, especially those of a younger generation, his contributions to medicine in general, and his interest in medical science.

He was the first to announce to the world the discovery of modern anesthesia. For a year or two after this discovery, it was he who administered most of the ether used at the Massachusetts General Hospital. As the result of this experience, he first clearly showed its advantages, dangers, and the precautions to be taken in its use. Of him, in this relation, it was said by the late Dr. Edward H. Clarke: "He did more than any other living person to bring it before the medical public of this country and of Europe, to assert its real value, and to point out the best methods of utilizing it. How much more even than all this he may have done in the matter is, as yet, unwritten history. To have been thus identified with the greatest blessing ever discovered for mankind was his fortune and desert before he had been two years in practice."

The period in Dr. Bigelow's life which has a particular interest for me is that first, developmental decade, when what he was to accomplish was unknown,

what he was capable of doing must have been anticipated. That he was the most gifted and brilliant young man among his coevals there can be no doubt. We all know what his maturer years accomplished. We want to know the sentiments which inspired the earlier years of his professional life, and which served as the basis of the superstructure which rose to so great a height. It is for his contemporaries, now so few, to give this information from their point of view. Fortunately for us, his own writings at that time, though also few, give decided assistance.

At the age of twenty-three Dr. Bigelow received the Harvard medical degree, and spent the subsequent three years in Europe, chiefly in Paris. Two years after his return he was appointed one of the surgeons of the Massachusetts General Hospital, and at the age of thirty-one he became Professor of Surgery and Clinical Surgery in the Harvard Medical School.

At the height of his professional activity surgery to him was eminently utilitarian. However much he might admire science in the abstract, it was his chief work to investigate problems the solution of which would add to the physical welfare of mankind. His career at this early day was distinctly scientific. The knowledge he was acquiring had no apparent immediate application to the art of medicine, but it served to develop his intellect, and he fully realized the importance it bore in fitting him for his subsequent life. It is possible at this time he may not have known whether his footsteps were to follow those of Hunter, or those of Sir Astley Cooper, whose career his own, perhaps, more closely resembles than that of the other eminent surgeons of history.

He returned from Paris at a time when the influence and teachings of Louis were paramount. The advocates of the so-called numerical method of studying medical problems were crying from the house-tops. In 1846, as President of the Boylston Medical Society, he made an address which was entitled "Fragments of Medical Science and Art." It was an appeal for the use of the inductive method in medicine, and advocated the exercise of the imagination for the promotion of medical discoveries. It indicated the reaction of his own mind against what seemed to him the mere accumulation of duplicate facts. New facts were what he desired, and more of them. These were to be found by chemical reagents, the microscope, and other means of physical examination. We are thus not surprised to learn, that in his earlier years he served as a teacher of chemistry, and became an expert in the use of the microscope.

It is through his devotion to pathological anatomy at this period that one of the monuments of his industry remains, — unfortunately as fragments, but of such a size and character as to suggest the structure in contemplation.

He sought for and secured whatever pathological material bore upon surgical diseases. He took it to a laboratory which he had founded and furnished, and in which was an artist trained and employed by himself. Colored drawings were made of the gross appearances, and the results of his microscopical and micro-chemical examinations were drawn and described with the utmost detail. Years were spent in this work. The art of the lithographer was called upon to reproduce these drawings in a more permanent form, that they might serve as plates for a volume on surgical pathology. While in the midst of this work

the "Atlas of Pathological Anatomy," by Lebert, made its appearance. Dr. Bigelow saw that his task was done by another, even on a larger scale than he had contemplated. His plan of publishing an illustrated Surgical Pathology was thus completed. What the illustrations would have been is, in part, known to the generations of Dr. Bigelow's students, who have admired in their turn the magnificent diagrams with which he illustrated his lectures on surgery. The beauty of some of these pictures is so conspicuous, in virtue of color and outline, that one forgets the repulsive nature of the object, and simply admires the skill of the artist. No one gave the latter more credit than did Dr. Bigelow. Within a few months, when he gave this collection to the Harvard Medical School, he stipulated that each should bear the name of the artist, which has been indelibly impressed upon them. The original drawings are those which possess the highest artistic merit, but those reproduced from various other sources are often interesting. Among them is an enlarged copy of an illustration from Addison's paper, showing the emigration of the white blood-corpuscles, the rediscovery of which, many years later, has made the name of Cohnheim imperishable. That Dr. Bigelow should have sufficiently appreciated the importance of this observation to have made it the object of illustration in his lectures, forty years ago, is truly noteworthy.

It is interesting to see how Dr. Bigelow described the anatomical and histological appearances which he saw. In his "Notes from Clinical Lectures on Surgery" (1851), he speaks thus of cancer of the lip: "But in its early stage the epithelial disease of the lip generally shows upon section as, in this case, a dense, white, opaque color, and often upon minute examination, as here, vertical striae dividing it into apparent columns, which either terminate at the free, labial edge, disintegrating into a paste which furnishes a scab, or may rise above it to a considerable height. But the microscope leaves no doubt in the majority of cases. I will not say all cases; for though some observers have no question upon this point, I have not satisfied myself about it. In most cases the field, as in the present instance, shows unequivocal epithelial features. The white, caseous mass shows the normal epithelial cells and scales, every irregularity of the latter varying in size and shape; while the distorted cells often attain, with and without nuclei, enormous size. A careful observation also detects little groups of the minute cells in the first period of their growth."

In the same pamphlet are contained the following statements concerning certain superficial cysts:

"By 'encysted tumors' I mean a distinct bag or cyst, containing this peculiar, caseous, soft, white material. Serous cysts (if we except 'hydrocele of the neck') are excessively rare. Cysts containing glairy fluid (if we except the bursa) still more so. Nor should the term 'encysted' be applied to those hard or fatty tumors which happen to get surrounded by a little, condensed, cellular tissue, from which they 'peel out.' The true 'encysted tumor' is very common, and, being quite distinct from other growths, should have a monopoly of the name. It is said to contain either *atheroma* or *meliceris*, very ancient words, which often convey no distinct idea. Yet these terms are really very descriptive of the two varieties of the contents: the former signifies *pap*, the latter *honey-wax*; by which is meant, I believe, not clear honey, but chilled

or frozen honey, which it greatly resembles. They are in pathology nearly identical; but *atheroma* readily minglest with water; *meliceris* is waxy, sebaceous or oily, and sheds water. *Atheroma* is a watery fluid, filled with little plates or fragments of epidermic material, sometimes as large as grains of rice, and of a semi-translucent white. Under the microscope this shows numberless epithelial scales, of which these masses are composed; sometimes nucleated, sometimes not, and often very irregular. In *melioceris*, on the other hand, though there may be serum present in small quantity, yet the cells adhere to each other by a tenacious, sebaceous matter or concrete oil, and at least in four among the tumors of this sort which I have removed, and of which I have retained a careful microscopic record, there were no scales, but in their stead beautiful, translucent, oval cells, a few of them nucleated; and occasionally, as a few in this case did, presenting irregularities in form, and some being of minute size. Their usual diameter is rather less than that of an epithelial scale, and they are seen imbedded in and inseparable from the granular, sebaceous, oily mass, when the field is filled with water; but substitute oil for the water, between the glasses, and these granules are at once dissolved, the cells coming out clear and clean into the field, and being the most truly beautiful cells I have ever met with among morbid growths. They are almost hyaline, and may be rolled about like little bladders. In one case they partially collapsed upon the contact of oil, as by an instantaneous exosmose. The gross mass looks like lard at ordinary temperatures, and is sticky and greasy to the touch.

The cyst of *melioceris* and *atheroma* is sometimes lined with a beautiful epithelium. Sometimes the epithelium is irregular and rough. In two cases, at least, of *melioceris*, the epithelial lining was only partial, the rest of the surface being moist and divested of integument. This last character may, perhaps, have some influence in determining the quality of the secretion; whether watery, or sebaceous and waxy; whether epithelial scales, or those large and beautiful epithelial cells. . . .

"Of their cause we know nothing." Astley Cooper thought that they were obstructed, sebaceous follicles. Lebert states that they contain all the products of these follicles. This they certainly do, and in addition, often hair, free and attached; but they are often deep, and seem to me to have also other analogies than those offered by the sebaceous follicle."

The search for knowledge of the above sort was something more than utilitarian, but Dr. Bigelow never regretted the time spent in the pursuit. It was a pleasure to him in later years to call attention to his scientific work of this period, and to point out in his diagrams the observations then made.

Throughout his professional life he was accustomed to emphasize the importance of the study of pathological changes. In his address on "Medical Education in America" (1871), he says, "no single branch of education is more essential to the medical student than pathological anatomy, the corner-stone of medicine."

His own contributions in this direction were made at the beginning of that progress which none knew better than he was to result from a more minute knowledge of facts; such as hitherto were not even to be imagined, but which were to be discovered by the

use of finer and more searching methods of observation than those previously known and cultivated.

In precept, as well as example, he advocated that scientific acquirement should be the only standard of professional opinion. In his introductory lecture of 1849 he thus disposes of the *tactus eruditus*: "A skilful surgeon detects fluid, not because his tactile papillæ are more sensitive, but because his ready knowledge furnishes him with natural groups of symptoms, which now exaggerate and now disconcert the value he would attach to the indications of the tactile sense." And in his address, in 1859, on "Science and Success," we find one of those gems that often sparkle in his essays. "No quality is more essential to sound medical practice than sound judgment, . . . an enlightened judgment is as necessary as an informed conscience."

The first decade of Dr. Bigelow's life now came to an end, and with it the opportunities for devotion to the more purely scientific research. The demand for his services in the practice of the healing art became greater and greater as the years rolled on. Others could accomplish the work which first interested him; he alone could fill the gap which lay before suffering humanity, and which, through his labors, has been freed from some of its terrors.

The main object of his subsequent medical life was usefulness — usefulness not only to his immediate surroundings, but to all mankind. He said, "Utility does not demand great intellect, . . . the prizes fall to industry; and sometimes to a tenacious, I had almost said, insane, pursuit by each of his own chimera." But in this pursuit of the useful he made two of the most important discoveries of his life, the significance of the Y-ligament in hip-dislocation and the tolerance of the bladder to prolonged operations.

These were the years in which his wisdom was so conspicuous. As physician or surgeon, as medico-legal expert, in the daily affairs of life, he was *facile princeps*. The difficulties which surrounded the beginner faded away as his advice was taken. A complicated code of ethics became in his hands, simple, sensible rules of life, an adherence to which enabled the follower to avoid the pitfalls and surmount the obstacles placed in his way by ignorance or design.

His wisdom was based upon a profound insight into and a knowledge of character which lead him to anticipate action and to control it. This wisdom, this knowledge of human nature, enabled him to rule men by showing them what they might accomplish. The delicacy of his tact made it easy for him to turn aside opposition from the one quarter, while the vigor of his intellect and the power of his arguments would cause other opponents to yield, even if not convinced. It was his first task to see the objections which might be presented, and, in seeing them, to discover the appropriate control. He was a master of details, and allowed nothing essential to escape his grasp; with a remarkable power of condensing, he retained the latter and set aside the rest. His wisdom might seem conservative to those who sought for change, but it was based upon an enlightened experience. He was always willing, in virtue of the imaginative qualities he so urgently commended, to make new trials. But these trials must not be so rash or so chimerical as to promise failure or to hazard an existing good.

A conspicuous instance of the exercise of this wisdom is to be found in his advice to make haste slowly when

radical changes were contemplated in the system of education at the Harvard Medical School. His views were presented in an address under the title, "Medical Education in America," delivered before the Massachusetts Medical Society in 1871. As might be supposed, they were eminently practical.

Since a medical school was a place for the education of practitioners of medicine, it was important, first, that it should give "a plain, sound, solid education, without error, if without ornament." It might, then, if able, meet the demand for a higher education. It should give "the highest average development of which the man is capable in the three years of study." At the same time, "it would be desirable to raise the average level of medical acquirement, skill and capacity, the world over. . . . But the standard of medical education should be raised gradually and with certainty by making the best of opportunities available to the largest number." Since, "of two classes educated to the same standard in the same community, the larger will yield the greater product of wheat as well as of chaff," any reform in medical education in this country should aim at educating at least an equal number of students to a higher standard. The student of average preliminary training and acquirement, after three years of honest devotion to medical study, should possess "a knowledge at once adequate to the immediate practice of his profession, and a germ of future growth in the right direction — knowledge unmistakably medical, practical, comprehensive, and rooted in the soil of modern science."

In devising a plan to raise this standard, he agreed with Huxley in preferring regulations which would open to the medical student a most liberal scientific opportunity, and insist upon a competency strictly medical. He did not agree with the details of the plan drawn by his colleagues, since, in his opinion, too much stress was laid by them upon the less applicable sciences, instead of giving more time to the study of medical sciences, especially to medical art. He anticipated that such a plan would result in a diminished attendance and diminished receipts; the immediate usefulness of the school would be impaired in accordance with the loss of numbers, and its life might be imperilled. He was ready to raise the standard of medical education, but preferred to do so gradually and with certainty, giving the best opportunities to the largest numbers.

Although the plan adopted by his colleagues resulted in a diminution of the number of students, the finances of the school were rather improved by the adoption of better methods of conducting the business of education. This diminution in the number of students and the increased cost of educating them are, perhaps, causes of an increased influx of medical graduates of other institutions whose standard is less high, into the towns of Massachusetts and other parts of New England.

Dr. Bigelow's objections to the teaching of a disproportionate amount of less applicable knowledge are now being advocated by some of those who were then his most vigorous opponents. They complain that enough, perhaps too much, has been done for the development of laboratory teaching in the scientific branches of medical study, and too little to foster and promote increased facilities for clinical instruction.

Dr. Bigelow, as I knew him, was a wise man, of brilliant talents and of great energy and power. Ac-

cepting a favorite definition of his own, he was a genius. For "genius is talent with a marked taste to direct, and a strong driving-power to work it." His qualities appealed rather to the head than to the heart, but he was not accustomed to wear the latter organ upon his sleeve. He kept his own counsel. Those in whom he was interested, and in whom he trusted, found him loyal in the extreme, ever ready to aid and encourage by word and deed, with all his might if needed. He asked no thanks, nor sought gratuitous service. He read character so unerringly as rarely to be mistaken in his judgments of men. Whatever he undertook to do by himself, he usually accomplished. His charm of manner, the depth of his knowledge, his sense of humor and keenness of wit, made it a privilege to be in his company. How great that privilege was, is first fully realized when it is no longer possible. He died like a philosopher: conscious of his ills, and accurate in his analysis of them, yet uncomplaining; his mind dominating his body till the very end, when he went to sleep peacefully as a child.

CLINICAL VALUE OF THE BACILLUS OF TUBERCULOSIS.

BY A. K. STONE, A.M., M.D.

I wish by the narration of a few cases which have fallen under my observation to show what a valuable aid in diagnosis the presence of the tubercle bacilli can be. The cases have occurred both in private and hospital practice and I have to thank the physicians for permission to use the material.

CASE I. The first case which I shall present, came to the Boston City Hospital in February, 1887. The patient was a well-built man of twenty-two years. There was no phthisis in his family. He, himself, had never been sick before. He was a bar-tender, and drank some liquor every day, otherwise his personal history was good. For some two weeks previous to his entrance, he had not felt quite like himself, but he had had absolutely no cough, though during the winter he had had several "colds."

One week before he had several times vomited (?) bright blood in considerable amounts. At the time of the examination he was weak, but felt first-rate. He had "no cough" but raised from time to time a small amount of sputa streaked with blood. There were signs of consolidation at the right apex, consisting of dulness, extending broad finger's breadth below the clavicle, whispered and spoken bronchophony, with broncho- and broncho-vesicular breathing over this area, and a few moist rales in the back.

Such was the result of my examination, for the case had been given me as a "clinical case," and I gave my diagnosis as phthisis.

To my great discomfort the physician in charge of the case had a different opinion, and overthrew all the weak arguments advanced in the support of the theory of phthisis. Indeed, as I found later, the patient had been presented to the third-year students on the previous day, as a well-marked case of pneumonia with the unusual symptom of severe haemoptysis. Though unable to hold my ground in argument, I was unconvinced, and after the hour procured a specimen of the sputum which on examination showed the tubercle bacilli in small numbers, yet easily found in each preparation. A week later the official diagnosis had been changed on account of the pneumonia showing no tendency to resolve.

CASE II was a private patient of Dr. Greenleaf's. A young man with both parents alive and well advanced in years. He, himself, was tall and thin, a lawyer by profession. He had been steadily at work through the summer, and though of late he had not been feeling quite as well as usual, attributed it to a slight pharyngitis, and to his need of a vacation.

About the last of August, he suddenly, and without any previous sickness, spit up several teaspoonfuls of clear blood. So little was he disturbed by this occur-

rence, that he came to town and tried to work, but after a few hours he gave it up and called upon the doctor. He was promptly sent home and sent to bed, and the next day a physical examination was made which failed to disclose any abnormal physical signs in the chest. During the next few days the patient from time to time and without any cough, spit up a little blood. At the end of about three days there appeared a slight cough and a small amount of sputa.

Meanwhile the patient was much displeased with being kept in bed as he felt perfectly well. I was asked to make an examination so that all possibility of phthisis could be eliminated. But the examination showed the presence of tubercle bacilli in small numbers. I will add that at the present writing, over a month from the first attack, the only sign of trouble is a persistent slight cough, while repeated physical examinations have failed to detect any modification of either resonance, or respiratory sounds.

CASE III. A few weeks ago a boy of sixteen years came to the Massachusetts General Hospital, out-patient department, service of Dr. Ernst. Up to one week before he had been quite well, when he had an attack of vomiting accompanied by headache. During the week he had two slight hemorrhages. He had the day he presented himself, a hot, moist skin, some cough with bloody expectoration; severe pain in the right chest; a temperature of 100°, and a pulse of 90.

Physical examination showed diminished resonance over the whole right chest, vocal fremitus and resonance both slightly increased, and moist rales, both coarse and fine, were present.

The general condition of the patient suggested pneumonia, and directions were accordingly given for treatment. But partly from the element of doubt which presented itself, and partly as an exercise in differential diagnosis with the microscope, Mr. Bowen, Dr. Ernst's assistant, was asked to stain some of the sputum to see whether the pneumo-coccus or the tubercle bacillus could be found, and numerous bacilli of tuberculosis were found, thus giving a positive diagnosis.

The next two cases illustrate the assistance which an examination of the urine for the tubercle bacilli may give in certain genito-urinary troubles.

The first patient appeared at the Massachusetts General Hospital in the service of Dr. Beach. He was a carpenter of forty-six years of age with good family history and good general health till within the last six months. There was no venereal history whatever. Four years ago he had had a fall on some rocks which had caused pain and swelling of the penis and perineum, accompanied by a slight urethral discharge. All of these symptoms, however, disappeared at the end of two months. Five months before the entrance to the hospital there was gradual increasing frequency of micturition accompanied by some pain and smarting. He had been treated by the passage of sounds, but the symptoms of acute cystitis steadily increased until there was necessity for micturition every hour. On entrance, the heart and lungs were found normal, and the urine, according to Dr. Woods's examination, had much sediment; a specific gravity of 1,024; was acid; had a trace of albumen and also of sugar; while the sediment consisted of an excess of small round cells, bladder epithelium, a few blood globules.

During the next three weeks the condition improved

a little, the temperature was normal, and the cystitis was less severe. A few hyaline casts appeared in the urine, which otherwise remained as before, excepting that the sugar had disappeared. Repeated physical examinations by the medical staff gave no clue to the general condition of the patient, and examination with the *dry lens* failed to show any tubercle bacilli. At the end of a month and a half there was no marked change, excepting that the patient's strength had gradually but surely failed, while the temperature had gradually increased till it was 101° - 102° each evening. Dr. Beach made up his mind that it was not a surgical case, all medical authority to the contrary, and sent the urine for a bacterial examination, with the result that tubercle bacilli were found present in moderately large numbers, thus establishing a diagnosis.

The second case occurred in the private practice of Dr. F. C. Shattuck. It was an ordinary case of pulmonary phthisis which had been running about a year and a half, when a cystitis suddenly appeared, persistent and severe from the first. An examination of the urine at once showed the presence of the tubercle bacilli and made the diagnosis of tubercular cystitis.

The two following cases show that the absence of the tubercle bacilli may prove an important factor in settling a difficult diagnosis.

The first occurred in the service of Dr. F. C. Shattuck at the Massachusetts General Hospital. The patient was an Irishman, about forty-eight years of age, with negative family history; who had had no previous sickness, excepting pleurisy, twenty-five years before. He entered the hospital December, 1886. The patient stated that four weeks previously, he had taken a severe cold and had coughed a good deal and felt very weak. At the end of a week he had a chill which was followed by fever. A constant pain came in the left side which was increased and lancinating on cough or deep inspiration. On entrance there was pain on the left side, a slight cough with a small amount of white and frothy expectoration; headache and shortness of breath. The physical examination was as follows: the left chest expanded less than the right; below the angle of the scapular to the junction of the fourth rib with the sternum, there was flatness, absence of respiration and of vocal fremitus, otherwise normal. Heart was moved a little to the right. The expectoration gradually became sero-purulent and the area of flatness extended while the patient began to have night-sweats.

January 7, 1887, I examined the sputa and found no evidence of the tubercle bacilli, though other bacteria were found in large numbers. This report so surprised the physicians that the sputa was again examined January 17, but with similar result. Meanwhile the flat area became somewhat less, and on January 22d, the patient was reported as gaining in strength, with respiration to the very base of the left lung, with moist and dry râles. By February 4th there was no cough, and no night-sweats; with only a slight dulness at the base, and with fair respiration everywhere present, and only a few dry râles. On this date the patient was sent to the Convalescent Home, where he continued to improve steadily, and was finally discharged, weighing one hundred and seventy-nine pounds, or thirty-one pounds more than he weighed when he first was able to sit up, and nineteen pounds more than when he left the hospital.

The sputum from the following case was sent to Dr.

Ernst by Dr. D. W. Cheever with the simple request that it should be examined for the tubercle bacilli. Careful examination, however, failed to show any, but Dr. Ernst was struck by the large number of cocci which appeared to have a capsule; probably Friedländer's pneumo-cocci. The result of the examination and the conjecture that the sputum came from a pneumonic process, was returned, together with the request that there should be another specimen of the sputum sent together with some account of the case. Dr. Cheever replied that it was a case in which a diagnosis of phthisis had been made, and indeed the tubercle bacilli were reported to have been found (but this was probably due to a *dry lens*). Dr. Cheever was inclined to think the case one of chronic pneumonia and sent the sputum for examination with the complete confirmation of his opinion.

The patient from this time on began to gain so rapidly that no more sputum could be obtained for further examination, and to-day, September 21st, the man has completely recovered and is enjoying perfect health.¹

A large number of cases, ordinary, every-day cases, might be given where an early and sure diagnosis has been made by the sputum examination; but enough have been cited to show to any one who has taken the trouble to read the above, that the presence or absence of the tubercle bacilli is often of the greatest importance in settling difficult diagnoses, and what is of more importance, making the prognosis and line of treatment clear.

One word as to the methods. To learn to stain the bacilli is not a difficult task, and when they have been well-stained it is not hard to recognize them, provided one has sufficient light and a suitable lens. But it is absolutely useless and will lead the observer into all kinds of error to attempt to search for the tubercle bacilli if he does not have a sub-stage illuminator and an oil emulsion lens. Where the bacilli are present in large numbers (and I have seen them in such large masses in sputum as to be recognized with a Zeiss A. A. objective), they can be seen with a *dry lens*. But when there are only four or five in a cover-glass preparation, though these may be perfectly typical in form and color, it is very easy to entirely overlook them or else to call them bits of colored detritus; while in cases where none are present, small crystals and dirt can too easily take on the appearance of bacilli and lead to a false diagnosis, and what is of more importance, cause an unfavorable prognosis.

A CASE OF HÆMOPHILIA AS OBSERVED AT THE FIRST MENSTRUAL PERIOD.¹

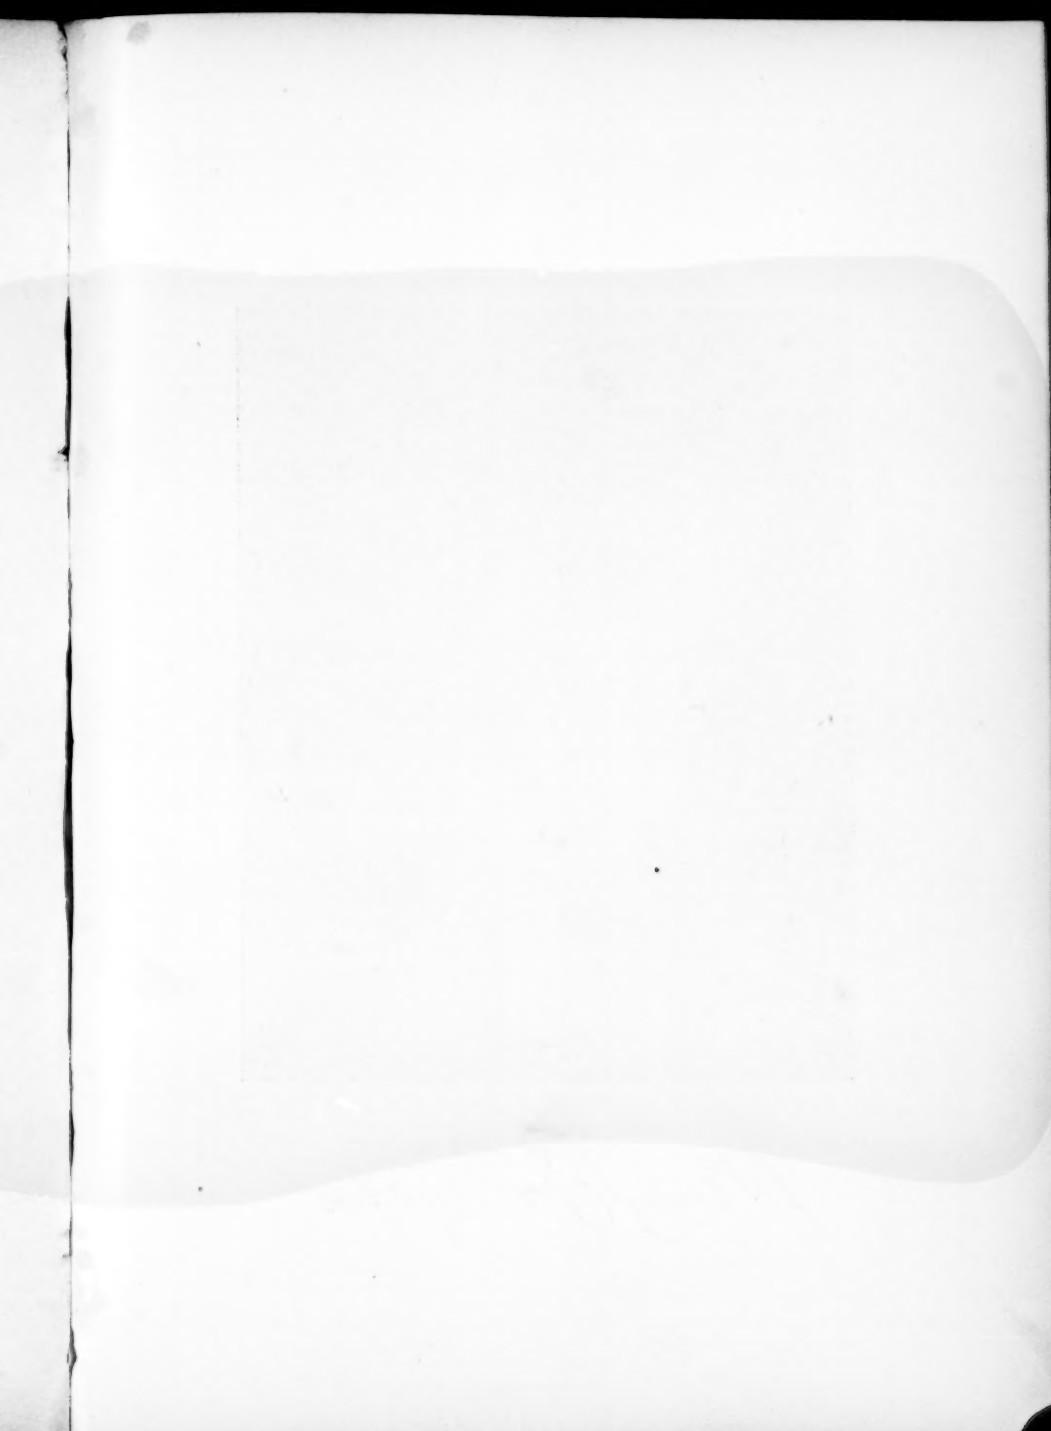

BY CHARLES W. TOWNSEND, M.D.

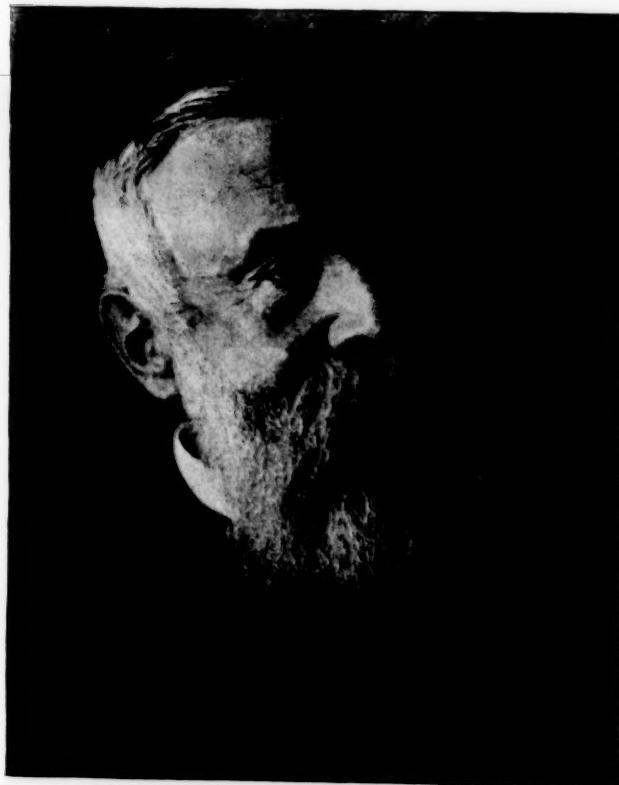

N., AGED thirteen years, comes of a healthy family. No bleeders are known to have occurred. A grandmother on the mother's side had three "blue babies," that died young. The patient has only one sister, and she is not a bleeder.

When N. was a baby it was noticed that any bruise, even that made by the hands in lifting her, caused a black and blue spot due to an effusion of blood under

¹ Read before the Obstetrical Society of Boston, October 11, 1890.

¹ This case is mentioned in the Proceedings of the Association of American Physicians, 1890.

Henry Ford

the skin. These effusions were at times extensive. On one occasion she was struck on the leg with a stick resulting in a large blood tumor which was slowly absorbed. Twice she bled profusely when the first teeth were extracted, once all day and night, another time all night before the hemorrhage could be controlled. A slight cut on the hand caused on one occasion a serious hemorrhage. Mosquito bites were scratched and would bleed freely. Slight scratches did not, as a rule, bleed long, although ecchymoses sometimes formed, as was observed once after the scratch of a cat. The patient has had severe attacks of epistaxis, but none since the removal of some mucous polypi. She has never had swellings of the joints reported in many cases of hemophilia.

As a rule, the patient was strong and full of life, enjoying out-door sports; quick at her studies and

of pale, watery-looking blood leaking through the tampon.

The patient was tossing about the bed, throwing off the bed clothes and calling constantly for water. She had constant nausea and frequent vomiting, the latter coming on after taking even a teaspoonful of water. This vomiting began two days before on April 21st.

The patient was at once restricted in the amount of water by the mouth to a teaspoonful every half-hour, as the constant vomiting following its frequent ingestion was rapidly exhausting her, and an attempt was made to nourish her and make up for the loss of fluids from the body by the use of enemata (one raw egg, three ounces of peptonized milk) every three hours. These were always well retained. On the following day she took two and a half ounces of milk and lime water by the mouth, and twenty-eight ounces of enemata, vomiting only seven times, and on the next day only once and this for the last time. The amount of food by the mouth was gradually increased, so that by the 28th of April she took thirty-eight ounces of beef tea, and six ounces of peptonized milk, besides chewing some steak and taking twelve ounces of egg and milk by enema.

The intense thirst, which was the most urgent symptom, and made the patient almost unmanageable at first and necessitated the banishment from the room of the family, who could not resist her constant appeals for water, began to diminish about the fifth day of treatment, but continued in a milder degree for several days longer.

The tampon was removed April 25th, without any recurrence of the severe hemorrhage, but a slight, bloody discharge continued for six days longer.

On April 26th, a slight gain of color in the lips was noticed, and from that time the daily improvement was very marked, so that on April 30th she had a decided color in her cheeks.

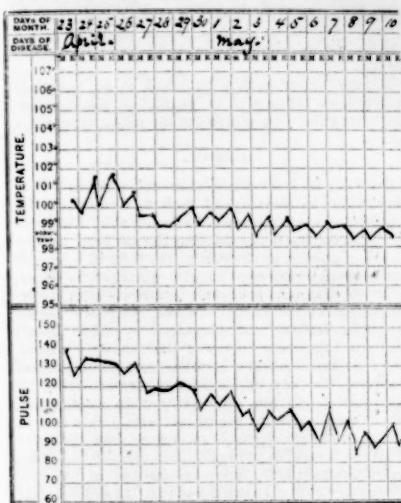

While she was tossing about the bed several pale red ecchymoses formed on the shoulders and elbows.

The accompanying chart shows the moderate elevation of temperature during the anemic period, and the slow but steady diminution in the pulse-rate as convalescence was established.

In the numerous articles on this interesting affection, very little is said, except in a general way, of the disease as it concerns menstruation, and I have been unable to find any detailed accounts of such cases. For this reason I may be pardoned for having reported the present case at such length.

Oslar, in his article in Pepper's "System of Medicine" on this disease, says: "In girls menstruation is sometimes early and excessive, but happily in the female members of hemophilic families neither this function nor the act of parturition bring with them special dangers."

Dunn, in Keating's "Cyclopaedia of Children's Diseases," says: "In girls menstruation may be early and excessive, but is unattended with special dangers," not the fact, certainly, in the case I have reported.

very bright. Physically she was well developed, having a fine skin, rosy complexion, and bright red lips.

Last March, at the age of thirteen, a slight "show" of blood appeared at the vulva, and three napkins were stained two weeks later. A week later—April 11—she began to flow, and flowed profusely for four days. On the fifth day, as the flowing had almost ceased, she went out of doors, but the flowing returned at once. This continued, notwithstanding the use of ergot, until April 22d, when her attendant, Dr. G. W. Tinkham, of Weymouth, inserted a cotton tampon. I first saw the patient on the following day, Dr. Tinkham, owing to the distance from his patient, having transferred the case to Dr. Wm. L. Richardson, who asked me to assist him. The patient was at that time very much blanched, the finger-nails being white and the lips having but a faint trace of color. The heart was normal in size, a loud blowing haemiac murmur being present over the base. The pulse was 140, very weak and thready; respiration at times sighing. The tongue was nearly dry. There was a moderate amount

— An exchange says that the surgeon in a military hospital was much surprised one morning to find the belly of a major, who was a patient, very much swollen. On inquiry he discovered that the nurse, in place of writing down one injection for number twelve, had written down twelve injections for number one.

REPORT ON PROGRESS IN THERAPEUTICS.¹

BY FRANCIS H. WILLIAMS, M.D.

SACCHARIN AS A MEANS OF ACIDIFYING THE URINE.²

WHILE it is usually not difficult to render an acid urine alkaline, our means of rendering an alkaline urine acid are less satisfactory.

When saccharin was first announced, it was mentioned among its properties that it was unaffected by the digestive fluids and was eliminated unchanged in the urine. Some time later, Dr. Andrew S. Smith had occasion to manipulate with this substance, and was struck with its strongly acid property; it occurred to him that so decided an acid, of such a stable composition as to resist decomposition in the system, and electing the kidneys as its way of exit from the body, would supply exactly the agent required for acidifying the urine.

The idea was tested on a boy suffering with transverse myelitis, whose urine, which required to be drawn with the catheter, was ammoniacal and very offensive. A few grains of saccharin, administered three times a day, promptly changed the reaction of the urine to acid, and did away completely with the offensive odor; not only so, but the irritation of the bladder became less and the formation of pus was diminished.

Shortly after this Dr. Smith was in attendance upon a case of subacute meningitis in a child twenty months old. The urine, which dribbled constantly into the diaper, was alkaline, and its odor, though not ammoniacal, was peculiarly sickening. Every effort was made in the way of cleanliness, but the atmosphere about the bed was extremely disagreeable. Small doses of saccharin were prescribed, and immediately removed the fetor, to the great relief of the parents and attendants.

It is probable that a part of the efficacy of saccharin in these cases is due to its being a powerful antiseptic, in addition to its acid property.

SOME OF THE RECENT APPLICATIONS OF MENTHOL.³

The most familiar employment of this camphor is as a local application for the relief of pain, and menthol cones are prepared and sold in the shops for this purpose. The relief obtained from such applications is usually but temporary, yet in some of the milder forms of facial neuralgia and so-called rheumatic pains the remedy is of real service. In pruritis also, the analgesic properties of the drug have been turned to good account. It is employed for this purpose in ointment, spirit, or liniment, in the strength of from one part in twenty to one part in ten. A very good preparation for this purpose is that recommended by Eloy, of a solution of fifteen grains of menthol in one ounce of forty per cent. alcohol.

Still another use for the remedy, as externally applied, is in the treatment of furunculosis, and more especially of furunculosis of the external auditory canal. Here the bactericidal properties of the drug, as well as its analgesic action, come into play. Dr. Cholewa has made trial of menthol in these cases, and recommends it most highly. He applies it by means of a pledget of cotton moistened with a twenty per cent. solution, and inserted into the canal. The appli-

cation is said to cause a little smarting at first but this is soon succeeded by entire relief of pain, and a speedy subsidence of the inflammatory process.

For nasal and pharyngeal catarrh much benefit is often derived from sprays of menthol dissolved in oil or fluid vaseline in the proportion of one to twenty or thirty per cent. In hay fever, William Hill, of London, has found menthol an excellent substitute for cocaine. He applies a ten or twenty per cent. solution in olive or almond oil to the sensitive area within the nose by means of a brush or atomizer. In the chronic bronchitis of old age, Nyes speaks favorably of inhalations of menthol, which, he says not only facilitate and rapidly diminish the expectoration, but also allay the cough and reduce the number of paroxysms. These inhalations have been used with good effect in whooping-cough.

Menthol has not yet been employed to any extent internally, although it is said to act efficiently when so given, in controlling certain painful affections. The dose for internal administration is fifteen to sixty grains per day.

If these effects should be found to be uniformly produced, we might well be justified in placing menthol among the most valuable of the minor therapeutic agents.

ARISTOL.

Dr. P. J. Eichoff⁴ has used aristol, which is a compound of iodine with thymol, both as a substitute for iodoform, and also in some forms of skin disease in which the application of iodoform has not been successful. It is applied to the skin in the form of a ten per cent. ointment, and covered with gutta-percha paper. He has already used it in cases of varicose ulcer, ulcerating lupus of the face, chancroid, psoriasis, herpes tonsurans, eczema, and congenital syphilitic ulcer. From his experience he draws the following conclusions: Aristol is always harmless, non-poisonous and odorless. In only one case — chancroid — was its therapeutic action less satisfactory than would have been expected with the use of iodoform. In a case of psoriasis, although slower in its action than the older agents — chrysarobin, pyrogallic acid, etc., — it possesses the advantage of being non-poisonous and of not producing unpleasant concomitant effects. In another class of skin diseases, the mycoses, aristol is quite as efficacious and at least as rapid and unirritating in its action as other remedies. In cases of varicose and syphilitic ulcers a quicker result may be expected from its use than by any other means. The same may be said of its use in lupus. The author recommends that it be given a thorough trial in surgical and gynaecological practice.

DIURETIN, A NEW DIURETIC.

The diuretic action of caffeine being open to the objection that it may be accompanied by sleeplessness and restlessness, it has occurred to Dr. Gram,⁵ of Copenhagen, to employ a sodio-salicilic compound of theobromine, to which he has given the name of "diuretin." Notwithstanding the strong resemblances between theobromine and caffeine, diuretin is alleged to produce strong diuretic action without in any way affecting the central nervous system, and to give satisfactory diuresis in cases of renal cardiac dropsy in which digitalis and strophanthus has been inoperative.

¹ Concluded from page 493 of the Journal.² Medical Record, November 16, 1889.³ Medical Record, November 23, 1889.⁴ Monatshefte für Prak. Dermatol., 1890.⁵ Lancet, January 4, 1890.

USE OF BORAX IN EPILEPSY.

Dr. Stewart,¹⁷ assistant medical officer at the Glamorgan County Asylum has reported seven cases illustrating the value of borax in epilepsy, and he infers that borax exercises a peculiar influence over nocturnal seizures, and that it is in cases where fits are entirely of that kind that the greatest good may be expected; that bromide on the other hand, exerts a more powerful influence over diurnal seizures, and that in cases characterized both by day and night fits, a combination of these two remedies will be productive of most benefit.

ANTIMONY IN INFLAMMATIONS.

In the *Practitioner*¹⁸ for March, 1885, Dr. Spender pointed out that antimony, in frequently repeated small doses, one-sixth of a grain of tartar emetic, every hour or two, has the power of completely dissipating early local inflammations. Acting on this suggestion Surgeon-Major Laurie began the use of small and frequently repeated doses of antimony in the treatment of surgical inflammation at the Afzaling Hospital in May, 1885. Since then its use has been gradually extended, and he has come to look upon it as one of the most valuable of drugs, as useful in local inflammations as quinine in malarial fever.

It may be given without fear of causing nausea and diarrhea or depression, even in diseases where its use would appear to be contraindicated—for example, in mucous enteritis, a most fatal disease to children on the plains of India. It has been employed in the treatment of typhoid fever, and is said to cut the disease short in a most remarkable way.

Tolerance of this drug is very soon established; there is no depressing effect unless it is pushed so far as to cause its own peculiar nausea and diarrhoea. It can be administered with cardiac tonics, and there are few, if any, cases which are susceptible of benefit by it, in which it cannot be employed in sufficient quantity to do good without fear of inducing depression.

ALCOHOL AND ALCOHOLIC SOLUTIONS IN THE ABORTIVE TREATMENT OF HERPES.

In a thesis published by Dr. Dupas,¹⁹ of Lille, the following directions are given for the treatment of this common and often troublesome condition. Alcohol, ninety per cent. strength, or a solution of two parts of resorcin to one hundred of alcohol, can be employed as a dressing; or one per cent. of thymol or three per cent. of menthol in ninety-five per cent. alcohol. If the solutions cause too much pain, a little cocaine may be added. Compresses moistened in one of the solutions are to be applied upon the lesions and over this spread some impermeable material, or absorbent cotton may be used. These dressings must be changed frequently during the day. The herpetic eruption aborts rapidly under this treatment. The element of pain is also subdued, and it is not rare to see rebellious neuralgia from herpes zoster give way in a few hours to this treatment.

DEATH FROM CHLORATE OF POTASSIUM.

Dr. William Anderson,²⁰ of Brooklyn, N. Y., reports a fatal case of poisoning with chlorate of potassium. The patient was a married lady of about seventy years of age, who took nearly an ounce of the

drug, thinking it was Rochelle salts. The mistake was discovered about an hour afterwards, and emesis was produced by mustard. No symptoms appeared until about four hours after the drug had been swallowed, when the patient suddenly fainted while defecating. The lips became blue, the tongue purplish, and the face ashen, but she said on recovering partially, that she had no pain. There was profuse vomiting of mucus, but no blood. The temperature rose to 100°; the pulse, which reached 100, was weak, but not irregular. She was given digitalis and whiskey, but died comatose, at the end of fifteen hours. The urine passed freely after the draught was taken, but was not examined.

HYDRONAPHTHOL IN THE TREATMENT OF ENTERIC FEVER AND OF DIARRHEA.²¹

Some experiments on the effect of hydronaphthol upon digestive processes seem to show that it has a very distinct retarding influence on the digestion of egg-albumen by peptic fluids, and a very slight effect upon milk by the same. On the pancreatic digestion of milk or albumen and on the conversion of starch into sugar, it has no effect. It is, therefore, inferred by Dr. Clarke that hydronaphthol may be given to patients, who are taking milk only, without fear of interference with digestion. If there should be sickness whilst it is being administered, it is probably due to retardation of peptic digestion and accumulation of undigested curd in the stomach. In the latter case the remedy may be given in pill-form, coated with creatin, in order that it may pass through the stomach and first be set free in the duodenum. Generally it was prescribed in gelatine capsules or simply suspended in milk. Two or three grains every two hours is a sufficient amount; in diarrhea, after the first three to six doses, it may be given every three to four hours, provided the effect is maintained. For children under one year, the dose is half a grain, to older children, one-half to one grain every hour or every two hours, or less often, according to circumstances.

Five cases of typhoid fever were treated with hydronaphthol, and all of them did well. Nausea was troublesome in two patients. It is best to begin with three or four grains every two hours in cases of enteric fever, and when the diarrhea is checked, to give the same dose every three hours during the whole period of pyrexia.

BROMOFORM IN PERTUSSIS.²²

Stepp²³ has reported a hundred cases of whooping-cough in which bromoform was used with success, and recently Dr. Newmann has treated sixty-one cases with this drug or with antipyrin, phenacetin, quinine, resorcin or benzoin (insufflations). Fifteen of the patients were less than a year old, and a number of the cases were severe in character, though there were few serious complications. Bromoform is conveniently administered suspended in sweetened water, half a drop to a drop every two hours to a child two years old.

The intensity and the number of the attacks in the twenty-four hours is diminished. The duration of the disease is not shortened, according to Dr. Newmann, though Stepp is of the opinion that this is also a result of its action. It is harmless, not difficult to administer.

¹⁷ Lancet, April 26, 1890.¹⁸ American Journal Medical Sciences, July, 1890.¹⁹ Journal of Cutaneous and Genito-Urinary Diseases, No. 87.²⁰ Medical Record, December, 1889.²¹ Practitioner, July, 1890.²² Therapeutische Monatsschrift, July, 1889.²³ Deutsche Med. Wochenschrift, 1890, Nos. 31, 44.

ter, and is worthy of a trial, though it is no more a specific than are quinine and antipyrin. Dr. Löwenthal, after using the drug in more than one hundred cases, is enthusiastic about its results.

It is important to use a preparation which is perfectly clean and has not become discolored through decomposition by exposure to the light. Children up to one year of age may have two to four drops three times a day; from two to four years, three or four drops three or four times a day. Up to eight years, four or five drops three or four times a day, according to the number and intensity of the attacks.

The good effects of the drug were apparent sometimes on the second or on the third or fourth day. The course of the disease is shortened, the children being relieved in from two to four weeks. The appetite is improved; in simple cases languor and drowsiness were noticed after each administration of the bromoform. In one case, a weakly child fifteen months old, where too large a dose had probably been given, narcosis ensued.

ELIMINATION OF SALICYLIC ACID BY THE KIDNEYS.

The danger attending the use of many drugs, even when taken in small doses, in cases of renal affections, has led Dr. Chopin²⁴ to investigate the conditions governing the elimination of salicylic acid by the kidneys, both in the healthy and diseased state. From the author's results it appears that in all cases where there is a renal lesion, the economy retains the medicine considerably longer than in the normal state, and it seems that salicylic acid, which, when the kidneys are normal, increases the quantity of urine; in acute nephritis, on the other hand diminishes it. So when moderate-sized doses are given in cases of kidney affection, the well-known symptoms of intolerance of salicylic acid appear in the first or second day of its administration, for the reduction in the amount of urine retards elimination, and so leads to the accumulation of the drug.

These results have an especial importance in indicating the wisdom of prohibiting the use of salicylic acid as a preservative of foods, for even when given in the smallest amounts, if the kidneys are affected, toxic symptoms supervene. In France, it is stated, more than one hundred thousand pounds of salicylic acid were used in 1880 for the preservation of foods, and the facts given above certainly justify the conclusion of the French Academy in prohibiting the use of the article for the purpose of preserving foods.

— The Polish count who was brought into court for sequestering four children, and rearing them as animals, has been acquitted. It is reported that they had been confined in a large, well-lighted and heated and ventilated room, well fed, and occasionally washed by a deaf mute; that they were unclad, never punished or restrained in any act; that two of the children had been confined thus three, one four, and one four and a half years. The defence of the count was that he was conducting a scientific experiment to learn what were the natural instincts and the intuitions really innate in the human species. The age of the children is not reported. They did not speak, and made barking, growling noises, and precipitated themselves upon their food like animals.

Clinical Department.

MENORRHAGIA IN A PATIENT AFFLICTED WITH HÆMOPHILIA.¹

BY H. F. VICKERY, M.D.,

Physician to Out-Patients, Massachusetts General Hospital; Instructor in Clinical Medicine, Harvard Medical School.

MISS E. M., a single woman, twenty-four years old, born in Russia, now lives in Boston, and works as a "stripper" in a cigar manufactory. She is on her feet very little. The family history is fairly good, and no relatives are known to have had symptoms like her own.

Since childhood she has been subject to the eruption of purpuric spots on the arms and legs, especially the latter. She has also had frequent nose-bleed, once or twice profuse; for instance, last winter an epistaxis lasted three days, so that a physician was summoned to check it. Since the menses began, in her fifteenth year, the nose bleed has sometimes accompanied them. The catamenia have been regular and not excessive, although lasting five to seven days.

August 3, 1890, the regular monthly flow appeared, but it stopped in three days, a shorter time than usual. On August 27th, flowing recommenced and gradually became alarming. It was for this that I was asked to see her by her physician, Dr. B. Lecherzack, of Boston, on September 9th. The patient had kept at work till three days before. I found her weak and with a small and rapid pulse. Purpuric spots were abundant. The possibility that her condition was due to an abortion was considered, but there were no physical signs of recent pregnancy, nor any reason to believe that pregnancy had been possible. Hot water douches mitigated the hemorrhage, but it seemed best for the girl to enter the Massachusetts General Hospital, where she came under the care of Dr. W. W. Gannett, who has kindly consented to my publishing the case.

On the 17th of September, she was up and dressed; and on the next day the already scanty flow entirely ceased, having lasted three weeks.

Dr. Gannett found that pinching the skin would readily produce an ecchymosis.

A brief report of the above seemed justifiable, because hæmophilia is comparatively rare in women, and even when present, seldom affects the menstrual flow.

Reports of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.¹

The Address on Surgery was delivered by DR. STEPHEN SMITH of New York, on the subject of

THE LIGATURE OF ARTERIES.

The history and physiology of the subject was given, and the contributions of American surgeons to the improvement and development of the ligature.

THE THERAPEUTICS OF EXOPHTHALMIC GOITRE.

DR. E. D. FERGUSON read a paper with this title.

¹ Seventh Annual Meeting, held at New York, October 22-24, 1890. Continued from page 471 of the Journal.

¹ Read by invitation before the Obstetrical Society of Boston, October 11, 1890.

Exophthalmic goitre, he said, was not a common disease and yet it was not so rare as to render it a curiosity and though the disease was one with sufficiently well-defined characteristics to allow of its ready recognition, still errors of diagnosis might and doubtless did occur. The fact that enlargement of the thyroid body was not peculiar to the disease, and that a frequent pulse was attendant on a multitude of morbid conditions, occasional prominence of the eyes might be added, from causes not the same as the condition of determining the development of exophthalmic goitre.

The conclusions that the condition was not, at any rate, a pathological unit, had been strengthened in the judgment of the writer, from the use of digitalis, for in every instance in which he had felt confident of the diagnosis, that drug had not only failed to afford relief, but was apparently productive of injury.

The writer then gave in detail the histories of several cases of exophthalmic goitre treated with straphanthus. The administration of this had afforded prompt relief, the patients being able to return to their ordinary occupation. In no instance had either the exophthalmus or the goitre been entirely removed, and so far as the latter was concerned, the author would not expect its removal, for when the enlargement had existed for some time it became of so dense or fibrous a consistency as to preclude the idea of its complete removal. There was, however, a notable degree of improvement, both in the exophthalmus and the thyroid body, but it was impossible to express in mathematical terms the changes in these features of the disease, so well as could be done in the rate of the pulse. Not only were the rate and rhythm of the contractions favorably influenced, but in these cures there undoubtedly existed a dilatation of the left ventricle which improved so as to leave no physical or symptomatic evidence of cardiac lesion. Recent pathological considerations tended to place exophthalmic goitre in the category of the neuroses, and to find the locus of its origin in the floor of the fourth ventricle. Still the evidence was not such as to give any clue concerning its etiology or treatment, aside from clinical observations, and subsequently there was no explanation to offer as to the method by which straphanthus afforded relief, aside from the idea that first suggested its use, and that was to relieve an apparently overtaxed heart through the lessening of the resistance in the systemic circulation which was claimed to be its action. Aside from any theoretical consideration, as to the way in which the agent acted, the fact remained that benefit was apparently the direct result of the use of straphanthus, a benefit so notable as to almost justify the claim of a cure in some of the cases. The only preparation used by the writer was the tincture, given by the mouth, three times daily, at each meal, the initial dose being from eight to ten drops, which was increased, if necessary, to reduce the frequency of the pulse, to fifteen or twenty, or even twenty-five drops. Whether its apparent utility would bear the test of time and larger experience, was still problematical, at present it seemed to be our most valuable therapeutic resource in exophthalmic goitre.

DR. CRONYN was glad that the speaker had given digitalis its proper place in the treatment of the disease.

DR. CARROLL said that he had been impressed with the difference which existed in the preparations of the drug straphanthus, now in the market. He thought he was the first to employ it here after the publication

of the first paper on the subject. His case was one of dilatation following valvular lesion. Its exhibition had been practically inert. He had then directed that another preparation should be procured. This had produced marked physiological action after a few doses.

OBSTETRICS.

This subject was made the basis of especial and general discussion, the following questions being propounded:

- (1) How may the present prophylactic measures in obstetrics be more extended and applied?
- (2) Is the present technique, in the management of labor and convalescence, in accordance with sound physiology?
- (3) To what extent have the surgical means of treatment of labor complications been successful, or should these complications and the process of repair have been more generally left to nature?
- (4) What influence would a more advanced obstetric science have on the biological and social condition of the race?

DR. S. B. W. MCLEOD presented the first paper on this subject. He said that, as a science, obstetrics was conservative, but was pre-eminently progressive as an art. Antiseptics, midwifery, and prophylaxis were then fully dealt with. The support of the perineum was the subject of much consideration. The dural or lateral position of the patient in labor and the use of the bandages had its advocates, and these a few. It was worthy of especial attention that while there were about one hundred and thirty medicines now before the profession, those that were designated "New Remedies" a few of these, perhaps eight, were of use in obstetrics. Ergot as an oxytocic still remained without a successful rival. The tears in ruptured uteri were sewed under antiseptic details and these lesions always offered prospects of recovery.

DR. G. T. HARRISON said that the most important work of the obstetrician was to see that he did not infect his patient. Vaginal examination should be made only in the interest of the mother and child. The most extreme limitations and even entire omission of internal examination might be very well compensated and substituted by external methods. Antiseptic vaginal douche should not be given before or during the birth in a normal condition of the pregnant or parturient woman. These were also contra-indicated under the same conditions immediately after the birth and during the puerperal state, as they were not only useless but positively injurious. It must be borne in mind that the course of births was mechanically retarded by the loss of the vaginal mucus.

The author would not interfere with the placenta unless there was some obstacle in the way of its complete expulsion, and would not adopt external manipulations. The natural forces were fully adequate to the detachment of the placenta, and there was no necessity of any kind of active interference on the part of the obstetrician to assist the physiological act. In regard to hemorrhage, Crede's method or Schroeder's modification were not objectionable when properly employed with reference to retained portions of decidua and chorion. Too much emphasis could not be laid upon the importance of an ocular inspection of the external genitals immediately after the delivery of the placenta in order to ascertain the existence of any

wound about the vaginal outlet. All the pelvic organs were in a condition of relaxation and the uterus was enlarged and swollen, if, therefore, the patient laid persistently on her back, and the bladder was allowed to become distended, and if the rectum, in addition, was left permanently filled, it must follow as a necessary consequence that the fundus uteri was forced backward, on the one hand, and the cervix was anteposed on the other hand, the retractions were hindered in their involutions and retro-uterine flexion was the result.

DR. T. J. McGILLCUDDY thought that the skilful use of the forceps undoubtedly decreased infantile mortality, but its bungling manipulation increased it. It was said that the forceps were applied much more frequently in private than in hospital practice. This was to be deplored because in many cases the child often lived only a week or two, and generally died from some cerebro-spinal lesion. Episiotomy was an operation which did not often do what was expected of it.

DR. A. P. DUDLEY, in speaking of the point as to whether the complications and processes of repair should be more generally left to nature, spoke very emphatically upon the subject of the Caesarean section. It was a measure, he contended, now very nearly perfect in technical detail. If properly done he believed it would in time become more successful than craniotomy done when a woman was thoroughly exhausted by her own efforts to deliver the child naturally, or by the efforts of the physician to do so with the forceps. One of the chief conditions of success in this operation was that it should be begun early before the patient became too exhausted. He had never given a vaginal douche before the birth of the child, and had never had a case of sepsis. He would suggest that the existence of a condition of pyosalpinx was likely to prove a very fertile source of infection at the time of delivery. In such event the uterus might have been washed out and every antiseptic precaution have been taken, there might exist no injury to the cervix or perineum, and still puerperal fever would develop and the patient die. The same result might ensue from any diseased condition about the bladder. He thought he had seen such cases in hospital practice. As a matter of fact it was seldom that sepsis occurred except as the result of gross neglect. It was his rule never to consider a case of labor ended till he had examined the uterus. It was very easy to pass a speculum. He was in the habit of delivering the woman on her side. In this position he had the perineum well in view and under control. He could sew up a tear and the patient never knew it. A few drops of cocaine was all that was necessary. He then introduced a needle at the top of the rent and repaired the injury with an over and over catgut suture. His answer to the second question propounded would be "no."

DR. A. L. CARROLL said that for a proper consideration of the fourth problem, we should possess statistical evidence of the mortality and morbidity of mothers and children, respectively, due, immediately or remotely, to parturition, and of the degree in which such mortality and morbidity might be regarded as preventable. This evidence, however, was in all respects scanty, and in some cases absolutely non-existent. "Still-births" were not officially registered, either as births or deaths, and even in the very imperfect occasional records of them it was impossible to separate

the fetal deaths before the beginning of labor, from the deaths during or soon after birth. Nor could we determine, outside of a few hospital reports, which reported an infinitesimal fraction of the total childbearings the proportions of abnormal presentations, of maternal pelvis, or of spontaneous or artificial deliveries in these alleged still-births, the whole volume of private midwifery being virtually a sealed book. There were no means of ascertaining how many of these dead-born were due to death during the act of parturition, but that the number was very great might be inferred from a comparison of spontaneous and artificial deliveries. A tabulated condensation of Mme. Lachapelle's experience was here given, the ratio of the dead-born being three and a half per cent, while in the artificial deliveries it rose to twenty-five per cent. As regarded the effect of dystocia on the later life of the child, little could be learned.

From a prophylactic point of view, it was desirable to discriminate the deaths directly due to the act of parturition, from those caused by secondary puerperal diseases, and this had been done by Farr in his separate classifications of "metria" and other accidents of child-birth. Nearly the whole of the mortality under the head of metria ought to be avoidable by aseptic midwifery and after-management, vastly diminishing the perils of the lying-in chamber, especially to the primiparae, and obstetric skill might lessen that from other accidents of child-birth.

Inprudence or mismanagement after parturition was a fertile source of local disease, or general ill-health, reacting almost of necessity upon subsequent offspring, and so, to a certain extent, upon the biological condition of the race. As regarded social conditions, the writer had but little to say beyond expressing the belief that nursing rather than midwifery was responsible for most of the degradation which blotted our vaunted civilization. Recent anthropometric examinations of convicts had frequently detected cranial malformations or asymmetry; it was not yet proven, however, that this was more common in criminals than in the law-abiding class, and if it were, the wildest flight of fancy would fail to reach a guess of its possible connection with dystocia. The speaker closed his paper by saying that he thought the question of heredity had little relation to obstetrics.

DR. C. C. FREDERICK said that he thought that the point of primary importance to the race to come, was the question of the present preservation of the health of the species. Reviewing the accidents during labor, he said the predisposing causes of injuries of the ureters, at that time, were found in a low position of the bladder and ureters, and an impaired nutrition of these organs during gestation, due to oedema and pressure. When the membranes ruptured before dilatation was completed, the cervix and the bladder were carried down into the pelvis before the advancing head, thus exposing the ureters to danger of injury. The use of forceps in such cases was a frequent cause of injury. To prevent injury of this kind, complete dilatation should be secured, if possible, before the membrane ruptured. If they did rupture early, and the cervix was tense, support should be given to the bladder and anterior vaginal wall, and retraction of the cervix over the vertex secured as early as possible. The discussion between the advocates of the expectant method of placental delivery and the followers of Credé, still continued, especially in Europe.

THE PHYSICIAN AS A WITNESS.

DR. MARTIN CAVANA, of Madison Co., in a telling paper on this subject, urged upon the profession to take more pains to qualify for the work of expert testimony before going into the witness box. Then it was well to adhere to the one or two authorities which had been studied and to disclaim any familiarity with others. While the main anatomical features likely to come up should be looked up, the witness need never hesitate to admit such portions of the matter as he cannot readily recall. He, having forgotten, could then take the opportunity to remind the court that even the lawyers are obliged to consult their authorities. It was well to secure favor of the entire court by manifesting a spirit of fairness to both parties in the action. Technicalities should be avoided, and the purport of every question by the cross-examination well weighed before answering. People with no business in the autopsy-room should be kept out of it. If a fire-shovel or wood-saw is used in making the dissection, it would be well not to let any non-professional spectator witness the fact lest it should lay the operator open to unpleasant remarks.

SOME OBSERVATIONS ON BONE AND SKIN GRAFTING,

was the subject of a paper by DR. B. M. RICKETTS.

Grafting or dermepenthesis in the vegetable kingdom had been developed to such an extent that there was hardly any limit as to what could be done in the way of repair and production, beauty and financial gain being the greatest desiderata. While the results of grafting animal tissue were less gratifying than those of the vegetable tissue, much had been done to convince us that the limit was far beyond anything yet attained. Of the many questions that arose relative to the subject of bone and skin grafting, there were three most prominent; namely, (1) When and how should skin be grafted upon raw surfaces caused by injury or by the removal of malignant or non-malignant growths? (2) How and when might bones be restored? (3) Should fragments of normal bone be permanently removed except in case of amputation? The author limited the first question to the cases where the edges of the resulting wound could not be immediately coapted, coaptation being given preference under all circumstances. In the second class of cases, he included those in which the restoration of the bones of the hands, feet, arm, or legs had been removed by trauma or surgical interference without amputation. Bone grafting or osteopenthesis, while not so far advanced, was subject to the same successes as skin grafting. Enough had already been done to show that its confines were not narrow by any means. The third question, bone fragments in either compound or compound comminuted fractures, where a bone was crushed or broken into two or more pieces, the greatest care should be taken to replace the fragments and to offer every opportunity for their union, that its strength and original shape might be preserved. That this might be more certain all clots and foreign matter should be cleared away, and all shreds of tissue removed from between the fragments which should be immediately restored to their proper places. In some cases, as in the long bones, the fragments might be firmly brought together with silver wires which could afterwards be removed. The author looked upon exploratory incisions in cases where the conditions of the bone

could not be determined, as justifiable, and as being the only means of knowing the exact condition; clean surgery being the safeguard. A number of specimens of bone-wiring in the dog were then exhibited.

THE NEW YORK ACADEMY OF MEDICINE.

COMMEMORATION OF THE OPENING OF THE NEW BUILDING OF THE ACADEMY.

The formal opening of the new building of the New York Academy of Medicine, on the evening of November 20th, was a notable event in the medical annals, not only of the city of New York, but of the entire country. The various features of this spacious structure, so beautiful in design and so admirably adapted for the purposes of a working institution like the Academy, were fully described in the JOURNAL at the time the plans were adopted, and it need only be said that the expectations of those most deeply interested in the success of the great enterprise, have been more than realized by the splendid result now consummated. On the occasion of the inauguration ceremonies, there was present a large gathering, thoroughly representing the culture, wealth and beauty of New York, as well as the local medical profession, and that of Brooklyn, Boston, Philadelphia, Baltimore, Washington, Trenton and other cities; and the brilliant incandescent electric lamps shone upon a most inspiring scene.

There were probably nearly fifteen hundred people in attendance during the evening, and the corridors and upper halls were filled with those who were unable to gain admission to the main hall, although the reception and dining rooms were thrown open into it by raising the movable partitions separating them. After an invocation by the Rev. Dr. Howard Crosby, Dr. Alfred L. Loomis, President of the Academy, delivered the opening address. He first paid a tribute to the founders and deceased Fellows of the Academy, among whom were such men as John N. Francis, Alexander Stevens, Alexander Hosack, Joseph M. Smith, Valentine Mott, Francis Delafield, Austin Flint, Wm. T. Van Buren and J. Marion Sims, and then went on to say:

"Our membership has reached nearly seven hundred, and includes most of the active workers in our profession in this city, and many in the State. Every specialty in medicine is represented by those who have become distinguished in their chosen lines of work. There are now established and well-organized sections in all the special departments of medicine and surgery, so that each Fellow may find a place with congenial workers for making public the results of his own observations and experiments, under the sifting criticism of experts: and thus learn what may have been done by others in the way of support or in opposition to his own work. The combined scientific labors of our general meetings and sections are not only to a large degree leading and guiding the medical thought and research of our own country, but its influence is being felt in the medical councils of Europe. We are also exerting an increasing influence on public thought and action. We are becoming a power in this city and State, which is being more and more felt in the legislative and economic work of our Commonwealth. The public health and safety of our citizens are being more

and more committed to our hands, with the conviction that by wise counsels and practical methods, we shall protect them from the ravages of disease by an ever broadening and more perfect sanitary science. Our profession was never so full of promise as at present; never before were there so many strong men in its front ranks as now, never were there so many cultured and brilliant minds entering it as to-day. If this great and daily increasing power can be centralized, as is possible, within these walls, its influence on the social, domestic, business and religious life of our city cannot be estimated; already the better minds in all departments of science are turning to us for help and inspiration. There is no longer a strife of sects or creeds, but a struggle for the supremacy of intellectual power and broad culture over weakness and charlatanism. There is no place in the broad field of scientific medical inquiry for the would-be medical man who talks of the potential power of infinitesimal abstractions and the so-called scholastic illusions. We are living in and are part of an age of facts, not fancies; work, not theories. . . . The days of doubt and anxiety are past, success has ceased to be a question, the auspicious present marks the beginning of a new and broader career for our Academy. It is here in the centre of this great city to do its part in stimulating its intellectual and moral forces; with increasing opportunities come deeper obligations. Our future must not be gauged by past successes or present advances. We are under obligations to the past, but under bonds to the future. As we in turn pass this trust to our successors, to those who in the future are to be the exponents of the lofty mission to which this building is dedicated this evening, it must not have suffered in our hands, but have grown and broadened under the impulse of true enthusiasm and faithful work. Yesterday we read the history of the past; to-day we make history for the future, and, whether he will or not, every Fellow in our number must leave his mark, be it little or much, in the records of this Academy."

DR. EDWARD L. KEYES then delivered the anniversary oration, which is made each year before the Academy and invited guests by one of its distinguished Fellows selected for the purpose. In the course of it he compared the New York Academy with the Academy of Medicine in Paris and the Royal Medical and Chirurgical Society of London, upon the general plan of which its organization was outlined. Each, he said, had a building of its own, that of the French Academy being a temporary one. The Royal Medical and Chirurgical Society was founded in 1805 and has now a membership of 700. Seating capacity of largest hall, 300; area of hall, 40 by 50 feet; foundation area of buildings, 50 by 200 feet. The Academy of Medicine, Paris, was founded in 1826. Present membership, 110; seating capacity of largest hall, 92; area of hall, small; area of building, small. The Academy of Medicine, New York, was founded in 1847. Present membership, 700; seating capacity of largest hall, 350; plus extra opened-up space, 250, equal to 600; area of hall, 42 by 57 feet, and two extra smaller rooms that may be opened into it; foundation area of building, 75 by 100 feet. "All," he continued, "have libraries; but on this point we may seek a wider field for comparison. Our library, which is, I believe, the youngest on the list, and which always gratefully recalls the names of its chief munificent donors —

Purple, Dubois, Bumstead, Stone, Jacobi, and many others whom time forbids me to detail — was founded by donations in 1877, and never bought a book until 1879, eleven years ago. Yet now, safely housed in a fire-proof home, we are proud in possessing the third place numerically among the medical libraries of America, and the fourth place, as far as I can learn, among the purely medical libraries of the world."

DR. A. JACOBI delivered an address on the library, in which he stated that a special library fund of \$20,000, or one-fifth of the sum required for the perpetual endowment of the library, had now been secured. The following passages in it were especially worthy of note: "This library has started from small beginnings, like medicine itself. It comprehends the labors of thousands of workers assiduously employed through long centuries. Pondering over the shelves, you behold abstracts, scientific treatises, works on practical therapeutics, and books on art and appliances, all of them composing our beloved 'medicine.' Remove the theoretical works on anatomy, histology and embryology, experimental physiology, physics and chemistry, — what remains? The wreck of the edifice, the foundation of which is torn away. Look at the shelves holding special literature. Then the specialist will comprehend that his doctrine and art are but a minimal tribe when compared with the surrounding wealth, and that the basis and link of all specialties is general medicine. Every one of them evolved from a minute bud of the great tree, and but few have ever been able to grow up with anything like independence. Thus, medical science and art are shown to be an organism of slow, consistent, historical growth. Even the very excrescences — call them fallacies, superstitions, theories, schools, sects, or what you will — do not disturb the organic economy. In accordance with this your very library, the representative and exponent of all medicine, is no longer a mere collection, but a vitalized organism.

"That is why there is an atmosphere of solemnity in your large library; for you are standing in the presence of the spirit and soul of all previous ages, each evolving from and connected with its neighbor. That is why a library is to the scientist what the church is to the pious, or a museum of a hundred gems, like that which generous Fellow presented to our reception room, to the artist. No consideration of lucre invites you here. While nourishing your mind you disconnect yourself from the embarrassments of trivial employment and deliver yourself from the merely terrestrial. In that way is nurtured idealism, without which no feeling and thinking man can be, and without which no nation can expect to live. When she lost it, even Hellas perished, though she had given birth to Solon, Pericles, Aristides and Sophocles."

Congratulatory addresses were next made by Drs. Fordyce Barker, of New York; John S. Billings, of Washington; S. Weir Mitchell, of Philadelphia; and Reginald H. Fitz, of Boston.

In the course of his remarks, DR. MITCHELL said: "Some years ago I had occasion to visit one of the famous academies of the old world, that of Paris, in search of an ancient volume in its library. I was struck with the poverty of the building, the poor accommodations, and the absence of a catalogue, without which a library is like a man without a memory. I asked one of the members why they did not get a suitable building for the vast treasures they possessed, and

I was told that they were waiting for the government to erect it. If our Academy had had to wait for the government to put up a building for it, how long do you suppose it would have been without one?"

The exercises were brought to a close by Dr. Loomis, who announced that letters of regret had been received from Ex-President Cleveland, Drs. Henry L. Bowditch, N. S. Davis, Wm. H. Welch and others, and then proceeded to read the following characteristic letter from Dr. Oliver Wendell Holmes: "Academies have been too often thought of as places of honorable retirement and dignified ease, roosts where emeritus professors and effete men of letters, once cocks of the walk, could sit in quiet rows, while the fighting, the clucking and the crowing were going on beneath them. No doubt, to be a member of the French Academy — one of the forty immortals — is an honor worth striving for, in spite of Piron's epigram. But the academy which fulfills its true function is a working body. It deals with living subjects; it handles unsettled questions; it sets tasks for its members and furnishes, so far as it can, the appliances for their prosecution; it offers rewards for meritorious performances; and sits in judgment on the efforts of aspirants for distinction. It furnishes the nearest approach we can expect to a fixed standard of excellence, by which the work of new hands and the new work of old hands can be judged. It is a barrier, a breakwater, against the rush of false pretensions, which are constantly attempting to find their way into public confidence.

"Nowhere is such a defense more needed than in the sciences and arts which deal with the health of the community. The public is so ready, so eager to be deceived, and the traders in deception are so willing, so hungry to deceive those who will listen to them, that it needs a solid wall of resistance, a close united phalanx of men of recognized sense, knowledge and character to stand against them. The various forms of what I will venture to christen as pseudo-pathy and pseudo-therapy — though they are known to the public by other names — can never loosen the hold of the intelligent, thoroughbred physician on the enlightened members of society so long as the best heads in the profession are banded together in a noble institution like this academy. We look to this great and able body of men to guard the sacred avenues to the temple of science against all worshippers of idols. The medical profession will always have to fight against the claims of wrong-headed and too often dishonest individuals and 'schools,' as they call themselves. There are a certain number of squinting brains, as there are of squinting eyes, among every thousand of any population. There will always be a corresponding number of persons calling themselves physicians ready to make a living out of them. Long may it be before the wholesome barriers are weakened that separate the thoroughbred and truly scientific practitioner from the plausible pretender with his pseudo-pathy and his pseudo-therapy. We trust it will always be enough for a physician to say, 'I am a member of the New York Academy of Medicine.'

The arrangements of the evening were very satisfactory as a whole, though, on account of the large number of persons present, it was, of course, impossible for all to hear the addresses. At the conclusion of the literary exercises a bountiful collation was provided, while the music of Lander's orchestra added not a little to the enjoyment of the Academy's guests. Alto-

gether, the affair was a brilliant and most successful one, and the profession of New York may well feel proud of the manner in which the occasion passed off, as well as of the achievement which the evening's festivities commemorated.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING October 11, 1890.

DR. VICKERY reported, by invitation,

A CASE OF MENORRHAGIA IN A HÆMOPHILIC.¹

DR. TOWNSEND reported

A CASE OF HÆMOPHILIA AS OBSERVED AT THE FIRST MENSTRUAL PERIOD.²

DR. G. W. TINKHAM of Weymouth, present by invitation, related the subsequent history of the latter case as follows:

The patient began to menstruate for the second time June 25th, and although she was kept perfectly still in bed, flowed profusely for several days, the flowing ceasing on July 3d.

On the 13th of August she again came on unwell and for the following eleven days bid fair to have a moderate flow and but little disturbance to the system. I was called on the 21st of August. From this date to the 31st there was a constant increase in the amount of blood lost.

On the 28th I tamponed, and although less fluid escaped, together with coagula, there was, nevertheless, as much being lost, as was afterwards found when the tampon was removed. On removing the tampon on the 31st a profuse rush of coagula escaped from the vulva and was followed by profuse hemorrhage. Alarming syncope coming on, I plugged, rather than scientifically tamponed, the whole vaginal canal. Up to that time there had been no marked rise of temperature or pulse as shown by my chart. Through over-persuasion the plug was not removed until the 9th of September. At that time marked septicemic symptoms had manifested themselves, and the outlook was bad. When the plug was removed, it bore evidence of having rested for many days in contact with the external os, and the distal end of the plug was bathed in the mucopurulent discharge that had been present on the napkins for several days previous. Carbolized douches had been used freely for several days before the plug was taken away.

Much as I hesitate putting this experience on paper, I should regret it all the more, did not your honorable members know some of the reasons of the "wherefore and the why." The following two or three weeks brought with them all of those conditions which follows loss of blood and septic absorption. Ptosis of left eyelid continued for some ten days. Dimness of vision, palpitation, extreme languor and lassitude continued until the temperature and pulse had nearly reached normal. From time to time during her illness bluish discolorations would make their appearance on the legs and arms, and on the chest. On the 9th day of October and the fifty-eighth day of her illness her pulse and temperature had returned to their normal condi-

¹ See page 520 of this Journal.

² See page 516 of the Journal.

tion; appetite, sleep and digestion were all satisfactory.

DR. RICHARDSON said that when he first saw the case reported by Dr. Townsend it seemed to be very doubtful whether the patient would survive. She seemed to be almost moribund. It was certainly a clear case of hemophilia.

DR. SWIFT asked about the pathology of these cases and said that a patient was brought to the Carney Hospital in a perfectly blanched condition after flowing for one week. She died suddenly and nothing could be found post-mortem to account for it.

DR. TOWNSEND said that with the exception of thin walled blood-vessels in some cases, of which Dr. Vickery had spoken, it was the fact that nothing, as a rule, was found in these cases, and that the true pathology of this curious disease was as much a mystery as ever.

DR. MINOT said that these cases suggest the spontaneous hemorrhages seen in the new-born where no constant pathological conditions are to be found. The hereditary character of this disease is well-known. In one family under his observation there have been three children with this tendency. One died of cerebral hemorrhage. In another there was umbilical hemorrhage and ecchymoses in the skin, eyelids and tongue. The first-born child bled from the umbilicus and from a slight scratch on the scalp made by the forceps, but she is still living at the age of twenty-six. A cousin in the same family by the father's side, lost several children in the same way. Dr. Minot supposed it was a disease of the blood-making organs. He had recently seen a case of precocious and copious menstruation, in a girl aged twelve years and eight months. She began to menstruate a year ago last April, since when, at irregular intervals, she has lost large amounts of blood, and suffered considerable pain. The patient had large breasts and was a well-developed woman. On examination it was found that a slight touch of the external organs caused them to bleed. She was much relieved of dysmenorrhea by the use of antipyrin and improved under the use of pulvis ferri.

In two other cases of profuse menstruation in young girls he had used dialyzed iron in doses of twelve to fifteen drops three times daily with good effect.

DR. SINCLAIR had used a sulphate of magnesia and iron mixture in these cases with good effect.

In answer to a question DR. TINKHAM said that the tampon he used being small simply restrained the amount of flow without stopping it.

DR. RICHARDSON said that by packing the vagina solidly, using a large number of small wads of cotton, the flow could, he thought, be entirely checked.

DR. SINCLAIR said that he considered ordinary cotton wool far preferable to absorbent cotton in these cases, and that if the vagina were thoroughly plugged it would be possible to stop all bleeding.

DR. VICKERY had used hot douches of 110° to 115° F. in his case with good effect.

ANNUAL MEETING OF THE MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY.

THE Annual Meeting of this Society was held at the Medical Library, 19 Boylston Street, on Thursday afternoon, November 20th. The Treasurer presented his financial report, showing a permanent investment fund of about \$30,000; and eleven beneficiaries had

each received an annuity of one hundred dollars the past year. As the by-laws of the Society require that a beneficiary once upon its rolls continues there for life, provided there is no substantial proof of immorality, it is evident that this Society can do a permanent good to any unfortunate who has once seen better days, and who can thus appreciate the blessing of a permanent income. The class of investments for the permanent fund is restricted to mortgage notes, United States bonds or municipal bonds, so that though the income does not represent a high percentage on the amount invested, yet there is hardly any danger of loss of capital or shrinkage in its value.

The officers elected for the ensuing year are: Dr. Henry W. Williams, President; Dr. R. M. Hodges, Vice-President; Dr. Francis Minot, Treasurer; Dr. Robert Amory, Secretary; Drs. F. I. Knight, J. P. Maynard, E. G. Cutler, David W. Cheever, C. M. Green, C. H. Cook, G. E. Francis of Worcester, W. L. Richardson, and Charles G. Weld, Trustees. The Society received during the past year a legacy of \$500 from the Amos Cotting heirs.

The objects of the Society are to aid members of the medical profession crippled by age or disease, and their families when in need.

The fee for admission into the Society is three dollars, and two dollars annually thereafter, payable at or before the annual meeting (last Thursday in October). The payment of \$25.00 in one sum constitutes a life member (free from annual assessments). "The donation of \$50.00 or more at one time shall entitle the donor to be inscribed among the benefactors of the Society" (By-law, Art. 5).

A special charter from the Commonwealth of Massachusetts incorporated the Society and authorized its holding personal property to the amount of \$50,000.

Miscellany.

EN ROUTE TO BERLIN.

QUITE a number of New York physicians have already gone to Berlin to make a personal investigation of Koch's inoculation treatment of tuberculosis. Among those who sailed during the past week were Dr. Charles E. Quimby, Assistant Professor of Practice in the medical department of the University of the City of New York, who is sent out by the Faculty of that school; Dr. Joseph Linsley, who is the accredited representative of the New York Post-Graduate Medical School and Hospital; Dr. Alexander Aronson of the German Polyclinic; Dr. G. Bettini di Moise, who is sent out by the Italian newspaper, *Il Progresso Italo-Americano*; and Dr. David H. McAlpin, of the Carnegie Laboratory. Dr. Edward K. Dunham, another instructor in the Carnegie Laboratory, has already been in Berlin for some weeks. It is said that a number of physicians, headed by Dr. H. H. Holbrook Curtis, are about to open an institution for the special treatment of consumption, and that Dr. D. O. Edson, as their representative, has started to Berlin for the purpose of sending over inoculating material and studying Koch's methods. *Frank Leslie's Illustrated Newspaper*, through Mr. William J. Arkell, having received permission from Professor Koch to send a tuberculosis subject from America to

Berlin for treatment, Dr. George F. Shrady, editor of the *Medical Record*, has selected a suitable case from St. Francis' Hospital, and the patient sailed on the 22d. Should the result be favorable in this instance, Mr. Arkell announces that he will erect a hospital for consumptives at Mt. MacGregor.

The thirty-fifth anniversary of the Woman's Hospital in the State of New York, was held November 19th. The report of the Medical Board, read by the Secretary, Dr. Henry D. Nioll, showed that during the year, 661 patients were treated in the hospital, of whom 220 were free patients. In the out-door department the number of cases was almost 6,000. During the year three beds have been endowed by the payment of \$5,000 for each, two of them by Mr. Jay Gould and his daughter, in memory of Mrs. Gould.

— Accompanied by physicians and others, Succi, the faster, took a horse-back ride to and across the Brooklyn Bridge, on the sixteenth day of his fast. He crossed the bridge at a sharp trot; stopping in the centre, however, long enough to have his picture taken. On this day his weight was 125 pounds, a loss of 224 pounds since he commenced his fast. His general condition is good, and his confidence unabated.

— By the will of the late Thomas C. Sloane, who was a member of the Corporation of Yale University, the Sloane Laboratory at Yale, which was founded and endowed by his brother and himself, receives a bequest of \$75,000. Of the institutions in New York to which he left money, the Presbyterian Hospital receives \$10,000, and the Hospital for the Ruptured and Crippled, \$5,000.

REPORTED MORTALITY FOR THE WEEK ENDING NOVEMBER 15, 1890.

Deaths reported 2,860; under five years of age 969: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 494; lung diseases 378; consumption 377; diphtheria and croup 171; typhus fever 101; diarrhoeal diseases 63; scarlet fever 23; measles 18; whooping-cough 13; malarial fever 14; cerebro-spinal meningitis 11.

From scarlet fever, New York 7, Philadelphia and Brooklyn 5 each, Chicago 3, Baltimore 2, St. Louis and Cambridge 1 each. From whooping-cough, New York 7, Brooklyn 4, Chicago 2, New Orleans and Salem 1 each. From malarial fever, Philadelphia 4, New York, Brooklyn and Baltimore 3 each, Charleston 1. From cerebro-spinal meningitis, Washington 3, Chicago and Lynn 2 each, New York, Brooklyn, Nashville and Worcester

1 each. From measles, New York 11, Chicago 4, Boston 2, Brooklyn 1.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,559, for the week ending November 8th, the death-rate was 20.8. Deaths reported 3,881: Acute diseases of the respiratory organs (London) 463, measles 175, diarrhea 86, scarlet fever 85, fever 74, diphtheria 73, whooping-cough 48.

The death-rates ranged from 12.7 in Brighton to 29.3 in Manchester, Birmingham 20.2, Bradford 21.8, Leeds 20.8, Leicester 15.8, Liverpool 24.1, London 20.5, Newcastle-on-Tyne 22.7, Nottingham 14.7, Sheffield 20.7.

In Edinburgh 18.5, Glasgow 23.6, Dublin 20.7.

SOCIETY NOTICES.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY. There will be a meeting of this Section, at 19 Boylston Place, on Wednesday evening, December 3d, at 8 o'clock.

Dr. Paul Thorndike will show "A Successful Case of Thiersch's Skin-Grafting."

Dr. John Homans and Dr. G. L. Walton will report "A Case of Successful Trephining for Subdural Haemorrhage produced by Contre-Coup."

Dr. E. W. Cushing will exhibit Improved Apparatus for Sterilizing Instruments and Dressings.

GEORGE H. MONKS, M.D., Secretary.

BOSTON SOCIETY FOR MEDICAL OBSERVATION. — A regular meeting of the Society will be held, at 19 Boylston Place, on Monday evening, December 1st, at 8 o'clock.

Readers: Dr. F. E. Bundy. "A Report of Two Cases of Diphtheria"; Dr. F. C. Shattuck. "Tricuspid Stenosis, with the Report of a Case and Specimen."

Business: Election of associate members; proposed change in the By-Laws.

T. F. SHERMAN, M.D., Secretary.

BOOKS AND PAMPHLETS RECEIVED.

Analgnesia in Insanity. By J. M. Keniston, M.D., Middle-town, Conn. Reprint. 1890.

Twenty-first Annual Report of the State Board of Health of Massachusetts. Boston. 1890.

Transactions of the Obstetrical Society of London. Part III, for June and July, 1890. London. 1890.

The Physician's Visiting List. (Lindsay & Blakiston's) for 1891. Philadelphia: P. Blakiston, Son & Co.

A Clinical Study of Forty-seven Cases of Paralysis Agitans. By Frederick Peterson, M.D. Reprint. 1890.

Report on the Examination of One Hundred Brains of Feeble-Minded Children. By A. W. Wilmarth, M.D. Reprint.

Causes and Treatment of Sterility in Both Sexes, and Fecundation by Artificial Method. Translated from the French.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Ninety-second Annual Session. 1890.

The Early Operation for Hare-Lip, with the Report of a Case, Illustrations, etc. By Thomas H. Manley, A.M., M.D. Reprint. 1890.

An Address on Ether-Drinking: Its Prevalence and Results. By Ernest Hart, Editor of the *British Medical Journal*. Reprint. 1890.

Saunder's Question Compendia. Essentials of Practice of Pharmacy. By Lucius E. Sayre, Ph.G. Philadelphia: W. B. Saunders. 1890.

On Double Consciousness: Experimental Psychological Studies. By Alfred Binet. Chicago: The Open Court Publishing Company. 1890.

Subjective Delusions; or, The Significance of Certain Symptoms in Mental Disease. By Joseph Draper, M.D. Brattleboro, Vt. Reprint. 1890.

The Patients' Record for the Use of Physicians and Nurses. Compiled by Agnes S. Brennan. New York and London: G. P. Putnam's Sons. 1890.

On Infectious Dyspepsia and its Rational Treatment by the Antiseptic Method. By Frank Woodbury, A.M., M.D., Philadelphi. Reprint. 1890.

The Physician's All-Required Time and Labor-Saving Account Book. Designed by William A. Seibert, M.D. Philadelphia and London: F. A. Davis.

Another Hitherto Undescribed Disease of the Ovaries. Anomalous Menstrual Bodies. By Mary A. Dixon Jones, M.D., Brooklyn. Reprint. 1890.

Index-catalogue of the Library of the Surgeon-General's Office, United States Army. Vol. XI. Washington: Government Printing Office. 1890.

Cyclopedia of the Diseases of Children, Medical and Surgical. Edited by John M. Keating, M.D. Volume IV. Philadelphia: J. B. Lippincott & Co. 1890.

Philosophy in Homeopathy. Addressed to the Medical Profession and to the General Reader. By Charles S. Mack, M.D. Chicago: Gross & Dolbridge. 1890.

Post-Mortems; What to Look for and How to Make Them. By A. H. Newth, M.D. Edited by F. W. Owen, M.D. Detroit: The Illustrated Medical Journal Co.

NOTES ON THE NON-OPERATIVE TREATMENT OF ENLARGED PROSTATE.¹

BY A. T. CAROT, A.M., M.D.

THE operative treatment of obstructive disease of the prostate has excited so much interest of late years, and the operations of prostatotomy and prostatectomy have been so earnestly advocated, that this seems a peculiarly fit time to look at the subject from another point of view, and to review the possibilities of the non-operative treatment of this disorder.

The successes obtained by the operative treatment are made familiar by abundant examples, and this important advance in surgical practice is so firmly grounded on sound mechanical principles that its future high value is sure as long as the cases so treated are properly selected.

There have been, however, mingled with these successes a considerable number of total or partial failures, which show that the obstruction cannot always be cut away, and that in some cases, even when the passage is made free, the bladder does not recover an expulsive power sufficient for the act of micturition.

The exact proportion and conditions of success and failure have not yet been determined; but there is enough uncertainty as to the result of these operations to show us that they should only be resorted to in cases in which milder measures fail to bring comfort and safety to the patient.

Modern methods have also made great improvements in the palliative treatment of hypertrophied prostate, and it is my object to present in this paper some considerations which should not be lost sight of in guiding the care of these patients, and which, though familiar to specialists, are sometimes not sufficiently borne in mind by general practitioners in whose hands the early treatment of these cases usually falls. A case properly directed from the outset will usually run a course which will keep the question of operation entirely in the background; while a failure to understand the condition at the beginning may start the patient on a mistaken course of treatment, which will bring him into a condition from which an operation offers the only hope of escape.

The general and hygienic treatment of these cases is of great importance; for a judicious arrangement of the clothing may save the patient from many surface chills with consequent attacks of congestion of the prostate. Also, in dry inland resorts, he may safely pass a summer that would have been made miserable on a damp seashore, by aggravation of his trouble. The diet and drink, too, have much to do with the irritating or non-irritating quality of the urine, and the symptoms may often be modified by the administration of medicine.

These matters are passed over here, not because they are not of great importance in the conduct of these cases, but because they are more generally understood, and it is desired to call attention now to their mechanical or surgical treatment, the correct appreciation of which is of the first importance, but in regard to which the general practitioner is not so thoroughly informed.

Guyon has divided the clinical history of enlarged

¹ Read before the Boston Society for Medical Improvement, October 27, 1890.

prostate into three periods: (1) That of congestion, affecting mainly the prostate, but also in less degree the bladder and kidneys. (2) That of partial retention of urine. (3) That of serious retention of urine, with distention of the bladder, and usually secondary changes in the kidneys.

This classification divides the cases in accordance with the mechanical condition of the bladder, and is, therefore, useful in helping us to lay out our plan of treatment; for the proper management of the bladder is the key to success in these cases.

The symptoms of the first stage are mainly due to the condition of congestion in the prostate. One of the first things the patient notices is an increased frequency of urination, which is especially marked at night or early in the morning. Guyon ascribes the increase of frequency during recumbency to the passive congestion which becomes more marked when the circulation is quieted by inaction.

Pain is not prominent in the first stage, although there may be some scalding in urination, and a dull aching or dragging sensation in the perineum, the rectum and behind the pubes is sometimes felt.

The force of the stream is diminished by the encroachment of the swollen mucous membrane on the calibre of the urethra, and by the already commencing enlargement of the gland.

The treatment of this first stage is almost wholly hygienic and medical. If the urine is irritating from too great acidity, an alkaline diuretic is indicated. In case of pain anodynes may be required. Counter-irritation to the perineum is sometimes useful, and hot applications around the pelvis will do something to relieve irritation.

In the absence of complications, and before there is any retention of urine, interference with instruments should be avoided, as it only aggravates the congestion and introduces the danger of infection.

It will sometimes not be easy to determine, from the symptoms alone, whether a case is still in the first period of the disease, or whether there is already retained urine. To decide this, it will be necessary to pass a catheter after full urination. When this is done, precautions should be taken to reduce the irritation of the catheterization to a minimum. To this end, it is well to use the catheter at the patient's home and to introduce it at night, when he will have a long rest in the horizontal position afterwards. The instrument selected should be small (No. 6 English), of soft rubber, and the utmost cleanliness should be observed in its use. Even with all care, a little irritation will sometimes be set up, but will usually subside under rest and simple remedies.

It sometimes happens, when a catheter is used carelessly or unadvisedly in the first period, that the congestion is so increased by its use as to give rise to inflammation of the neck of the bladder, with uncomfortable, sometimes serious, symptoms. When this happens, it is the more unfortunate, for it often convinces the patient, and sometimes his physician, that his bladder is unduly sensitive to the use of instruments, and that the catheter must never be used again, for fear of even more serious consequences. If then, afterwards, the disease moves on into the second or third stage of retention or distention, it is extremely hard to persuade the patient to again resort to catheterization.

As the second stage establishes itself, and the blad-

der begins to contain residual urine, the discomforts of the first stage become more pronounced. Sometimes an unsatisfied feeling is left at the end of urination, as if the bladder had not wholly freed itself. This feeling is, however, often wanting, and its absence should not put one off the track of looking for residual urine.

The frequency of urination, which during the first stage may have been most marked at night, becomes, in the second period, almost equally troublesome in the daytime. As the bladder is always partly full, it takes but a small additional quantity to distend it to its full capacity, and the calls to urinate are frequent and imperative. Sometimes, however, the bladder shows remarkable tolerance of distention, and the amount of retained urine becomes considerable before the patient is made uncomfortable by it.

The only positive means of ascertaining the condition of the bladder is by physical examination; and this should be made in every doubtful case. If the bladder is very full, it may be perceived above the pubes by palpation and percussion, but a moderate degree of retention cannot be detected in this way. During the rectal examination of the configuration of the prostate, the finger can be carried up on to the posterior bladder-wall, and by combined manipulation with the other hand over the abdomen, may determine with some accuracy the degree of distention of the bladder. The passage of the catheter is, however, the most accurate means of settling the amount of retention.

It is wise to use the same amount of care in commencing the use of the instrument in this stage as in the first. We are never certain that the kidneys have not already begun to be affected; and if they have, an undue amount of irritation of the urethra or neck of the bladder may precipitate an attack of renal congestion. Also it is of the first importance not to set up an inflammation in the prostate which may so increase the obstruction of the urethra as to wholly stop the natural passage of the water and so oblige the patient to depend on the catheter to relieve the bladder.

If residual urine is found, we shall be guided in our subsequent treatment by the amount of it. In case there is but three or four ounces of it, the catheter should be passed once a day to draw it off, preferably at night. Not infrequently it will be found that under this systematic use of the catheter the amount of residuum steadily diminishes, until finally the bladder is again capable of entirely expelling its contents. In short, the disease is moved back from the second stage to the first. When this occurs, the catheter may be dispensed with, but should be passed occasionally to make sure that the urine is not again accumulating.

If the residuum does not diminish under the regular use of the catheter once a day, the water should be drawn also in the morning after the patient is dressed; and if a residuum is found at that time too, it is well to empty the bladder in the morning as well as at night.

The time after dressing is selected for this test, because it is a common habit of these patients to pass their water several times while first moving about in the morning, so that the bladder empties itself more completely at that time than at any other part of the day. When the residual urine is in large amount (from eight to sixteen ounces), it indicates an amount of obstruction in the urethra and a loss of power in the bladder that is not likely to grow less, and that will probably require the regular use of the catheter for the rest of

the patient's life. Even in such a case as this, however, the patient should begin gradually, and accustom himself by degrees to its use.

After the catheter life is established, it is usually found sufficient to empty the bladder four times in the twenty-four hours. Three times a day, or once in eight hours will sometimes suffice, but if the least uneasiness is felt, the bladder should be emptied oftener; for a painful, forcible retention of urine after the desire to pass it is felt, occasions more irritation to a sensitive bladder than a somewhat more frequent introduction of the catheter. In order to reduce the necessary irritation of catheterization to a minimum it is important to select the proper instrument for each case, and to see that it is passed in the best manner.

When it will pass, a soft, rubber catheter is the best instrument, as it can do no harm to the urethral walls, and requiring no guidance, it can be entrusted to an unskillful patient. A small size is the best, unless the urine contains thick mucus that will not flow easily.

If the soft rubber catheter will not pass, we must use a stiffer instrument. Sometimes a French bougie-pointed catheter will succeed in such a case, and it, too, has the advantage that its introduction does not require skilled guidance. It is stiff enough, however, to perforate the urethral wall if pushed with force against an obstruction, danger which the patient should fully understand, and should have the intelligence to avoid. The other instruments that are used for these cases are given particular shapes to avoid the pockets and projections which obstruct the passage.

In the old patients from which these cases are drawn the urethra is a comparatively lax tube as compared with the condition in younger men. The firmness of the urethral walls is largely dependent upon the support of the muscles that surround it, notably of the accelerator urine muscle. As the muscular fibre relaxes with old age, the walls of the urethra offer less support and guidance to instruments. The first point where the lack of support is felt is in the bulbous portion, in front of the triangular ligament. As the urethra passes through this fibrous sheet, its walls are held up and kept in a constant relation with the arch of the pubes, while just in front of this opening the bulbous urethra, when it lacks the support of the muscle surrounding it, sags down and forms a pocket. This pocket being situated on the lower side, just where the passage turns upward towards the bladder, is almost certain to catch the point of any straight instrument. If a soft catheter catches there, a French bougie catheter is even more likely to, as it is somewhat stiffer, and follows the floor of the passage even more closely in turning the corner below the pubes. Just in front of the prostate the same mechanism is likely to form a similar pocket.

After entering the prostate, the lateral walls of the urethra may be pressed snugly together, and so resist the passage of a soft, pliable instrument; but the only obstruction that is likely to catch the point of the instrument is the third lobe, which, when enlarged, projects from the floor of the canal, either as a prominent tumor or as a bar.

Thus we see that all of the obstructions likely to resist the passage of an instrument are on the floor of the passage; and in order to avoid catching an instrument on them, its point must be made to run along the roof of the canal.

The *coudé* catheter of Mercier is a familiar instru-

ment constructed for this purpose, and when properly managed, and passed so that its point is directed upwards, it rides over the obstructions described above most admirably, and can be successfully used by patients of moderate intelligence.

There is one criticism that I should like to make on these instruments, as at present furnished, and that is that the turned-up end is not long enough to ride over many of the obstructions that exist on the floor of the passage. The end should be, at least, three-fourths of an inch in length; and, as I have often proved, an instrument with such an end will frequently succeed in passing when one with the shorter beak now furnished has failed.

Lastly, we come to speak of stiff instruments, which require especial guidance, and to which various forms have been given.

This subject is so thoroughly treated of in the books that there is little that is new about it; but it is worth while to emphasize the importance of avoiding the pitfalls on the floor of the urethra in their introduction. The pressure of the hand in the perineum as the triangular ligament is being passed, and of the finger in the rectum as the point rides into the prostate, will often make easy what would otherwise be almost impossible. And it is well to know that this pressure must often be very great indeed to accomplish its object.

If the catheter is going right in one of these cases, it slips along with ease, and if it is caught and will not advance, it may be concluded that it is not rightly following the canal.

If false passages already exist in the urethra, it is a good plan when the point is caught to always withdraw for a considerable distance and then to try forward first on one wall of the passage and then on another, always remembering that in the majority of cases the false passage is on the floor.

We must expect in a certain number of cases to see a cystitis develop on commencing catheterization. This may be due either to the too sudden emptying of a distended bladder, or to the introduction of dirt upon the catheter, or to the irritation from the constant use of the instrument. Usually the cystitis due to this cause can be kept within moderate bounds and presently subsides as the bladder and urethra become accustomed to the changed conditions.

It is important that the aggravation of symptoms caused by this inflammatory onset, shall not lead the patient or doctor to infer that the catheter is doing harm and should be given up. It should, however, lead to a careful consideration of the method in which the catheter is being used, and extra care should be taken to see that the instrument is not causing any irritation.

Sometimes in spite of all care, attacks of inflammation of the prostatic urethra and bladder arise, and give much trouble. The urine becomes thick with muco-pus, and there may be considerable haematuria. The frequency of urination under these circumstances becomes very troublesome, and often accompanied by much painful spasm of the bladder.

When this condition of things becomes established, especially in a patient who cannot void his urine, and who therefore is constantly suffering from spasm, something must evidently be done to give the bladder a rest.

It is under these circumstances that an operation for

bladder drainage, and for the removal of obstructing portions of the prostate is often undertaken, and would seem to be proper. There is, however, another means of draining and affording rest to the bladder which is very efficient, and is much less dangerous than any operation. It is by fastening a catheter into the bladder (*sonde à demeure*). It is often surprising to see how quickly and entirely one of these sharp attacks of cystitis with bladder tenesmus is relieved by the continuous drainage through a catheter. The urine often clears with surprising rapidity.

The siphonage which is obtained by carrying the urine through a rubber tube into a bottle on the floor, is a valuable aid to keeping the bladder really empty, and forcibly sucks out clots of mucus and blood, that would certainly stop up a catheter that only dropped into a vessel between the thighs.

It is important, in adjusting the catheter, to so fasten it that the point shall neither press into the posterior wall of the bladder, nor escape into the prostate. Four threads fastened to the catheter, and then attached to a band of adhesive plaster about the penis is a common and tolerably efficient way of fastening it. The disadvantage of this method, however, lies in the fact that the penis is a movable organ, and sometimes allows the catheter to come so far out of the bladder that its point catches in the prostate.

A safer method is to fasten the threads to a ring of rubber tubing that encircles the penis and scrotum, and is held in place by being fastened in front to a waist-band, and behind by two perineal bands carried around in the folds of the nates, and brought up to the waist-band on the sides. This fastening holds the ring of rubber firmly down against the pubes, and if the catheter is then secured to the ring, it is held in constant relations to the pubes and bladder, no matter what changes of position the penis may undergo. It should be fastened as before by four threads, two of which are attached to the ring well towards the back to prevent the catheter riding up.

The catheter usually used for this purpose is the English gum elastic catheter, which soon gets soft and pliable throughout all that part of it that is in the urethra, but of which the outer part retains its stiffness sufficiently to prevent its doubling up, and so coming out.

A soft rubber catheter may be fastened in by attaching to it strips of adhesive plaster, which run back over the penis, and are held there by an encircling band of plaster. These plasters must be attached to the catheter close down to the meatus, as otherwise the catheter will work out of the urethra beside them. In fact, if there is much expulsive power in the urethra, it will often expel the soft, flexible catheter in spite of the most carefully arranged fastening.

When a catheter is properly arranged there should be a steady drip of urine from the tube, and if this ceases for more than a few minutes, the cause of the stoppage should be investigated. It will usually be found due to one of three causes, either the catheter is too far in, or it is too far out, or it is stopped by a plug of blood or mucus.

If moving it in and out does not start the stream, the tube may be stripped with the fingers so as to empty it of air, and it will then act by suction to draw the clot along. If this does not succeed, the catheter may be washed out with a syringe.

The catheter should be taken out and a clean one

introduced every four to six days, as in a longer time it becomes encrusted with the salts of the urine, and acts as an irritant.

Ordinarily, such drainage as this soon relieves the symptoms, and it can be discontinued, and ordinary catheterization resumed in from a week to a fortnight. If relief does not follow, it is probable that there is some undiscovered cause of the continuance of the trouble, perhaps a stone, or pyelitis.

The third stage of the disease always comes on insidiously. The tolerance of the bladder is so great that it becomes greatly distended without the patient being aware of anything more than a frequency of urination which he knows to be common in old men, and therefore neglects. Finally, it is often the incontinence which results from overflow that leads him to consult a surgeon. Long before this, however, the kidneys have usually begun to suffer serious changes. There is almost always an interstitial nephritis, which may or may not be associated with dilated ureters and pelvis. Not infrequently the secondary heart changes of Bright's disease may be discovered. When this condition is found thoroughly established the surgeon has a difficult problem to solve, for he knows that if left to itself the disease must soon prove fatal, and he has also great reason to fear that any interference may only precipitate the fatal result. Guyon has laid down a rule, for deciding whether to interfere in these cases, that is a practical one. He says, that such patients, who are almost always suffering from general debility usually associated with a disturbed digestion should be put upon a tonic course of treatment, and if they respond and improve under this, that it shows a sufficient power of recuperation to make it advisable to use the catheter, and to endeavor to better the condition of the bladder. If they do not improve under general treatment he advises letting the bladder alone.

When it is decided to interfere in such cases, it is even more important than in the second stage to take care that the bladder is not emptied too abruptly.

The patient should be put to bed, and but a portion of the contents of the bladder should be drawn off at a time. It may take a week or more to gradually reduce the amount of residuum to the point where it will be safe to empty the bladder.

If, before the patient is accustomed to the use of the instrument an attack of inflammation sets in, there is great danger that it will extend up along the ureters and set up a pyelo-nephritis.

This backward extension of the inflammation may possibly be prevented by establishing thorough drainage of the bladder, so that the urine shall flow out of it as fast as it comes down from the kidneys. This may be accomplished either by cystotomy, or by a permanent catheter. The patients with partly disabled kidneys do not bear cutting operations well, and the catheter drainage, if it works well would, therefore, be preferable in these cases.

— In a late number of *La Lyon Médicale*, attention is drawn to an article by Dr. Filatoff, of Moscow, showing that heliotrope can be substituted with advantage for quinine. The plant, it is stated, has for some time been in use as a popular remedy against fevers in Russia, in Turkey and in Persia. In each of these countries a tincture is prepared by macerating in alcohol the leaves and stalks of the plant.

TWO CASES OF PREGNANCY COMPLICATED WITH TUMORS.¹

SERVICE OF DR. E. H. BRADFORD, *Boston City Hospital.*

BY JAMES R. CHADWICK, M.D.

ON January 22, 1890, Dr. Bradford invited me to visit the City Hospital and examine two patients whose diagnosis had been the subject of much discussion and varied opinions. I did so; and after careful examination, had to confess with chagrin that in neither instance could I clear up the doubts. I was not contented, however, but returned the next day and succeeded in eliciting data for diagnosis which in both cases subsequently proved correct. As the cases were both grave and peculiarly complicated I have secured Dr. Bradford's permission to report them to this Society, making use of the hospital records.

I. PREGNANCY AT THE EIGHTH WEEK COMPLICATED WITH MULTIPLE FIBROIDS OF THE UTERUS.

Mrs. McK., thirty-four years of age, entered the hospital January 17, 1890, having been married but a few months. Menstruation had always been regular until two months before when it had ceased. Nausea and vomiting had been most marked mornings. The breasts had been growing larger. For two weeks almost nothing had passed the bowels; attempts at defecation had caused pain in the suprapubic region and down the thighs. Micturition had been difficult.

Examination showed the pelvis to be filled with a hard, rounded mass (like the fetal head at full term) rising into the abdomen above the navel, its upper surface being irregularly lobulated; low down to the left was a specially prominent nodule, yet firmly connected with the main mass. Both flanks were tympanitic. Per vaginam the cervix could just be reached by the finger, it was anterior to the pelvic tumor above the pubes and a little to the left of the median line.

The rational signs pointed exclusively to pregnancy; the physical, exclusively to fibroids of the uterus. Were both groups of signs correct, or was one misleading? I elicited the additional facts that she had been conscious of a lump in the lower abdomen for a long time, and had observed a decided increase in its size during the last two to four weeks; also, that constipation, which had been habitual, was so increased of late, as to amount almost to obstruction of the bowels. From these and the previous data I argued that multiple fibroids had existed for a long time, but that the recent growth was too rapid to be explained on any other assumption than that pregnancy had supervened. This reasoning reconciled the diverse signs, and led to a diagnosis of multiple fibroids complicated with pregnancy at the second month. As the fibroid in the pelvis already obstructed the bowels, and could not be dislodged, and presented an insuperable obstacle to the passage of a child later, immediate relief by operation was unmistakably demanded. Laparotomy was accordingly done by Dr. Bradford on January 27th, by a median incision of the abdominal wall. The fibroid mass in the pelvis was only extracted after many efforts at traction from above combined with pressure from the vagina. A clamp was put about the supravaginal cervix, and the mass of uterine body and fibroid tumors removed. The stump was treated extra-peritoneally.

¹ Reported at the meeting of the Obstetrical Society of Boston on June 14, 1890.

The pain after operation was incessant, requiring much morphine. The vomiting was persistent; nutritive enemata were ejected after the third day. The bowels were not moved. The dressing was changed twice, when the wound was found aseptic. She died on February 4th (eighth day) of peritonitis.

An examination of the mass removed showed a six to eight weeks' ovum in the cavity of the womb.

Exploration of the abdominal cavity after death showed the wound to be clean, but just above the stump was a mass of intestines bound together by delicate fibrous adhesions. There was no pus.

II. PREGNANCY AT FIVE OR SIX MONTHS, COMPLICATED WITH AN OVARIAN CYST.

Mrs. K. L., entered the ward January 23, 1890. She had had three children, the youngest being fifteen months, and still being nursed. The patient had menstruated once six months before, but not since. The abdomen had always been large, but had increased greatly in the past five weeks. There had been no subjective symptoms.

On examination the abdomen was found to be enlarged to the size of pregnancy at full term. By palpation and percussion a soft tumor was recognized, rising from the pelvis and filling nearly the whole abdomen. A transverse sulcus could be made out three inches above the umbilicus, above which fluctuation could be detected, but not below. Just above the pubes on the left side, the mass was more resistant, and at that point a distinct *bruit* could be heard.

The vagina was moist and soft; at its entrance I recognized the sign of pregnancy to which I have so often called attention as having great value when present, the bluish discoloration. While this sign alone I regarded as sufficiently characteristic to warrant the diagnosis of pregnancy, it was confirmed at my second visit by feeling ballottement of the fetal head.

Her distension was already so great as to threaten serious results if pregnancy were allowed to go to full term. Under these conditions Dr. Bradford made a median incision of the abdominal wall on February 4th, and removed a bilocular ovarian cyst, severing some slight adhesions to the uterus and intestines. Pregnancy existed at the fifth or sixth month. The patient made a good recovery, without requiring any opium.

On the fourth day after operation the patient was delighted to feel fetal movements. The abdominal incision healed by first intention. On the thirteenth day the patient sat up, and on the nineteenth day made her own bed, without permission. On February 27 (twenty-second day) the patient was discharged from the hospital.

The former of these cases illustrates the importance of recognizing the sudden, rapid growth of fibroids as occurring only under the stimulus of pregnancy; and the other, the value of the blue discoloration of pregnancy; to both of which points I have drawn attention in previous papers.

— A dentist was recently tried for manslaughter in Switzerland, a patient of his, a young girl, having died after an injection of cocaine into her gum. The court held that it was not proved that the administration of cocaine was the cause of death. The defendant was, however, fined fifteen francs for the illegal practice of medicine, cocaine being an anesthetic which should be administered only by a qualified physician.

RECENT PROGRESS IN OPHTHALMOLOGY.

BY MYLES STANDISH, M.D.

OCULAR DISEASES FOLLOWING THE INFLUENZA.

FUCHS¹ reports four cases of tenonitis, that is, inflammation of Tenon's capsule with exudation into the space which separates it from the eyeball, following the influenza.

In the first case the conjunctiva was injected, edematous, and thickened; upwards and outwards from the cornea, it presented a loss of substance laying bare the sclera; a similar gap was present below the cornea, about over the anterior limit of Tenon's capsule. Purulent secretions escaped from both these openings. There was pus in the anterior chamber; the pupil was small and adherent; tension was reduced and light perception lost. The patient suffered also from catarrhal pneumonia. Pneumococci were found in the pus which escaped from Tenon's space; mice inoculated with the pus died of septicemia, and from them again cultivations of the cocci were obtained.

In the other three cases, the symptoms suggested a retrobulbar abscess, and in one an incision was made through the upper lid deeply into the orbit, but in all three cases the exophthalmus subsided in a few days, and at the end of two weeks the eyes were quite normal.

In the latter three cases, as there was no perforation or pus, it must be taken for a fact that the process was not suppurative, but serous or plastic. The great edema of the conjunctiva as compared with the moderate exophthalmus, the extreme impairment of the movements of the globe and the absence of changes at the optic disc, point to Tenon's space as the situation of the inflammatory exudation.

Primary tenonitis is rare. It may be purulent or non-purulent. Purulent may follow the use of unclean instruments in an operation for squint. The cause of the non-purulent variety is obscure. In many cases it is attributed to a cold.

Fuchs suspected that the cause was the influenza, because his cases all came under treatment within fourteen days, and before that time in a very large clinic, he had met with only one well-marked case.

Landolt² says that the most frequent ocular complication observed by him during the recent epidemic, was a special form of conjunctivitis, which came on usually during convalescence. Both the ocular and palpebral conjunctiva were affected and the episcleral tissue in many cases participated in the inflammation, the affection being in truth more an episcleritis than a conjunctivitis.

Fage³ records thirty-two cases in which the eye or its appendages were affected in connection with influenza. Most of the cases recorded, were ordinary varieties of conjunctivitis or corneal ulcers and paralyses of the recti muscles. He reports one case of amblyopia without ophthalmoscopic change.

ASTIGMATISM FOLLOWING CATARACT OPERATIONS.

Burnett⁴ says that the regular astigmatism following cataract extraction is not considered of sufficient importance by most operators, to be taken into account in the fitting of glasses in routine cases. The vision

¹ Wiener Klin. Wochenschrift, 1890, No. 11.

² Schweiz. Med. Wochenschr., 1890, No. 3, Ophthalmic Review, July, 1890.

⁴ American Journal of Ophthalmology, December, 1889.

of the majority of those operated on for cataract, does not exceed $5/18$, but as this is usually sufficient for the needs of ordinary life, there is a feeling of satisfaction and content on the part of both surgeon and patient, and no effort is made to secure anything better than can be had with spherical lenses alone.

Our author states that his ophthalmometric measurements agree with those of all other investigators, in showing that the astigmatism of a healthy cornea has its greatest refraction in the vertical meridian (axis horizontal). His examination of the cornea of the eyes which have been operated on for cataract agree with those made by Scimeni, in showing the meridian of greatest refraction to be the horizontal (axis vertical) or approaching it. As the incision in cataract extraction lies either upward or downward, the inference is that the manner in which the wound heals has something to do in bringing about this change.

Weiss⁴ supposed this to be due to a failure in exact coaptation of the wound, the lip of the flap coming forward in advance of the scleral edge of the incision. Scimeni, however, has shown by calculation, that in the larger number of cases, the great amount of astigmatism found could not be produced in this manner, since it would necessitate such an advance of the flap as to remove its inner edge beyond the outer edge of the scleral lip of the wound. Such a condition, however, undoubtedly does cause some of the astigmatism by increasing the radius of curvature in the vertical meridian, but does not produce it all. Burnett, as well as Scimeni, has found that there is nearly always associated with the diminution of refraction in the vertical meridian, an increase in the refraction in the horizontal.

Scimeni accounts for the phenomena by a contraction of the recti muscles, causing a gaping of the wound and a separation of its edges, and not simply by a sliding of the anterior lip forward as advocated by Weiss. Such a gaping of the wound would undoubtedly produce the phenomena observed, but whether this gaping is caused by a contraction of the recti muscles or by pressure of the lids, or by some fault in the incision itself, or by all three, Burnett still considers an open question. That this astigmatism should be more considered in ordering glasses than it is at present, is undoubtedly true, but the astigmatic corrections should be delayed for several months after the operation.

It has not yet been determined that one method of extraction has any advantage over another, in lessening the tendency to change in the form of the cornea, for those cases where extraction is made without iridectomy are as frequently attended with astigmatism as when it is made with iridectomy.

PERIPHERIC COLOR-SENSE.

Carl Hess⁵ under the guidance of Professor Hering in the Physiological Laboratory at Prague, has investigated once more the color-sense of the periphery of the retina, and some of the results obtained are an important addition to our knowledge of the subject.

Discs, three centimetres in diameter, were cut from various colored papers of dull surface, and viewed against a uniform white or black background. The observer's eye fixed the central point of the background, while an assistant moved a colored disc, in a radial di-

rection, either towards or away from the fixation point. Whatever the real color of the disc, it appeared, when it first entered the periphery of the field, to be colorless — white if the background were black, gray or black if the background were white. When moved a little nearer to the fixation point, it appeared in nearly all cases to be either blue or yellow. Each disc was withdrawn as soon as the blue or yellow appearance was perceived and all the discs thus employed placed in two groups, according to whether they appeared blue or yellow. The blue group was found to contain all the following colors: bluish-green, blue-green, blue, violet, bluish-red, and rose-red. The yellow group contained the following: spectrum-red, orange, yellow, green-yellow, and all the yellowish-greens.

When, in the same manner as before, a colored disc was moved towards the fixation point rather further than before, the initial appearance of blue or yellow changed, and tended toward red or green, according to the nature of the color employed. Grouping the discs as they appeared to tend towards red or green, the red group contained reddish-yellow, orange, yellowish-red, red, bluish-red, violet, reddish-blue, and rose; while the green group contained greenish-yellow, yellow-green, green, bluish-green, blue-green, and greenish-blue.

Reversing the experiment, the discs were moved from the centre toward the periphery of the field. Each disc, whatever its actual color, appeared in nearly all cases to lose this color and to become either pure blue or pure yellow, before it ultimately became colorless. For example, two similar violet discs could be so placed, one nearer to the fixation point than the other, that the one appeared in its true color, the other pure blue.

To this rule there are four exceptions. Pure blue and pure yellow undergo no apparent change except a loss of saturation; pure green and a certain red (not spectrum-red) do not, like all other greens and reds, appear to change into blue or yellow, but appear in their true colors up to the point at which they appear colorless.

It is possible, then, to find four colors, a blue, a yellow, a red, a green, which in indirect vision change only in saturation, not in color. They correspond to the four fundamental color-perceptions of Hering. The retina affords the means of determining them in a purely experimental manner, which is independent of all theories. They are, in themselves, definite and constant, but this does not imply that in successive experiments, conducted under varying conditions, precisely the same colors would be selected, for it would depend much on the nature of the illumination and upon the condition of the retina whether slight variations of color were perceived or not. Further, it must be noted that in conducting such experiments, it is important to exclude the region of the macula lutea, for the excess of retinal pigment in this region causes chromatic absorption and modifies color perception. Where great accuracy is required, therefore, only the extra-macular portion of the retina, that is, the part which lies more than about eight degrees from the fixation point, must be employed.

For the purpose of such comparison, it is necessary to employ colors which have the same white-value and the same color-value — that is to say, which excite color-perception with equal intensity. Two colors have the same white-value when in indirect vision they

⁴ Annali di Ottal. Anno xviii, fasc. 4, 5, 1889.

⁵ Von Graefe's Archives, vol. xxxv, part iv, p. 1.

both become invisible against the same gray background. They have the same color-value when their mixture, in equal quantities, appears colorless to the color-seeing zone of the retina. Experiment has shown that when a red and green disc of equal size, and of equal white- and color-values, are moved along the same radius of the visual field, they become colorless at the same distance from the fixation point. The same is true of the unchanging blue and the unchanging yellow.

EXAMINATION OF THE FIELD OF VISION.

Bjerrum⁷ proposes, what he considers, a useful addition to the useful method of examining the field of vision. The addition consists simply of making use of white objects which subtend a very small visual angle. The test objects generally employed in perimetric measurements are from one to two centimetres in diameter, which, at a distance of thirty centimetres, the radius of the perimeter arc, correspond to a visual angle of from two degrees to four degrees. Their images must therefore cover many thousands of retinal elements, so that the test is far from being a fine one, and nothing at all comparable to the tests made for direct vision. In order to be able to work without difficulty with small visual angles it is necessary to move the patient away some distance from the plane in which the test-objects lie. Bjerrum has generally made these examinations at a distance of two metres, using a large black screen which can be let down from the ceiling to the floor, and which is placed on the wall opposite the space between two windows, so as to get good light all round. The screen has, of course, to be pretty large (two metres in breadth), as at the distance of a couple of metres the blind spot, instead of measuring about an inch, as on an ordinary perimeter, measures seven inches in diameter; and everything else is in the same proportion. A screen two metres in diameter will admit of testing up to about twenty-seven degrees from the point of fixation, if that be in the middle of the screen; to about fifty-four degrees if it be at the edge.

PROPER ILLUMINATION FOR RETINOSCOPY.

Jackson⁸ in an article upon "Retinal Illumination for the Shadow-Test," says that the incandescent electric light does nicely for the measurement of simple myopia or hyperopia, but its shape quite unfit it for the detection of astigmatism, and that the best light is had by a circular flame, as in the Argand burner, "student lamp," or "duplex" burner for oil lamps. To get the sharpest boundary between light and shade, the source of light must have a sharp boundary; and the rays from it be focused upon the retina. The margin of any flame is somewhat nebulous, there is a somewhat gradual transition from light to darkness, and on this account, it is better to have recourse to the opaque metal chimney, for it shuts off this nebulous margin and gives a sharp boundary to the source of light. If the opening through which the light proceeds is made circular, its shape is more favorable than that of a flame for the detection of astigmatism.

While it would be desirable to have the source of light reduced to a single point, it is not practicable because: first, a single point, unless it be of the electric arc, would not give as much light as is required.

⁷ Nordisk Ophthal. Tidsskrift, II, 3, Ophthalmic Review, April, 1890.

⁸ Ophthalmic Review, February, 1890.

Second, if the source of light be smaller than the sight-hole of the mirror, it will disappear in it every time the mirror is rotated, causing great annoyance and uncertainty. It is this matter of the sight-hole that really limits the exactness possible with the shadow-test. The size of the aperture for the source of light, which has proved most satisfactory to the writer, is a circle eight or ten millimetres in diameter to be cut from the metal chimney at such a height as to come opposite the brightest part of the flame. The sight-hole in the mirror is three or four millimetres in diameter.

INTRAOCULAR EXAMINATION WITHOUT AN OPHTHALMOSCOPE.

Koller⁹ writes of a device for the intraocular examination of the eye without the use of an ophthalmoscope.

It is an old and well-known experiment that the fundus of an eye becomes visible without any further apparatus when the eye is placed under water, and, provided the pupil is large enough, one sees the optic disc and the retinal blood-vessels clearly defined in about their natural size. The reason for this is, that the exterior surface of the cornea, the most active part in the whole dioptric system, no longer borders on the air; but is surrounded by water, which has the same index of refraction as the corneal substance, and, therefore, eliminates the cornea in an optical sense.

Several years ago Bellarmainoff advocated the examination of the fundus by the following method: He anesthetized the cornea with cocaine, and dilating the pupil, pressed a plain glass plate against the cornea, thus flattening it and eliminating its optical action.

Koller's method is simply a modification of Bellarmainoff's. He had glass shells made similar to artificial eyes with the plain surface on the outside. Such a shell is easily inserted into the conjunctival sac in front of the eye, previously anesthetized by cocaine, and is so nicely kept in place by the lids that it is unnecessary to press the glass plate against the cornea. The pupil is previously dilated with homatropine. If the conditions are favorable, that is, if the anterior plane surface is moistened with a drop of water and strong light, either the light of a white cloud or an artificial light, is thrown into the eye by means of a reflector, the optic disc and retinal muscles appear with great clearness. The small size of the vessels presents a striking and unexpected appearance, as they are seen only their actual size, instead of being magnified as we are accustomed to see them in the ordinary method of examination. The large area seen by this method is somewhat remarkable.

Koller suggests that this device may have some possible practical value in determining the location of echinocci, foreign bodies, or membranes in the vitreous.

He thinks that elimination of the cornea will probably allow a better view, and more natural conception concerning the extent and situation of such membranes.

OPERATION FOR MEMBRANES IN THE VITREOUS.

Bull,¹⁰ in an article upon "The Surgical Treatment of Fixed Membranous Opacities in the Vitreous," reports a series of twelve cases, which, in addition to seventeen cases reported by the author in 1888, make twenty-nine in all, in which the membrane was lac-

⁹ American Journal of Ophthalmology, July, 1890.

¹⁰ Ophthalmic Review, June, 1890.

erated by a knife or needle thrust through the sclera between the external and inferior recti muscles, just in front of the equatorial region, parallel to the plane of the iris, and behind the lens. In many cases no fixation forceps were employed to rotate or steady the eyeball, and no loss of vitreous occurred through the small opening in the conjunctiva. Little or no reaction followed, save in exceptional cases; and the application of a protective bandage, and the instillation of atropia, were needed but for a few days.

The facility and thoroughness with which laceration may be done, depend largely upon the position of the membrane in the vitreous. If the membrane is far back, it is more easily reached in the proposed operation.

In regard to the improvement of vision, our author states that laceration of a membrane in the middle or posterior parts of the vitreous always, or nearly always, promises improvement of the sight, if no serious lesion of the fundus is present. If the membrane runs fore and aft in the vitreous, and especially if it is attached anteriorly to the posterior lens capsule, the chances of improving the vision are comparatively slight, though even in such cases, the writer has seen decided improvement in vision following the operation, especially in eccentric vision.

EVISERATION OF THE EYEBALL.

Prince,¹¹ in an article upon "Evisceration of the Contents of the Globe," states that he early found that the pain was more prolonged and severe than in enucleation, and that the healing was more protracted. He thought the pain due to the effects of pressure and inflammatory irritation on the long ciliary nerves left exposed by the operation, as they run forward in grooves on the concave surface of the sclera. He, therefore, was led, at the completion of the operation, to cauterize the whole interior of the sclera with pure carbolic acid. The use of carbolic, in this way, seems indicated both for its antiseptic and anesthetic powers.

It closes the tissues subjected to it against the adhesion of micro-organisms; and it destroys the power of the sensory nerves to give rise to pain.

He advocates packing the scleral cavity with powdered iodoform. After some weeks the mass of iodoform is expelled; but there seems to be some gain in the final stump. In none of the cases packed with iodoform was there subsequent suppuration.

THE ANILINE VIOLETS AS ANTISEPTICS.

Stilling¹² reports several cases of hypopyon-keratitis with deep marginal ulceration of the cornea, in which the healing took place under methyl-violet and auramine so rapidly that he predicts that this treatment will soon replace actual cautery in these affections. He saw immediate improvement in a case of sympathetic ophthalmia in a boy when the aniline solution (1 to 1000) was dropped in the eye.

Stilling explains the powerlessness of the antiseptics hitherto in use to arrest suppuration which has once begun by the fact that they readily form precipitates, and are not diffusible. Some aniline colors, and particularly the violets, possess, according to Stilling, all the properties of a good antiseptic, as they not only readily kill micro-organisms, but quickly permeate the tissues in which suppuration has taken place. The result of bacteriological experiments, made in conjunc-

tion with Wortmann, was to show that aniline violets retard the development of bacteria, even in such feeble solutions as 1 to 64000. More concentrated solutions (1 to 1000 and 1 to 2000) were found to kill at once the bacteria which might be present, and altogether prevent their further appearance.

Berry¹³ says, in reviewing the above paper: "A therapeutic agent which is brought to one's notice with such a flourish of trumpets must, one would imagine, possess some of the advantages claimed for it. It is hardly likely that others will be able to confirm Professor Stilling's report in all particulars, even although they should hold the same views as to the micro-organismal character of the various inflammations met with in the eye. From some personal experiences of methyl-violet in the solution of 1 to 2000, I can confirm its non-irritating nature and its diffusibility; but I have not seen that it has any power in checking suppuration at all, and, indeed, its antiseptic properties seem to me to be but slight."

Clinical Department.

SUDDEN DEATH PROBABLY FROM ÖDEMA OF THE GLOTTIS.¹⁴

BY FRANCIS MINOT, M.D.

THE patient was a lad, seventeen years old, who had always enjoyed good health.

On Monday, October 20th, he complained of pain in swallowing, and was first seen by Dr. Minot on Tuesday afternoon. He was in bed; pulse, 100; breathing perfectly quiet and natural. His only complaint was difficulty in swallowing, from pain. The voice was thick, as if from inflammation of the tonsil. In fact, the left tonsil was swollen, and could be felt from the outside. The palate and fauces were somewhat redder than usual. There was no deposit or membrane to be seen on either tonsil, or on any other part of the mouth or fauces. The temperature at 6 P. M. was 101.8°.

On Wednesday morning, October 22d, the pulse was 84, temperature 100.6°. His sleep had been disturbed by the pain in swallowing, but he felt much better. No exudation could be seen. A puncture was made in the swollen tonsil, but no pus was reached. There was moderate bleeding from the incision, which appeared to afford relief. No fetor of the breath could be perceived. The breathing was perfectly free. He continued to improve in his general condition during the day, and towards evening he got up, of his own accord, dressed, and went down to dinner with the family. He was able to swallow two tumblers of milk, and was in the best of spirits. After dinner, went up to his bed-room without the least difficulty. When seen afterwards by Dr. Minot his pulse was 76, temperature 100.8°. He was very cheerful, and said he felt much better. After going to bed he slept quietly for an hour and a half, and then awoke suddenly with a feeling of suffocation. He went to the bath-room, adjoining, gurgled his throat, and returned to bed. He had hardly lain down before he expired.

A digital examination of the mouth and fauces was made soon after death, but nothing abnormal was dis-

¹³ Read before the Boston Society for Medical Improvement, October 27, 1890.

¹⁴ Ophthalmic Review, July, 1890.

covered beyond the swollen condition of the left tonsil. There was no autopsy.

The death was evidently caused by some sudden obstruction to the breathing at or near the glottis. It is possible that the case was one of diphtheria, in which the exudation was confined to the larynx, a fragment of the membrane having become detached and arrested at the glottis; but there had been no special symptom of diphtheria, and not the slightest difficulty of breathing until just before death.

A more probable explanation of the sudden death would be œdema of the glottis, the result of extension of the pharyngitis to its immediate neighborhood.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, October 27, 1890,
DR. W. L. RICHARDSON in the chair.

ANATOMICAL SPECIMENS.

DR. A. T. CABOT showed a calculus removed from the ureter of a woman through the vagina, and also read a paper on

THE NON-OPERATIVE TREATMENT OF ENLARGED PROSTATE.¹

DR. F. S. WATSON: There are several things which I would like to speak of in this connection. The large majority of cases which come under one's observation require the non-operative, rather than the operative, treatment, and they form far the more important class of the two. The question as to when to use the catheter, to institute catheter life, is one which I think comes most prominently as the first and most important question. As a rule one has not the choice, for the reason that the patient generally does not seek relief until the symptoms have become very decidedly annoying, and then interference is almost always required. I do not know that an absolute rule can be laid down as to the amount of residual urine which should determine the use of the catheter. The plan which I think a fair one to act upon is that when the residual urine exceeds two ounces, and the patient is suffering from more than one or two calls during the night to urinate, that the catheter should be used, and, if it works well, continued. The quality of the urine is another factor in deciding whether the catheter should be used. Where the urine is clear, and there is no special irritability, and the amount does not exceed more than two or three ounces, then it is safe, with occasional testing to see that it is not increasing, to leave that bladder alone, as a rule, as far as the catheter is concerned. Where, however, there is pus or mucus or blood, the necessity of catheterization is much greater. In regard to the passage of the catheter, there is one little point which is often noticed by the surgeon, and that is that the patient will frequently be able to pass the catheter in one position more easily than in another. One patient passes it more easily lying down, another sitting on the edge of a chair, another standing up; and sometimes the difficulty may be entirely overcome, if there is a slight obstruction to the

passage of the catheter, by change of position. I am very glad Dr. Cabot accentuated the precaution in regard to the beginning of catheter life, with reference to the care with which it should be surrounded, because in spite of all the warnings uttered on this subject, I do not think that that is borne in mind sufficiently. I cannot help thinking that it is a frequent practice, especially away from large medical centres, for the practitioner to keep a silver catheter knocking about in his case, and when a patient comes in with retention, in the most dangerous stage of prostatic enlargement, he takes it out of the drawer, pushes it into the bladder, and empties the whole bladder at once. That I do not think can be too strongly condemned. As Dr. Cabot says, the soft rubber catheter, when possible to use it, should be used. The cleanliness of instruments is another problem which is very difficult, and one very often neglected. The plan I have adopted is to keep the red rubber catheters in carbolic acid, in which they can be kept for years without becoming brittle. I instruct the patient to get one of these tubes in which to keep the catheter. The catheter is washed with warm water before and after using, in order that the carbolic acid may not be too irritating. The form of catheter, which is the one that I think, as a general rule, will pass in more cases where there is a difficulty than any other, is the *coudé* catheter of Mercier. The elbow of this instrument can be made longer than it is by using the stylet of Guyon, which can also be introduced into the catheter in such a way as to make it into a *bicoudé* or double-elbowed catheter. These two forms of catheters, the *coudé* and *bicoudé*, I think will pass in the difficult cases, as no other forms of catheters will. I have never had to use the silver instrument, and I don't believe I ever shall use one. Except in trained hands they are exceedingly dangerous, and are responsible for many false passages. As to the frequency of the use of the catheter once its use has been begun. That, of course, must be determined by circumstances. If the patient has a very irritable bladder, in spite of the daily passage of the instrument, there is no harm in the nature of things in passing the catheter more often. Where no urine can be passed spontaneously, it is well to imitate the frequency of the natural calls to urinate, using the catheter once in three or four hours. It may prove to be harmful, and if it does, other means must be considered, as, for example, drainage of the bladder, cystostomies, etc., that is if the case goes on from bad to worse. The character of the urine as indicating renal incompetence is of the utmost importance, and it is the danger signal in these cases. Low specific gravity and the neutrality of the urine are pretty sure indications that the person with enlarged prostate has damaged kidneys, and that you are going to have trouble ahead. The dangerous class of cases are those that come with overfilling bladders, where there is incompetence of the bladder, the patient coming in that way to the surgeon for the first time. He is almost sure to have damaged kidneys, and whether you catheterize or don't, he is probably going to die. If you catheterize, catheterization gets the blame. A suggestion which Mr. Harrison made is valuable in this connection, and that is aspiration of the bladder over the pubes with a fine needle, which obviates the introduction of air or dirt into the bladder, a thing which is likely to occur, and his suggestion is well worth considering. He has met with marked success in treating these large overdistended bladders

¹ See page 529 of the Journal.

with sometimes repeated aspirations, in one or more cases instituting the catheter later. The dangers of aspiration are comparatively small.

The subject of bladder washes, when the urine is alkaline and foul with pus, I think Dr. Cabot did not speak of. I have no question, however, that he considers it a decidedly important part of the treatment in certain stages of the trouble with regard to this matter. I think that one may be pretty well satisfied that the attempt, which was made a few years ago to clean up these dirty old bladders with the strong antiseptic solutions, is a failure, and that they should not be used. Corrosive sublimate solutions and carbolic acid I do not think are successful, and they are apt to produce more pus, more mucus and irritation. The milder remedies, as borax and glycerine, or boracic acid, or permanganate of potash, where the cystitis is comparatively mild, are desirable. Where there is a great deal of mucus, and the urine is foul, nitrate of silver in weak solutions — one-fourth grain to the ounce, making it stronger if it works well — is decidedly beneficial.

The method of injection of the bladder is another important matter, — whether one shall fill up the bladder as full as it will hold, or put in a small quantity and let it run out. The former creates more irritability, and the latter method is the better one I think.

The atony of the bladder dwelt upon by the textbooks is regarded by most of them as a great misfortune. In my experience those have been the cases which have done well. They are the patients who do not have irritability of the bladder, and unless they have a very dirty urine, in which case they may do badly, they go on exceedingly well, as far as I have seen them. I rather greet them with pleasure; it is the small, hard-walled bladders that are the miseries.

In the early part of the disease, it is the practice of many to give diluents, and mineral waters, and specifics for allaying the irritability of the bladder. These are more or less diuretic, and unless the catheter is used regularly, are deleterious in that they increase the strain upon the bladder and back-pressure on the kidneys.

In restoring partially the atony of the bladder where it is marked, electricity and strychnia may be of value. It is important to recognize the point at which cases begin to go on from bad to worse, in order that you may advise operation over and beyond what you have done in the way of the palliation, of routine treatment, the latter failing.

DR. A. POST: It is not easy to add very much to the interesting paper of Dr. Cabot. He certainly has treated a most interesting subject in a most interesting and very thorough manner. The great majority of cases certainly do well with such palliative treatment as Dr. Cabot has outlined. There is one class of cases, which I see something of, which is difficult to manage, and that is the lowest class of hospital patients, men whose hands have been accustomed to no more delicate instruments than pick and shovel. They do not take readily to handling a small catheter, and it is a pretty delicate matter to teach such a man of seventy-five or eighty to handle so slight a thing. It requires a good many days, and a good many patient lessons with some of those patients. They can be made to do well in hospitals under proper supervision, only to relapse again when they go out. In such patients I

think that recourse to operation is justifiable much sooner than in patients with much more intelligence.

I was very glad indeed to hear Dr. Cabot speak in the way that he did in regard to the first use of the catheter. It is a delicate matter to interfere with a bladder that has a certain amount of residual urine, with kidneys, and perhaps heart, more or less damaged, and it is a very great temptation to do it in your own office. The patient comes perhaps from a distance. It is very inconvenient to see him elsewhere, and still he ought to be in his own house and in his own bed. Such patients it is sometimes necessary to send to the hotel, have them stay there over night, perhaps have them go home and come back again before you can really pass a catheter on them. Of course, such a precaution is an extreme one and may be unnecessary in many cases. To make that the rule is certainly to avoid some occasional unpleasant experiences.

I want to say a word in favor of the old English catheter, not to dispute in the least, anything that has been said in regard to the flexible catheter, French pointed elastic or the *coudé*. I heartily agree with Dr. Cabot's remarks in regard to them, though it seems to me he places the size of his flexible catheter a trifle small at number six. There is so much that can be done with the old English catheter, and it is so much the fashion to advise a modern one, that I have sometimes dreaded lest the old English catheter should go out of the market. The way in which they may be softened and manipulated by means of the stylet, made into the *coudé* or *bicoudé* ought to be remembered. Putting patients to bed and tying the catheter in has certainly proved a very valuable method in my hands.

The condition of the urethra in patients who first enter upon the habitual use of the catheter is a thing that I think ought to have some mention. I have, on more than one occasion, found strictures in the anterior urethra that could be overcome with comparative ease. I remember one man who came from the country entirely unable to pass a catheter. He seemed to have had some constriction which had irritated by trying to pass a catheter that was too large, and then by trying to pass one that was very small. A very few days' practice with catheters of gradually increasing size restored the calibre of his urethra and the condition of his mucous membrane so that he was able to again catheterize himself. Patients are sometimes alarmed by little accidents that happen to them in the use of the catheter, as sometimes a slight hematuria, and sometimes an epididymitis. An epididymitis is not a very unusual result of the habitual use of the catheter, and patients are oftentimes needlessly alarmed about it. It is a question what shall be done with patients with an inflamed testicle; but my experience in a few cases has led me to think that the use of the catheter may be continued during an epididymitis, provided the patient takes extra care during its introduction, and treats his inflamed testicle in a proper manner at the same time.

DR. J. HOMANS, 2ND: I wish to say a word as to the catheter itself, and to call attention again to the dust and dirt which may be concealed in the small space between the opening and the end of the catheter. Here may lurk the germ of many a case of cystitis. To avoid this, I have had made a silver catheter which I still venture to prefer, with the end filled solidly and the metal slanting opposite the eye, which is made

rather larger than in the ordinary catheter, so that there is no cavity at all beyond the eye. At the Home for Aged Men, where I am the physician, there are about fifty inmates varying in age from sixty to ninety-four years, of whom certainly ten use the catheter every day, yet with the use of the silver catheter there has not been a case of cystitis for six years.

DR. WATSON: There is one form of soft catheter which also has the end filled up. For years there have been attempts made to do that in the soft catheters. Codman & Shurtleff have an English catheter in which there is no *coul-de-sac* beyond the eye, and that can be made into the *condé* or used with the stylet. One often neglects to tell patients how often to change the catheter. These catheters crack, and occasionally you will find a patient rasping his urethra as with a file, with one of these cracked catheters. I don't think one catheter should be used more than three weeks or so, and with the utmost care taken to keep it absolutely clean, and then discarded for a new one.

DR. F. MINOT asked the reader if he had seen any advantages from the internal administration of drugs, as for instance, salol.

DR. CABOT said that in cases in which there was no residual urine he had seen very good results from the administration of benzoate of soda, boracic acid and salol. They all cleared up the urine very decidedly in cases where there was no residual urine, or where that was thoroughly drawn off.

Dr. Cabot, in closing the discussion, said that he had always been interested in getting rid of the dead space in the end of the catheter, and had spoken of it at length in a paper on the application of antiseptic principles to genito-urinary surgery some years ago. The soft rubber Jaques catheters differ very much in the size of the space, and by going over a large lot, several can generally be selected which have little or no pocket below the eye. The silk web catheter that Dr. Watson speaks of is a very good one, but many patients cannot get it into the bladder. It is a little too stiff for a soft catheter. A stylet cannot be worked with it very well, because, there being no pocket for the end of the stylet to fit into, there is some danger that it will escape and protrude. The reader said in regard to the size of the catheter, that Dr. Post spoke of number six (English) as small, and he used to think so too, and was taught to use a large catheter, but the more he had seen of these patients the more he had come to appreciate that a catheter that slips in without a sensation causes much less irritation than a larger one. If the urine does not contain mucus, a number six catheter draws it thoroughly, and at the same time slowly. It is another advantage that the bladder is then not emptied too abruptly. He said there were a great many points he did not speak of in his paper, because he wished to consider the mechanical rather than the clinical part of the subject. Low specific gravity is a most important point in deciding the condition of the kidneys. He said he had examined the urine repeatedly without finding a single cast, or any other evidence of kidney trouble; the low specific gravity being the only thing which pointed to a serious disturbance of them. He said he should like to ask Dr. Watson how many times a day Mr. Harrison did aspiration.

DR. WATSON said that Mr. Harrison quoted two cases, one in his own hands. He said it was completely successful, and that aspiration was continued for two

days, something like eight or ten aspirations in all. In the case he quoted, I think there were thirty-two or forty-two aspirations in something like six or eight days with no infiltration of urine following into the prevesical space, and with great benefit, the patient afterwards resuming the use of the catheter.

DR. CABOT said that he had seen aspiration used in that way and successfully, for the relief of the immediate condition, but the patients in the cases he had seen had always required other measures. In one case he was sent for to crush a stone detected by the aspirating needle.

In regard to the question of distending the bladder when washing it out, he said that he agreed with what Dr. Watson had said, and that it is best generally not to distend the bladder; this was Sir Henry Thompson's teaching. He had seen, however, in some cases of large, sacculated bladders, great good resulting from a complete distention during the washing out. It is only in this way that the side pockets can be reached and thoroughly cleansed. He said he had used strichnia and also ergot for atony, sometimes with benefit. Both of them have, however, had occasionally one uncomfortable effect in some patients, namely, they have caused so firm a contraction of the prostate that they have increased the obstruction, doing more harm in this way than they have done good, by increasing the power of the contractions of the bladder.

DR. R. M. LOVETT read a paper on

ACUTE CIRCUMSCRIBED ÖDEMA, WITH A REPORT OF THREE CASES AFFECTING THE HAND.²

DR. C. F. FOLSOM: I have seen a few cases of this disease. A few occurred when I had the out-patients of the City Hospital. They were cases of acute circumscribed ödema of the lower lip, and some of them lasted I think, for a month. They were typical cases, such as Dr. Lovett has described. They occurred in very much debilitated young girls, and the treatment was chiefly tonic. The third case which I saw was very extraordinary. It was in a lady about sixty years of age, where the ödema involved nearly the whole of the right leg. The condition there was rather different from the two cases I had seen, and those Dr. Lovett described, and most if not all of those on record. The leg was exceedingly hard and pitted slightly to the touch. At least one, and I think several gentlemen made a diagnosis of intrapelvic organic trouble, and probably malignant. Much to the surprise of everybody, in the course of four or five weeks the leg returned to its normal condition. That condition recurred at least three times, and I cannot say whether it recurred oftener than that or not.

A certain amount of ödema, which practically cannot be distinguished from this acute circumscribed ödema, occurs in the various forms of peripheral neuritis. I remember seeing a case not long ago of a lady with peripheral neuritis, I think it was universal peripheral neuritis finally which proved fatal, and the organic changes in the nerves were much greater than I had seen in fatal cases before, or had found on record.

DR. F. GOSS: Within a month a lady came to me with what I suppose was an example of this affection, about the eye, the inner canthus. It had come on suddenly without pain, and disappeared after three or four days without any treatment to speak of. A fortnight

² See page 409 of the Journal.

later her husband came and said the trouble was recurring. I told him I presumed it would disappear, and I presume it did. I recollect a case which I saw several years ago which occurred over the forehead. There was a good deal of swelling, which closed the eye on one side. This disappeared within a few days from the beginning of the attack.

DR. E. G. CUTLER: I have had several examples of this affection under my charge. The first occurred in the Out-Patient Department of the Massachusetts Hospital just after Dr. Curtis's paper was read; and after that there were several. I have seen it something like four times in the upper lip, most of the time in women. I remember one case where it occurred last year in a lady who came to my house just before going to a dinner party. Her lip and chin were swollen. She was very much frightened and thought herself unpresentable, but the edema went down in the course of the evening and entirely disappeared. I have seen it in two instances in the eyelids. It was in these cases recurrent several times. Within the past five years I have had sent to me the wives of two doctors who had the disease on the lower limbs, under the fear that they perhaps might suffer from disease of the kidneys. It was recurrent in the first case. It would appear for a few days and then disappear. It came in one leg several times, and then occurred in the other, and evidently it was dependent on some gastro-intestinal disturbance, with a condition not unlike an urticaria. In the other case it occurred only in one leg. I saw it once over the abdominal wall to the right, near the superior spinous process of the ilium, and it evidently had some relation to urticaria. The spot was about the size of the palm of the hand, always appeared in the afternoon toward night, was quite bad when the patient took off the clothes to go to bed, during the night disappeared, and in the morning was not to be seen. I have seen several cases where it occurred in the hand and twice in the tongue. There was brought to my ward in the hospital this summer, a child who had this disease in the tongue, which disappeared after a few days. A simple, ordinary astringent mouth-wash was given. The assistant was much excited at the appearance of the child when it came in, and had all the preparations ready for tracheotomy. The tongue was so much affected that it stood out of the mouth and was very striking-looking. Most of the cases I have seen have been in people who have suffered occasionally or frequently from disturbance of the digestive apparatus, and frequently from urticaria. I do not remember to have had any cases of erythema, which is sometimes noted in cases of this sort. As far as treatment was concerned, nothing in my hands seemed to do much of any good. The most protracted case I have ever seen, occurred in a man who was very strong and otherwise well, and it lasted the greater part of last winter. He consulted several different specialists for small matters, and nobody seemed to do him much good. Finally the disease disappeared without treatment.

DR. F. H. HOOPER: I have seen three cases of primary acute unilateral edema of the larynx that I think would come under this category. In all of these cases the edema came on very suddenly without any discoverable cause, and lasted between two and four days, and went away as rapidly as it came.

The first case was in a delicate woman, twenty-six years of age, whom I saw at the Massachusetts Hospi-

tal in 1881. She had been hanging out clothes on the shed in the morning, and in the evening when eating her supper she experienced great pain on swallowing, and the next day when she came to the hospital I found that she had an edema extending from the lingual surface of the epiglottis on the left side, and involving the aryepiglottic fold and the mucous membrane covering the left arytenoid cartilage, but there was no inflammatory action particularly of the pharynx or of the larynx.

The second case was in one of the ward tenders of the City Hospital. He was about twenty-five or twenty-six years of age, and in his case it disappeared in about two days. I cannot remember the details of that case, because I did not take any record of it.

The third case was in a private patient whom I saw last April. It was interesting from the fact that the man could locate exactly the moment his trouble began. He was twenty-five years of age. He said that at four o'clock Monday afternoon he was eating a chocolate cream in a drug store, and while eating it he experienced intense pain in the larynx, as if part of it had lodged there. Tuesday his throat was a great deal worse. He suffered intense pain on swallowing. I saw him for the first time Wednesday morning about nine o'clock. He was still suffering pain on swallowing. I found that he had great edema of the right side of the larynx; the right aryepiglottic fold and the mucous membrane covering the right arytenoid cartilage. I don't suppose the chocolate cream, of course, had anything to do with his edema. After talking with him regarding the cause of his trouble, he remembered that at lunch, on Monday, he had eaten fried oysters, and had removed two pieces of shell from his mouth. It is possible that a bit of shell wounded the mucous membrane and excited the edema of the larynx. No shell was ever seen, however, and the edema, as in the other cases, disappeared very quickly.

In all of these cases the opposite side of the larynx was normal in appearance.

DR. WATSON: I have seen four cases of this in the lips, two in the lower and two in the upper lip, one in a boy and three in girls. Compression with contractile collodion seemed to work exceedingly well.

DR. C. F. FOLSOM: I had forgotten two cases in my dispensary practice in 1872 or 1873. They were both in the lip and side of the tongue. When the first case presented itself, I did not recognize the affection. I put on four leeches, and to my surprise, on going to see the patient the next morning, the swelling had entirely disappeared, and it never recurred. I could not find in literature any report of similar cases, and when the next came, about six months afterwards, I did nothing in the way of treatment, and sent her to the City Hospital, where she stayed three or four weeks. Whether the leeches had anything to do with the favorable results in the first case, I do not know, but in view of the opinions in regard to the pathology of the trouble I think it possible they may have.

DR. CUTLER: The oldest of the cases I saw was about forty-five years, the youngest a child about five or six.

DR. POST: I must speak of a case I saw early this summer, which corresponds very closely indeed to one or two of the cases Dr. Lovett mentions. It was in the hand, running up on to the wrist, and lasted for four or five days, going down under a bandage over

some cotton. The reason why I speak of it at all is because it occurred in a woman ninety-one years of age.

DR. G. G. SEARS: I am very much interested in Dr. Lovett's report of the cases, particularly in hearing the complete histories of the two he was kind enough to show me. There was no question of rheumatism in those cases, and the peculiar interest seemed to lie in the fact that we could find no cause, which is generally recognized for such a condition.

During my service at the Carney Hospital last year four or five cases, all of the upper lip, presented themselves at the Out-patient Department. All the patients were anemic girls under eleven years of age, and all recovered in a few days without treatment. There seemed to be a close analogy in the milder cases to urticaria. Traumatism and alcohol, which seem to have been more or less prominent factors in the etiology of many of the reported cases, played no part here. Two cases, which I mention as they seem to have been overlooked by Dr. Lovett in his review of the literature, were reported by Joseph, at the German Dermatological Congress, I think a year ago. One occurred in a boy of five, whose indulgent parents allowed him large quantities of Tokay wine, and who had repeated attacks; in the other, a man, every excess in alcohol was followed by edema of the exposed parts, either the face or hands.

DR. GREEN: I had an attack of this affection myself a few years ago in the upper lip and extending into the roof of the mouth. It lasted three days, and disappeared. It frightened me a little for fear it would go into my larynx, but that was spared.

DR. F. MINOT reported a

CASE OF SUDDEN DEATH, PROBABLY FROM EDEMA OF THE GLOTTIS.⁸

DR. HOOOPER: These cases of edema of the glottis always make one very anxious, and ought to be constantly watched. The case Dr. Minot reports, I dare say, was one of general edema of the glottis. It is surprising what an enormous edema of the larynx we can have, and yet, as long as the patient is perfectly quiet, he breathes easily, and no one would suspect any narrowing there. You might look in with the laryngoscope and see no opening at all, and yet the patient breathes perfectly well, but if he gets out of bed and makes any exertion, inspiration sucks the parts together, and he dies in a moment. Dr. Edes reported a case of acute edema of the glottis in an athletic man a few years ago. That man died by getting out of bed and making some little effort. The absence of any difficulty of breathing in these cases is no criterion at all. It is the discomfort in swallowing that should excite our suspicion, and suggests a laryngoscopic examination.

DR. FOLSOM: Is it common in general edema of the larynx to have it so quiet? I had the impression that Dr. Edes's case died from severe dyspnoea.

DR. HOOOPER: I do not think he had dyspnoea before he jumped up.

— An Ohio city physician who attends the patients at police headquarters has asked permission to wear a police cap while on duty. In cases where he has to accompany prisoners to the station on the wagon he is frequently mistaken for the prisoner.

⁸ See page 536 of the Journal.

NEW YORK COUNTY MEDICAL ASSOCIATION.¹

DR. EDWARD VON DÖNHOFF read a paper on

THE MANAGEMENT OF FRACTURED LIMBS.

The solution of many of the mischievous consequences of bad management of fractures, he thought, was to be found in the ignorance of certain radical principles, and, growing out of this, an element of timidity on the part of the medical attendant. One source of trouble was that books on general surgery and even those especially devoted to fractures fail to definitely indicate the proper length of time during which it is necessary to maintain uninterruptedly a fixed apparatus upon a fractured limb. In most textbooks and surgical lectures there was also a failure to enforce that knowledge of detail which was so essential to success. The treatment of a fracture, he said, should begin with a correct understanding of the mechanical history and topography of the injury. In order to secure this, it was in his opinion necessary in the majority of cases — both as a matter of safety and accuracy of adjustment, the most essential initial step to success — to anesthetize the patient. This should at least be done in every instance where muscular resistance to effective manipulations is anticipated or a doubt exists as to the exact line of fracture. In the examination there should be noted the amount of enlargement growing out of infiltration of the surrounding soft parts with serum or blood, the probable amount of fluid — probably blood — lying in immediate contact with the fracture, and the degree and direction of displacement of fragments.

To illustrate his mode of treatment Dr. von Dönhoff described as follows a supposed case of simple comminuted fracture of the elbow: The diagnosis being complete, the limb should be scrupulously cleansed. Begin the first dressing by fixing the replaced fragments with a plaster-of-Paris roller adjusted over suitably arranged batting or other cushioning material in only sufficient quantity to prevent undue pressure. This roller is permitted to harden somewhat before the succeeding ones are applied, as its purpose is to secure the fragments in the position given them by the operator in such a manner as to prevent them slipping during the subsequent manipulations. The limb is now swathed as usual, and the plaster bandage adjusted, beginning at the distal extremity, over the first applied roller, and including the shoulder in a spica. In fractures of the elbow he had for a long time preferred a pose of about 110° because of the muscular equilibrium thus obtained, and the greater usefulness of the limb in this position should the joint become ankylosed. If great restlessness is anticipated at this time, the anesthetic may be prolonged for a few moments, which will suffice for the hardening of the plaster, especially if it be rubbed with powdered alum. When the patient is thoroughly conscious, and the surgeon convinced of his complete comfort, the first dressing may be regarded as properly adjusted.

As soon after this time — ordinarily from two to three days — as the more or less complete recession of the swelling is indicated by the general sense of comfort and the evidences elicited by careful percussion of the plaster casing, the casing should be carefully divided into two equal halves longitudinally, and the upper half carefully lifted off without in the

¹ Stated Meeting, October 20, 1890. Concluded from page 435 of the Journal.

least disturbing the limb. The exposed cotton is then smoothly teased away — the middle line being observed in the process — until the arm is perfectly bared for purposes of inspection. If, as is most likely, the swelling has receded, and the shapeliness of the limb indicates good apposition of the fragments, the removed half of the dressing should be trimmed down and reapplied, being fastened in position with a cheese cloth roller snugly applied.

At the end of two or three days longer, the patient should again be anesthetized, and the dressing carefully removed altogether. Slight passive motion should be made at the elbow, and the shoulder and wrist joints, as also the fingers, should be thoroughly moved. The limb, including the wrist but not the shoulder joint, is then lightly swathed in batting, which is held in position by a few turns of ordinary sewing thread. The whole is then covered with two leather splints previously cut and shaped by measurement. Birch-tanned saddle skirting, which I prefer, is made quite soft by dipping it quickly in very hot water (100° to 170°), and so becomes as adjustable as *papier mache*. The splints are quickly and accurately moulded to the limb, and held in position with turns of thread, to be directly followed by a cheese cloth roller. In a few hours this case will be found to be quite bone-like in hardness and having, of course, the exact shape of the limb. The day following the upper half is lifted off, and slight passive motion is made at the elbow and wrist. Everything progressing favorably, the slight remaining swelling of the limb will decrease visibly day by day, and the edges of the leather may be trimmed accordingly, to preserve a close fit. Each disturbance of the dressing must be followed by its careful readjustment.

On the eighth or tenth day I remove the whole casting, and fix its two halves together at their posterior border, with a series of points of wax-end sutures, while the anterior edges are provided with shoe-lace hooks. Thus a perfect and reliable boot is secured. This leather case is then replaced and laced in position, after the proper passive motion has been practised. During the succeeding four or five days the dressing is regularly removed by the surgeon and readjusted after passive motion, which by this time will be possible to an extent very nearly approximating the normal mobility. The patient may now be instructed to leave off the boot during the daytime, and reapply it only when retiring, in order that the parts may be protected against injury from involuntary motion during sleep. On rising, the patient, after bathing the limb with tepid water and subjecting it to gentle friction with a towel, should be required to make voluntary motion to the limit of his comfort, in imitation of all the normal movements of the arm. During the day he should carry a small round object in the hand of the injured limb, and manipulate it from time to time; and he should also be required to occasionally make complete pronation and supination. At the end of the fourth week the individual whose injury has been treated as above, may be safely dismissed from attendance. He will have been by this time sufficiently educated in the management of his condition, and can now be trusted to keep up the nightly adjustment of the apparatus during the ensuing fortnight. Bathing, massage, motion, etc., to be likewise assiduously practised.

This, said Dr. von Dönhoff, was a typical case ex-

emplifying his practice for the past fifteen or sixteen years, during which time he had seen no failures in the similar or other kinds of fracture managed in this fashion. Moreover, he had induced many other surgeons to practise the method, and some years he had tabulated and reported to the Kentucky State Medical Society a considerable number of cases (165) of fractures, very varied in character, which were taken from the practice of colleagues who contributed their experience with it. In no instance did a bad or at all questionable result follow, though many of the cases were of the gravest and most difficult character. Many were instances of surgical fracture of the MacEwen operation. A number of intra-capsular fractures at the hip were also contained in the list. The average duration of active treatment in all the cases thus recorded was twenty-eight days. In no case was there remaining any deformity, atrophy or vestige of fibrous ankylosis, and in none marked abridgment of voluntary motor capacity.

From an analysis of the supposititious case of elbow fracture, he went on to say, we might formulate rules of practice applicable to the management of every form of simple fracture of the long bones and joints of the upper and lower extremities, and based upon such unvarying physiological reparative phenomena, that they were quite self evident, as well as safe guides. As to the time of beginning passive motion in fractured joints and those necessarily included in the first fixation apparatus, it was only requisite to remember how readily stiffness, and a little later, ankylosis, appearances, develop in temporarily confined joints, to appreciate the necessity of taking advantage of the earliest moment of safety to interfere and interrupt fibrous formations between the articulating surfaces. Though such interferences, fortunately, need be very slight, indeed, neglect at this time would afterwards result in an almost if not quite complete nullification of our best efforts in other respects. His experience, based upon a great number and variety of cases, had perfectly satisfied him that it is safe and best, ordinarily, to leave "fixation apparatus," except during sleep, at the earliest possible moment, that is, about the fourteenth or fifteenth day, at which time the "pin" and "ensheathing" callous, and periosteum have been reformed and the new structures are sufficiently firm to support the part thoroughly against all reasonable chances of displacement. It was of the first importance to effect an accurate and exact adjustment of fragments, as well in fractures of bone as in divisions through the soft parts, in order to secure prompt union of divided structure. In conclusion, he said that if results such as he had narrated were desired in cases of fracture, it was not permissible to overlook or slight the least detail in their management.

DR. JOSEPH D. BRYANT said that many of the views expressed in the paper were certainly unusual and at variance with those of the great mass of surgeons. In making a diagnosis he thought that the first thing we should do was to study very carefully the contour of the corresponding limb. As to the practise of generally resorting to anaesthesia, he could not but take exception to this; for the treatment in this respect advocated by Dr. von Dönhoff seemed to him worse than the disease. In joint cases anaesthetics were sometimes called for, and were resorted to by all surgeons; but for ordinary purposes he deprecated their use as unnecessary and accompanied by more or less danger. As

to the length of time in which treatment was required and as to complications, we had to consider whether there would probably be future ankylosis. The reader, in laying such great emphasis on the necessity of passive motion, seemed to be unmindful of the paper which the late Dr. H. B. Sands published three or four years ago; and it was a well-known fact that, of late, surgeons have disregarded passive motion more and more. Voluntary confinement of a healthy joint certainly would not result in ankylosis.

As to the time a fixation apparatus should be worn, in the majority of fractures the dressing could be abandoned within four weeks, provided, as Dr. von Dönhoff had said, there were no untoward circumstances. But it was just the fear that the patient might make some unusual movement which induced us to be cautious, and in order to avoid possible accidents it was necessary, in his opinion, to keep up the treatment longer. He remembered that when he was an intern at Bellevue Hospital he removed the dressing from a fractured thigh at the end of four weeks, and the consequence was that the next morning he had another fracture to treat; whereas if he had kept the apparatus on for, at least two weeks longer, such an accident could hardly have resulted. He regretted that the text books on surgery did not lay down more definite rules; but this was not so great a fault as would at first appear. It was only the general principles applicable to fractures and their treatment which they could properly set forth, and if they attempted to give dogmatic rules the effect would only be disastrous, since the student or practitioner would be robbed of the necessary prerogative of reasoning in his own cases.

DR. S. T. ARMSTRONG also thought that each case should be judged by itself and according to the special circumstances attending it. The essential point of the paper seemed to him to be the feasibility of diminishing the time during which fixed dressings should be worn in fractures. He thought, however, that in making an examination at the end of two days after the first dressing had been applied there was great danger of interfering with the process of repair. Moreover, if in any case so treated, the result should be unsatisfactory, the patient might, perhaps, claim damages on the ground that such result was due to the fact that the surgeon had unnecessarily disturbed the dressing before firm union had occurred.

DR. VON DÖNHOFF said that he gave the anesthetic not for the purpose of making a diagnosis, but in order to secure passivity of the muscles. In his own practice he had never met with any untoward result in the use of anesthetics, and he believed that with proper care they could be employed almost with impunity. As to Dr. Bryant's case at Bellevue, it seemed to him that, owing possibly to some diathetic influence, or to the fact that the fragments had not remained properly adjusted, there never had been any union.

— A medical college in Jersey City, in which the length of time required to get a degree is three months, and where the professors rarely turn up for lectures, is asking the Supreme Court to grant a mandamus to compel the County Board of Health to register as physicians last year's "students" of the concern.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

THIRD ANNUAL MEETING, held in Atlanta, Ga., November 11, 12 and 13, 1890.

FIRST DAY.—MORNING SESSION.

The Association convened in Concordia Hall, and was called to order by the President, DR. GEORGE J. ENGELMANN, of St. Louis, Mo., at 9.30 a. m.

DR. GLENN delivered an Address of Welcome, the response to which was made by DR. R. B. MAURY, of Memphis, Tenn., who also contributed a paper entitled

HOW SHALL WE TREAT OUR CASES OF PELVIC INFLAMMATION?

The paper gave a comprehensive résumé of the pathology of chronic pelvic inflammation as it has been clearly demonstrated by Bernutz, by Polk, Coe and others, and by the results of abdominal section. This pathology is that of pelvic peritonitis dependent upon tubal disease not cellulitis. The author declared the term chronic cellulitis a misnomer, a pathological condition which existed only in the imagination of the physician, a term which had been productive of pernicious results in practice, and which should no longer be used in connection with non-obstetric pelvic inflammation.

When the pathology rests upon such abundant and positive evidence, the question might be asked, Why re-open a discussion upon it now? Because it is evident from our society proceedings and hospital reports that great confusion exists in the medical mind to-day in regard to it. Dr. Byrne's case, discussed in the New York Obstetrical Society during the present year, was taken as an illustration. In speaking of such cases, the great tendency to relapses in chronic pelvic inflammation was illustrated by two cases in which pus tubes were found five and seven years after attacks of peritonitis, and when it was supposed the patients were entirely restored to health. Upon the subject of treatment the writer admitted, that, by non-surgical therapeutic measures, large intra-peritoneal exudations are often absorbed, and even some tubal and ovarian inflammations entirely disappear, and recovery seems complete. But this is the exception, and by no means the rule. For the radical cure of chronic pelvic inflammation non-surgical treatment fails in a majority of the cases. A great many women suffering to a moderate degree, continue to do so in spite of the best directed non-surgical measures, and perhaps wisely elect not to undergo operation.

As a rule, the only radical and permanent relief is afforded by removal of the diseased appendages. The treatment of pus collections, of course, requires abdominal section.

DR. JOSEPH PRICE, of Philadelphia, followed with a paper on

THE MOTIVE AND METHOD OF PELVIC SURGERY, in which he said pelvic surgery must be considered apart from abdominal surgery. It is distinct from it, both in the nature of the lesions dealt with, in the difficulties it presents, and in the complications and embarrassments to routine technique.

Nowhere as much as in pelvic surgery does the distinction between the general surgeon and the spec-

ialist in pelvic disease stand out so clearly. Pelvic adhesions in appendicitis, for instance, Mr. Treves would deal with by the knife. If this is feasible, why not put the knife to ovarian and tubal abscess, to all intestinal fixation by inflammatory processes and the like? The very suggestion of such method to the mind of the specialist accustomed to deal with all the complexities of pelvic surgery is fraught with evil; and this mere suggestion only makes it clear that general surgeons, in so far as they are entirely wedded to the knife in removing disease, fall short of the demonstrated harmfulness of its application in pelvic work.

Relative to electricity, Dr. Price said that electricians yet talk learnedly of the undetermined place of electricity in the treatment of ovarian cysts; but tars, water and tractors have gone to their long rest. The time must yet come when the claims made for electricity as an universal panacea must be exploded, and its real, limited, and narrow horizon of usefulness be well defined. The pernicious effect of so-called cures of reported complicated cases, adhesions, inflammations, and the like, by men without training, who look only at the ampère-meter while they adjust a clay pad or introduce a galvanic sound, is not to be overestimated. He had repeatedly shown, by exhibited specimens, the fallacy of the claim of exact diagnosis made by these men, and the arguments are irrefutable. He believed that the only position assumed by the electricians that has the slightest foundation in fact, is that electricity will sometimes control hemorrhage and relieve pain. That it cures either is not proven.

In dealing with adhesions, the first point to be sought after is to find a crease or crevice, into which some progress can be made. In separating intestinal adhesions, they should be broken as far from the bowel as possible. The farther away the less liable would they be to bleed, and the absence of hemorrhage is a great comfort in these cases. The strings of adhesions may be dealt with according to their size, it sometimes being best to remove them, at others there is no necessity for this. In doubtful cases their removal is the better surgery. All bowel adhesions should be carefully examined after their separation. By so doing, fecal fistula will often be avoided by the careful placing of an intestinal suture. It hence is apparent that no pelvic surgery should be attempted, until the operator is competent to deal with intestinal wounds, even to resection and anastomosis. Once the adherent mass is removed, the ligature should be applied close up to the cornu uteri. The ligature should not be so heavy as to resist knotting, nor so light as to break easily. The ordinary surgical knot is the safest of all knots with which to tie the pedicle. It constricts more evenly and certainly, and will slip less readily. The leaving of sufficient button is of the greatest importance to prevent slipping of the ligature.

In the treatment of extra-uterine pregnancy his urgent advice is, to operate without delay when the symptoms point to the disease, with the assurance that delay will only complicate matters and sacrifice the life of the mother.

The field of pelvic surgery, said Dr. Price, is not one of experiment, or palliation, that it strives in all cases to remove the offending body in order to conserve the rest of the economy; that its tenets are founded on philosophy and fact, not fiction, and that its worth lies in its proven results. The surgery that plucks out the eye or casts aside the limb, to save the other

eye or limb or life, is greater, better and wiser, than a sentiment that preserves a shell to inclose a ruin.

FIRST DAY.—AFTERNOON SESSION.

DR. W. H. H. COBB, of Goldsboro, N. C., read a paper on
SUPRA-PUBIC CYSTOTOMY IN A CASE OF ENLARGED PROSTATE.

The patient, a farmer, aged forty-nine years, rheumatic diathesis, dated his trouble back to 1881; when he carelessly allowed over-distention of his bladder, and has suffered more or less since from nephritic colic and has passed on different occasions dark, gritty deposits. For the past three years he has suffered much with cystitis in a very aggravated form, with great pain and difficulty in defecation, urine containing much blood, pus and mucus. The patient consulted Dr. Cobb in June last, who suspected vesical calculus, but failed upon examination with sound to detect any stone. A digital examination, however, per rectum, disclosed the right lobe of prostate greatly enlarged, rough, indurated, exceedingly tender and sensitive. After consultation by letter with Hunter McGuire, he decided upon supra-pubic cystotomy as the only hope of permanent relief, which was done after the method of Dr. McGuire on June 23d. At the expiration of two months, he found the prostate perfectly normal with no symptoms of cystitis, and withdrew the plug, allowing the fistula to unite, which it did in about ten days. His patient performs the act of urination and defecation without the slightest trouble, and expressed himself as entirely relieved, and is at present following his usual vocation.

INFLAMMATION IN AND ABOUT THE HEAD OF THE COLON.

DR. L. S. McMURTY, of Louisville, read a paper on this subject. He said the teachings to be found in systematic treatises on surgery and practical medicine upon inflammation and its results in and about the caput coli are not only worthless, but positively misleading. This is true not only as to pathology and treatment, but even as to the anatomy and relations of the cæcum and its appendix.

Inflammatory changes in the veriform appendix are in almost every case the origin and seat of the inflammatory diseases about the caput coli. Inflammation of the cæcum is very rare, yet in a certain proportion of cases cœcitis, with perforation, occurs without involvement of the appendix.

Fecal impaction may be the cause of inflammation about the head of the colon. Pain over the cæcum, with a fecal mass perceptible on pressure often occurs, but rarely, if ever, associated with peritonitis. A few weeks since the speaker saw a case in conjunction with Dr. H. H. Grant, of Louisville, in which a localized peritonitis existed in the right iliac fossa, with a well-defined firm tumor. Abdominal section was done, and instead of appendicitis, they found the disease to be cancer of the caput coli. Irrigation and drainage rescued the patient from the immediate danger begotten by active peritonitis. The patient was a woman of middle age, and the engorged peritonitis presented the symptoms of an acute condition. Malignant disease of the cæcum has not, so far as the writer is aware, been mentioned by writers upon this subject as a probable condition in the diagnosis of deep-seated inflammations of the right iliac fossa.

The decision to operate should be determined more by the grade of the inflammation than by the time it has existed. When a diagnosis has been made, and three days have elapsed without subsidence of pulse and temperature, operation should be done.

The following conclusions were submitted: (1) Inflammation about the *caput coli* is, as a rule, inflammation of the appendix. (2) A certain proportion of cases will recover spontaneously by resolution. With these, recurrence of the disease is common. (3) In the larger proportion the disease will endanger life, and may at any moment assume a condition practically hopeless. (4) Early operative interference involves less danger than delay, and should be resorted to in all cases in which a high grade of inflammation is persistent. (5) The essentials of the operative technique are brief anaesthesia, quick and thorough work, removal of the appendix, irrigation and drainage. The lateral incision is preferable to the median.

FIRST DAY.—EVENING SESSION.

PRESIDENT ENGELMANN delivered an address entitled

THE CAUSES OF ILL HEALTH IN AMERICAN GIRLS AND THE IMPORTANCE OF FEMALE HYGIENE.

He showed that the health of the American girl is threatened and impaired by causes more or less avoidable, as they are due to our methods of life, our methods of training and education; that the physique of this girl, most favorably situated amid auspicious possibilities, is imperfect; her brain overworked, her nerve power exhausted, her function impaired, and reproduction endangered, all by reason of the susceptibility of her peculiar organization, and the increased impressibility of the sensitive system during the years of development, in which it is subjected to the most severe strain.

The remedy is attention to woman's peculiar organization and the cyclical waves of her dominant function, or, in other words, harmonious development and occupation of nerve and muscle; diminished brain-work and nerve stimulation with increased and co-ordinate physical exercise; increased protection and diminished compression of dress; self-knowledge and individual care during periods of heightened susceptibility. Changes are necessary in custom and fashion, in methods of labor and education. A harmonious education of mind and body should be approximated.

DR. ENGELMANN closed with a plea for the self-care of the American girl and her proper physiological instruction by the mother, which, alone, will mitigate or remove the initial cause of many of her ailments. Upon the mother he would impress that the perfect development of the female function, and the maintenance of this function, once developed, in a healthy condition, is essential to the perfect development of the girl and the perfect health of the woman; that self-care, a well-regulated female hygiene, is the foundation of her well-being.

SECOND DAY.—MORNING SESSION.

DR. C. A. L. REED, of Cincinnati, O., read a paper entitled

INDICATIONS FOR OPERATION IN ECTOPIC GESTATION.

The paper starts out with the assumption that the only proper treatment of ectopic gestation is by lapar-

otomy, or, more properly, coliotomy. While the profession has become practically unanimous that this is the proper line of treatment, the indications for operation have been less definitely decided upon. This conviction is forced upon the observer by encountering cases which have been advised against operation until hemorrhage within the pelvis has threatened a fatality, which is but too frequently realized. The most legitimate excuse for this dilatory practice, is to be found in the confusion which has arisen with regard to the supposed uniform causal relationship of ruptured ectopic gestation to pelvic hematocoele.

The treatment of ectopic gestation premises the diagnosis of this condition. This is obviously difficult, and in the majority of instances cannot be arrived at, or, if at all, only presumptively; but, in all these cases, conditions can be found in the pelvis, which if not conclusively of extra-uterine pregnancy, yet constitute conclusive indications for exploratory operation. The presumption of ectopic pregnancy can be arrived at before rupture, chiefly by a history of previous sterility, by a previous amenorrhea followed after a few weeks by irregular hemorrhage, by increased tumefaction to either side or back of the uterus, and by the existence of false decidua within the uterus. The latter fact may be safely determined by the judicious use of the Emmet curette forceps. The diagnosis after rupture is essentially the diagnosis of internal hemorrhage. Time wasted either to determine the cause of that hemorrhage, or to find out if it be primary or secondary, is criminal, the thing to do is to operate. The position has been taken that time should be taken for the patient to rally from the shock. One of the speaker's own cases died simply because he waited twelve hours for reaction—a lesson which taught him the fallacy of the old teaching, and which has since saved lives at his hands. The best way to overcome shock from internal hemorrhage is to stimulate the patient by giving ether, stop the drain by ligating the bleeding vessels and rouse the nervous system by washing out the belly with hot water.

Dr. Reed's conclusions are: (1) The only proper treatment of ectopic gestation is that by abdominal section. (2) The operation should be done in cases before rupture so soon as the condition can be presumptively diagnosed. (3) The operation should be done in cases after rupture so soon as the evidence of internal hemorrhage become apparent. (4) In cases in which the period of viability has already been reached without rupture pregnancy should be allowed to advance to term before operation, but only under the closest possible vigilance. (5) In all cases the appendages from both sides should be removed providing the condition of the patient will justify the extension of the operation.

DR. BEDFORD BROWN, of Alexandria, Va., followed with a paper entitled

THE LOCAL AND GENERAL TREATMENT OF GANGRENOUS WOUNDS AND DISEASES.

Many years ago, previous to the late war, the writer determined to institute a series of experiments to ascertain the capability of local and general treatment of all gangrenous wounds and diseases that came under his care either for their prevention or arrest. The object was to find local agents possessing active properties as stimulants of vital action in the affected parts, also as means of disinfecting and deodorizing

gangrenous sloughs, hastening their final separation and for the establishment of a healthy basis for granulation. In cases coming under his care he found that the old deodorizer failed to accomplish these objects. He then employed a solution (almost saturated) of sulphate of zinc and dilute sulphuric acid as a local application, which seemed to meet all the requirements. The first case in which it was applied was according to the following formula:

R Zinc sulphat.	3j.
Aqua.	Q.J.
Acidi sulph.	3ss. M.

After the free application of hot water at 110°, the solution was applied every three hours on bats of raw cotton. In the course of two days the slough separated rapidly, leaving a perfectly clean, healthy base for granulation. This solution evidently possesses active antiseptic properties. It is an admirable deodorizer; it is clean and cleanses the parts effectually. In cases of great loss of sensation in the parts, weak circulation, reduction of vital action, and depressed vitality, he knows of no agent better calculated to arouse nervous action and stagnant circulation, for as soon as the living basement is exposed it gives rise to intolerable pain. He has used this solution in all forms of gangrenous wounds and diseases, some limited, others extensive and associated with septicemic, with benefit.

Dr. Brown cited the history of several cases of different varieties of gangrenous wounds and diseases treated by various methods.

DR. W. L. ROBINSON, of Danville, Va., read a paper on

THE TREATMENT OF GENERAL SEPTIC PERITONITIS, in which he called attention to those cases which tended, by absence of pain and a seemingly improved condition after chill and fever, to mislead as to the necessity of operating, and instanced two cases of recent date in consultation, in which septic peritonitis and secondary abscess existed in spite of the seemingly favorable condition of the patient. He says that often there is an utter disproportion between the pathological condition and the amount of pain and tenderness, — a condition so often seen in puerperal peritonitis.

He states that traumatic abdominal injuries, appendicitis and pelvic inflammation, are the chief causes of septic peritonitis while, of course, any internal or external influence which produces suppuration, may be the indirect cause.

He agrees with Dr. G. Frank Lydston, of Chicago, that in children, falls, blows, etc., are the causes generally of peritonitis, and that because of their age, attention not being directed to the seat of injury, we often diagnose the disease too late. Dr. Robinson takes the stand that gonorrhœa is a frequent cause of septic peritonitis and the reason why it did not always produce it was, that it did not invariably invade the uterus, and even when it entered the tubes, the adhesions to the ovary rendered it self-limiting.

He holds that section, irrigation and drainage is the treatment, and that where adhesions are extensive, that salines should follow the operation in order that the peristaltic action of the bowel would prevent re-formation. Cases occur which, when seen by the surgeon, are too prostrated to undergo a complete operation and the proper plan is to rapidly do what one can by section, irrigation and drainage. Dr. Robinson instanced a case of recent date in which the patient was

saved when seen only in *extremis*. He urges the surgeon to go prepared to resect, anastomose, etc., as complications may indicate. Where conditions are diagnosed which will most likely terminate in septic peritonitis, such as recurring appendicitis, that preventive measures should be undertaken; and where great tympanites exists, he would adopt Dr. Davis's mode of opening the bowel and flushing it out with hot water.

DR. JOHN D. S. DAVIS, of Birmingham, Ala., contributed a paper entitled

THE CLINICAL HISTORY OF THE EPICYSTIC SURGICAL FISTULA, WITH CASES.

(To be continued.)

Recent Literature.

Essentials of Practice of Pharmacy. Arranged in the Form of Questions and Answers. Prepared especially for Pharmaceutical Students. By LUCIUS E. SAYRE, Ph.G., Professor of Pharmacy and Materia Medica, School of Pharmacy, University of Kansas. Octavo; pages viii, 180. Philadelphia: W. B. Saunders. 1890.

This number of Saunderson's Question-Compends was prepared with the object of assisting the student in holding the instruction he receives in the study of pharmacy, and to open up and map out the subject in a way that is comprehensible and easily followed. The Pharmacopeia is made the central figure of study and is but seldom departed from. The subject is considered under the classification of physics, pharmaceutical processes and manipulations, physical and chemical, pharmacy both practical and theoretical, official preparations, inorganic and organic compounds, dispensing and incompatibilities. The topics are treated in a simple practical manner and the work forms a very useful manual for the object intended.

The Physician's All-Requisite Time-and Labor-Saving Account-Book. Designed by W. A. SEIBERT, M.D. Philadelphia: F. A. Davis, Publisher.

This account-book has the great merit of simplicity. There is space on each page for the accounts of three persons or families for several months, obviating the necessity of rewriting names. It is published in two sizes, for six hundred and twelve hundred accounts.

The Physician's Visiting-List (Lindsay & Blakiston's) for 1891. Philadelphia: Published by P. Blakiston, Son & Co.

This well-known visiting-list is published in four sizes, with space for twenty-five, fifty, seventy-five and one hundred patients per week. Its popularity was well deserved. It is simple and compact, and yet contains all that most practitioners require.

— At the recent meeting of the Tri-State Medical Association a member from Arkansas, speaking of the use of calomel in malaria, said that the prejudice against it in his country was so strong that a shot-gun policy had been adopted, and that any one who gave a dose of calomel was liable to receive a dose of buckshot before he could get away.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, DECEMBER 4, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMREL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE MASSACHUSETTS HEALTH REPORT.

The twenty-first report of the State Board of Health of Massachusetts maintains the high standard of the series, and records each year an increased amount of executive work under the comprehensive laws in respect to water-supply, sewerage and inspection of food and drugs.

Extensive chemical and biological investigations of the complex questions affecting water-supplies and disposition of sewage are in progress. Forty-two applications for advice, many requiring much expert labor, were received by the board during the year, relative to sources of water-supply, sewerage and disposal of sewage. Nearly 150 cities and large towns were visited for collecting samples of food and drugs, of which 5,454 were analyzed, and 140 complaints were entered in the courts for violation of the acts. Chemical and biological examinations were made of more than 2,000 samples of water and a large number of specimens of sewage.

Sources of pollution were noted in thirty of the ice-supplies from 189 cities and towns, a few of which had been suspected as being a cause of illness. In the twelve appearing to be most polluted a chemical analysis showed that in freezing, color and salt, and eighty-seven per cent. of other impurities had been removed. The number of bacteria in the ice averaged 138, varying from 0 to 1,246, the latter in snow ice.

Reports from 152 of the 346 cities and towns in the State indicate intermittent fever in 86, as compared with 47 in 1880. Cases were reported from 25 towns in Middlesex County, 17 in Norfolk, 11 in Worcester, 10 in Hampden, 7 in Bristol, 6 in Essex and Hampshire, 4 in Plymouth, 2 in Berkshire, Barnstable and Franklin, 1 in Dukes. Fifty-two report the disease more or less epidemic.

A statistical report on the physique of women in Massachusetts, based upon measurements of 1,546, records a "fairly correct idea of the physical type of the adult young woman of this community," and includes an important discussion of the scheme of Galton's "percentile grades."

Dr. Abbott, the secretary of the board, closes a full and most interesting report on influenza with these conclusions:

(1) The first appearance of the influenza in Massachusetts as an epidemic, in the past season, may be stated to have been on the 19th or 20th of December, 1890, and the place of its first appearance was Boston and its immediate neighborhood.

(2) It increased rapidly in the number of persons attacked, and reached its crisis generally throughout the State in the week ending January 11, 1890, after which date it gradually declined in severity, and had nearly ceased as an epidemic by the 10th of February; so that the duration of the epidemic was about seven weeks. It reached its crisis earlier by several days in Boston than in the smaller cities and the remote parts of the State. Its course was still later in Nantucket, Dukes, and Barnstable Counties.

(3) The ratio of the population attacked was about 40 per cent. — or more exactly, as indicated by the returns, 39 per cent. — or about 850,000 persons of all ages.

(4) People of all ages were attacked, but the ratio of adults was greatest; of old people next, and of children and infants least.

(5) The weight of testimony appears to favor the statement that persons of the male sex were attacked in greater number and with greater severity than females.

(6) The average duration of the attack (acute stage) was from three to five days.

(7) The predominant symptoms were mainly of three general groups, — nervous, catarrhal and enteric, the last being much less common than the others; the special symptoms most observed in the nervous group being extreme depression, pain and weakness; in the catarrhal group, cough, dyspepsia and coryza; and in the enteric group, nausea, vomiting and diarrhoea.

(8) The chief diseases which followed in the train of influenza, and were intimately associated with it, were bronchitis and pneumonia. Phthisis, when already existing in the victim of the attack, was undoubtedly aggravated; and, in many cases, a fatal termination was hastened.

(9) The ratio of persons attacked in industrial and other establishments employing large numbers was about 35.5 per cent., or less than that of the population at large. That of the inmates of public institutions was still less, -- 29 per cent.

(10) The ratio of persons who were obliged to leave their work on account of illness from influenza was about 27 per cent. of the whole number employed.

(11) The average length of their absence from work was five days.

(12) Special occupations do not appear to have had a marked effect in modifying the severity of the epidemic upon operatives in such occupations.

While the atmosphere may constitute one important medium of its communication, human intercourse also suggests itself as an equally important factor.

The board reprints, in this report, their circulars on infectious diseases and adds to the pages on health of towns an admirable sanitary survey of Lawrence.

The general expenses of the board were \$8,164.71; for food and drug inspection \$10,156.27; for water-supply and sewerage \$26,533.97, — a good indication of the public confidence in the value of their work.

MORTALITY VS. IMMORTALITY.

THE Supervising Surgeon-General of the United States Marine Hospital Service in a recent weekly abstract of sanitary reports, presents the following refreshing bit of information in the shape of a quotation from the *Monthly Bulletin of the State Board of Health of Iowa*, for June, 1890.

In 1880 the annual death-rate of Iowa was 16 per 1,000 of the living population. In 1885, with an increase of population of

225,297, the annual death-rate was 4.5 per 1,000 of the population. In 1890, with an estimated population of 2,193,477, an increase of 340,564, the annual death-rate is estimated at a fraction over 4 per 1,000. In 1883 it was only 3.7 per 1,000 of the population.

The records show that fully 70 per cent. of the total deaths in 1880-81-82 were caused by contagious, and, therefore, preventable diseases. It was not till 1883 that the work of the State Board of Health began to realize. The saving of lives, therefore, through the sanitary and protective measures of the State Board is a record to be proud of. It is a record worthy the consideration of every thoughtful mind.

In the original report from which the above statement is quoted, the following data are also presented:

Cities.	Total deaths.	Population.	Death-rates.
Burlington	352	30,000	11.66
Clinton	228	17,000	1.3
Council Bluffs	229	35,000	0.66
Cedar Rapids	273	16,000	1.7
Davenport	438	33,715	12.99
Des Moines	438	58,000	0.75
Dubuque	327	25,000	0.28
Keokuk	142	13,151	12.99
Mt. Pleasant	65	1,500	4.3
Otumwa	169	16,000	0.94

The foregoing statistics are worthy of the genius of a Squeers. The conventional mode of expressing a death-rate is as a ratio per one thousand of the living population. The go-as-you-please method of the Iowa Board of Health can hardly be recommended for general adoption. Mortality is the common lot of all mankind and it is quite plain that there is such a condition as a healthy, or, to use a better term, a normal standard as a mortality-rate for a given community or population. By this is not meant the mortality-rate of selected classes. That of a carefully-managed life insurance company, for example, is usually low, since the aggregate mass of individuals included is made up of selected persons, of the vigorous, healthy period of life; the weak and feeble and diseased, and all below a certain age of life, and all those of old age being rejected.

The very lowest imaginary mortality-rate which Dr. Richardson hoped to attain in his typically sanitary Utopia (the Hygeian city of absolutely perfect conditions), was five per one thousand annually. No one, however, pretends that such a rate has ever been attained in any human population made up of persons of both sexes, of all ages of life. In his census volumes upon the mortality of the United States for 1880, Dr. Billings gives the rate for certain Western States as follows:

Arizona	7.20 per 1,000
Colorado	13.1 " "
Dakota	9.65 "
Minnesota	11.57 "
Montana	8.58 "
Oregon	10.67 "
Wisconsin	12.37 "
Iowa	11.93 "

These rates were estimated from the returns of the enumerators in the census year 1880, and the marked differences which they exhibited were not attributed to sanitation, but to other circumstances and conditions which usually control the mortality-rate in new communities. Arizona, Dakota and Montana, for example, had very low death-rates, since their population was made up mainly of young and vigorous emigrants from

the age of twenty to fifty, a class in which the death-rate is habitually low. The very young and the very old, among whom the death-rate is high, were greatly in the minority. Again, the sex distribution in these new States is very unequal, the ratio of males to females in Arizona, being as seven to three; in Dakota as eight to five, and in Montana as twenty-eight to eleven. With such a very unequal distribution in temperate climates, the birth-rate as well as the death-rate is usually low. In an older and well-settled State like Iowa, however, with a population of about two millions, in which the age-distribution as well as the sex-distribution (males eighty-five to females seventy-eight), are more like those of the older States, an estimated mortality of even 11.9 per one thousand in a census year must be considered as below the actual rate. It is safe to say, that all of the above rates are probably less than the actual rates, since some, if not all, of the States named have not at any time had a thorough system of registration.

The mortality of city populations, large and small, in the United States, may be stated with few exceptions, as from eighteen per thousand upwards; and for rural populations in well-settled districts, as from eleven per thousand and upwards. But when such figures as 3.07 per thousand for a single year for a population of about two millions are quoted, it is time to call for a recount of the ballots, and to inquire what are the sources from which such an estimate is made. It is not strange that such claims are made by a Western State; but when the head of a department which assumes to itself much of the sanitary care of the nation, and is supposed to be an authority in vital statistics, publishes such data seriously as a contribution to the vital statistics of the country, we would respectfully call them in question.

We do not intend to convey the impression that sanitation is useless in its influence upon mortality-rates; far from it. The effect of hygienic measures in lowering the death-rate, especially in large and densely populated cities, by thorough sanitary work, is beyond question, as was shown by the Ninth Report of the Privy Council of England; but when it comes to a reduction of three hundred or four hundred per cent., with a resulting death-rate of 3.07 per thousand, the data are simply reduced to an absurdity, and the field of public hygiene is exchanged for that of Munchausenism. The aim of the sanitarian is, and should be, to prolong life, to prevent disease, and reduce mortality-rates to their lowest terms; but that any community of human beings like that of Iowa has ever been brought by public sanitation so near to the goal of immortality (or zero per thousand) as 3.07, cannot be regarded as within the sphere of human attainment.

PHYSICAL TRAINING IN THE BOSTON PUBLIC SCHOOLS.

THERE is every reason to believe that we shall soon have in the Boston public schools an excellent system of physical training. The school committee has taken

the matter in hand, and a special committee has been hard at work on the subject. To furnish instruction which shall be both intelligent and systematic to a large number of public schools is not an easy task, but the committee has gone to work in the right way in selecting a competent man, and giving him a responsible position and complete control of details.

An office of Director of Physical Training, has been created, with a salary of \$3,000, and the committee has appointed to the position Dr. Edward M. Hartwell, who, for some time, has been connected with a similar department in the Johns Hopkins University, and who, by his education and experience, is exceptionally well-fitted for the work. He will enter upon his duties on the first of January, and after he has outlined his work will be given the requisite number of assistants.

The system adopted for the public schools is essentially the Ling or Swedish system, which, as recently explained by William M. Mowry, chairman on the committee on physical training, possesses the following advantages: It is a system fully elaborated and tested by more than half a century; it is admirably progressive, both as regards the day's order and the needs of the various grades, from the lowest primary to the high school; it is evidently designed to make healthy children and not to train athletes; it is well calculated to aid in discipline, since words of command take the place of music; it thus gives opportunity for the teacher to make suggestions and to give individual instruction; it devotes so much attention to the standing position and carriage of the pupils; the exercises are selected for beneficial ends and not simply because they are pretty; there is great freedom from liability to produce injurious effects; it is cheap, since no apparatus is essential for a time, at least; there is such an infinite variety of exercises that pupils do not tire of them.

SURGICAL TREATMENT OF APPENDICITIS.

At the meeting of the *Société de Chirurgie*, October 15, 1890, Berger reported four cases of appendicitis occurring in his practice; on all laparotomy was performed; three died, one recovered. The cause of the failure in the three first cases was, he thinks, due solely to the fact of the tardiness of the operation; surgical intervention, to be successful, he says, should be early. He inclines to the belief that perityphlitis may sometimes exist apart from appendicitis, and this is in accordance with the conclusions to which Schuchard of Stettin, has arrived as a result of several careful observations; these were nine in number, of perityphlitis without lesion of the appendix, and were reported by him at the last Berlin Congress.

MEDICAL NOTES.

— Surgeon-General Hamilton of the Marine Hospital, in a special report to Secretary Windom on the subject of immigration, takes a decided ground against

the existing immigration law, and makes a strong argument for its modification. The restriction of immigration, he says, is one of the most important questions which could be discussed in Congress; and he almost favors the total prohibition of immigration.

— Surgeon-General Jedediah H. Baxter of the United States Army is suffering from a recent attack of cerebral hemorrhage, followed by hemiplegia. The present indications are that he will hardly recover.

— A physician in Chicago was nearly mobbed by an excited crowd a few days ago for declining to attend an accident in his neighborhood until he was assured that he would be paid. He said that he had already done enough of that kind of work for nothing.

— The Southern Medical Society in Atlanta, has recently elected to honorary membership a boy phenomenon, who though only five years old, has already acquired a knowledge of anatomy which is fully equal to that of most graduates of medicine. He is a regular attendant upon the anatomical lectures at the Southern Medical College, though he is himself, at present, a matriculate of the kindergarten department of a local academy, where we are informed that his long golden curls, rosy cheeks, intelligent blue eyes, and amiable disposition make him a general favorite.

— It has been officially announced that the emperor has conferred the grand cross of the order of the Red Eagle upon Professor Koch. This is the first time that this decoration has been bestowed upon any one who did not possess the preceding classes of the order.

— Baron Nathaniel Rothschild, of Vienna, has been undergoing the famous nerve-cure of Father Kneip at the village of Waerhofen, near Munich. This cure, which lasts twenty-one days, consists in walking about barefooted, taking daily baths in icy cold water, and a diet of milk and vegetables.

— Recent deaths in the profession abroad: Professor Nasabbaum, surgeon in the University of Munich, aged sixty-one years. Dr. Alfred Vogel, Professor of Children's Diseases in the University of Munich, aged sixty-two. In Paris, Gustave Monod, formerly a professor of the Faculty of Medicine, aged eighty-six.

— The jubilee of Professor Virchow will be celebrated in Berlin next year with considerable ceremony. A committee has been formed under the presidency of Professor Waldeyer, and it is proposed to strike a medal in commemoration of the event. Pathologists all over the world will be eager to join their German brethren in congratulating Professor Virchow on attaining his fiftieth year as a scientific worker, and on still retaining to the full the industry and the fire which won for him renown at an early age, and still continue to earn for him ever fresh honors in many fields of scientific activity.

BOSTON AND NEW ENGLAND.

— During the past year the volunteer visitors of the Associated Charities visited 2,037 families: while, in addition to this, the co-operative efforts of agents

and visitors dealt with 1,980 other families. The table of the nativity of the applicants shows that thirty-two per cent. were born in the United States, nearly thirty-seven per cent. in Ireland and twelve per cent. in Canada.

— During the year ending September 30th, the Boston Provident Association aided 1,870 families, of which 1,311 were foreign. A large amount of coal, groceries, clothing and other necessities were distributed.

— The Boston Dispensary is in need of old cotton or linen cloth for surgical uses. Gifts will be sent for may be left at the central office, corner of Bennett and Ash Streets.

— A suit for alleged malpractice has been brought against the estate of a doctor in Ipswich who has been dead for two years. The plaintiff had his arm amputated some years ago, and has lately been obliged to have a re-amputation on account of a painful stump. He now brings a suit for \$20,000 damages, on the ground that the original operation was unskillfully performed.

— The class which graduated from the medical department of Dartmouth College on November 25th was the largest in the history of the institution. Of the twenty-nine students who received the degree of M.D., nine had previously received the degree of A.B. from some accredited college.

NEW YORK.

— At the annual meeting of the Children's Aid Society, the noble charity founded by the late Charles Loring Brace, it was stated that among the more than 100,000 boys, who, during the last thirty-six years have been in the Newsboys' Lodging House, there has been no case of any contagious or "foul-air" disease, and only one death from pneumonia (in 1858) has occurred. The other lodging houses have been almost equally fortunate — a distinct sanitary result of scrupulous cleanliness, ventilation and good food. Among the boys and girls in the lodging houses in the past year, no deaths occurred. There were during the year 12,252 different boys and girls, and 293,767 meals and 220,001 lodgings were supplied; 1,287 were aided with attendance, food and medicine through the Sick Children's Mission; 4,574 enjoyed the benefits of the Summer Home at Bath, Long Island, (averaging about 300 per week), and 4,721 mothers and sick infants were sent to the Health Home at Coney Island.

— At the last meeting of the Medical Society of the County of New York, Dr. Richard Kalish read a paper on "The Resorption of Immature Cataract," in which he claimed to have made a number of cures without operation, by a method devised by him, by using an instillation of a mixture of glycerine and boric acid solution. In the discussion which followed, the paper, Drs. H. D. Noyes, David Webster, and H. Knapp expressed their scepticism of the results stated by Dr. Kalish, which they contended were not substantiated by sufficient evidence. On the same evening

addresses were made by the retiring president, Dr. Alexander Hunter, and the President-elect, Dr. O. B. Douglas.

— The first regular meeting of the Women's Auxiliary of the Hospital Saturday and Sunday Association since its organization, was held November 25th, when eighteen committees of ladies were appointed to carry on the work of the Association among the different branches of retail trade. Through this agency it is expected that at least \$10,000 will be added to the fund collected in the usual way.

— The Society for the Improvement of the Condition of the Poor, has devised a scheme for free baths for the poor, similar to one now in use in Vienna, and which has the approval of the State Charities Aid Association and the County Medical Society. It proposes to erect first a building near Centre Market, with shower baths arranged so that the water will flow off at once. One thousand persons a day can be accommodated, and there will be one section of the building for those who can pay five cents for a bath, and another for those who cannot pay anything. A large part of the funds required for this experimental bath-house has already been contributed.

— On Thanksgiving Day, the twenty-second of his fast, Succi regaled himself with five ounces of Croton water and twenty ounces of mineral water. His weight was 119½ pounds, as against 147½ pounds when he began his long fast. The dynamometer registered 52 and the spirometer 1,575.

Miscellany.

PROFESSOR KOCH'S SUBCUTANEOUS SYRINGE.

THIS syringe consists of a graduated glass cylinder with a conical glass point ground to fit a hollow needle; and a hollow rubber ball, to which is fitted a stop-cock. To fill the syringe it is taken apart, and the cylinder

filled from the upper end, after which the upper half is fitted on. The stop-cock remains closed until the needle is under the skin and everything ready, when the injection is made by squeezing the bulb. The syringe is made by E. Kraus, Kommandanten-Str. 55, Berlin, S.

KOCH'S LYMPH.

ACCORDING to recent dispatches from Berlin, the German government has furnished Koch with a large amount of money to aid in carrying on his investigations. The government expects to take charge of the manufacture of the lymph, and has requested Koch not

to publish the method of preparation, so as to render its imitation impossible. Koch says that if improperly made, serious results might be caused by its injection. There are now seven hundred and fifty patients under treatment. Five have died after the injection of the lymph, one a soldier who was being treated for lupus. The rumor that exorbitant prices were being charged by the few who have access to the lymph, is denied by some of them, but there is no doubt that the supply is very limited, and that for the present, at least, it is absolutely useless to send patients to Berlin. There are already over two thousand doctors in the city, and more on the way, many of them from America. One of the hospitals has already refused the application of four hundred physicians who wished to study the method of treatment. A physician starting now, and in fact, many who are already well on their way, unless they possess exceptional influence, will have no better advantages for investigation than if they stayed at home.

FACIAL ERYSIPelas.

ALTHOUGH it is well known that erysipelas of the face often arises from a point of infection inside of the nose, it very often happens, as Lehrbecher¹ has pointed out that in the treatment of the disease, little or no attention is given to the nasal cavity. It is sometimes wonderful what a mass of thick, bloody, bad-smelling pus can be washed out of the nostril. A nasal douche of three per cent. boracic acid solution should be given every three hours, until the cavity appears to be perfectly sterilized, after which, to prevent drying of the mucous membrane, tampons with boracic acid ointment should be inserted. With these precautions the author has found that the duration and severity of the disease are much diminished. He applies nothing to the skin except cotton-batting or an oil compress.

HYPNAL.

THE following conclusions are given by Frankel,² as the result of a study of the drug, and a trial in a variety of cases in the clinic of Dujardin-Beaumetz. Mono-chloral antipyrin, or hypnal, is a well-defined chemical combination, is less soluble than either chloral or antipyrin, but is broken up into these two substances in a weakly alkaline solution, consequently in the intestines and the blood. It has no smell and almost no taste. It is both a hypnotic and an analgesic, the hypnotic power of the chloral being increased by the action of the antipyrin on the nervous system. It is especially useful in sleeplessness due to pain. The dose is from a half to a third less than chloral. It is not very soluble in cold water, but becomes more so on the addition of a little alcohol, or it may be given in capsules, containing five grains each. It is seldom necessary to give more than fifteen grains. The drug produces its effect in from half an hour to an hour.

At the meeting of the Société de Biologie, Drs. Quinquaud and Schmidt³ stated, as the result of their investigations, that they had found that the mono-chloral antipyrin possessed the advantages over chloral of more

ready administration and more marked hypnotic effects, with less marked action on the circulation. They were not, however, prepared to make any definite statements as to the analgesic properties of this compound.

PYOGENIC MATERIAL WITHIN BACTERIAL CELLS.

CONSIDERING the fact that chemical substances and sterilized bacteria cultures produce suppuration without the growth of organisms, Buchner⁴ made investigations with the Friedlander pneumonia bacillus, and proved the existence within the cells of an albuminoid matter, capable of producing suppuration. The bacterial cell must be broken up before this substance is set free. It is not found in the filtrate of cultures or in the nutrient material. The author concludes that in the tissues suppuration does not occur until some of the bacteria are destroyed. By coloring with methyl violet, this pyogenic material can be made innocuous while inside the bacterial cell.

THE MICRO-ORGANISMS OF STANDING WATER.

DRS. SCALA and Alessi⁵ have completed a series of experiments demonstrating that micro-organisms multiply in standing water, at the expense of the organic matter liberated in the water, this multiplication being but slightly influenced by a temperature a little above zero. They note the fact that micro-organisms diminish in water charged with carbonic acid. After demonstrating that light, movement, pressure, and cold have no influence on these micro-organisms, they experimented directly with carbonic acid, their experiments, resulting in the proof of the lethal action of carbonic acid on the micro-organisms of water. This action they consider analogous to that by which other ferments die in liquids produced by themselves.

A ROAD-HELP FOR THE COUNTRY DOCTOR.

No one suffers more than the country doctor from the lack of system which almost universally prevails in thinly-settled districts in naming roads and describing the location of houses. Most roads have no names, or are simply known by some such title as the Newtown Turnpike, or Mill-Village Road. They may be several miles long, and the better part of a day may be lost in hunting for a house on one of them.

Dr. Samuel O. L. Potter, in the *Occidental Medical Times* for November, describes the "Ten-Block system," recently devised by Mr. A. L. Bancroft to solve the question in a county of California. Some such system could, with very little modification, be made applicable to any part of the country.

According to Mr. Bancroft's "Ten-Block System," every road is divided into blocks of ten to the mile; each block, therefore, being 528 feet, or 176 yards, or 8 chains, in length of road frontage. Two house-

³ Therapeutic Gazette, September 15, 1890.

⁴ Berlin Klin. Wochenschrift, No. 36, 1890, and Centralblatt für Chirurg., No. 43, 1890.

⁵ Translated for the Marine Hospital Bureau from La Rivista Internazionale d'Igiene, August, 1890.

numbers are assigned to each block, one on each side of the road. Every house in a block is given the number of that block; the first one having the number only, the others being distinguished by the letters of the alphabet in addition, as 96, 96a, 96b, 96c, etc. The numbers thus arranged indicate the distance of the house from the beginning of the road. As there are two numbers to each block, and ten blocks to the mile, to get the distance in miles, the number of the house is divided by 2 and again by 10; thus, 96 divided by 2 gives 48, and this divided by 10 gives 4.8 miles, as the distance of the house No. 96 from the beginning of the road.

With such a system, all that would be necessary, to find at a glance the exact situation of any house, would be a small hand-book, with or without a map, giving the point of beginning of each road, either from a town, or from a number on some other road, and the numbers at the intersections of roads.

TREATMENT OF GONORRHEA.

THE following methods of treatment of gonorrhœa are collected from the *Deutsche Medizinal Zeitung*, Nos. 83 and 85, 1890.

Friedheim¹ made a careful investigation of the effects of different injections in the dermatological clinic at Breslau. Of mercurial agents the best is hydrargyri salicylate 1-270. The common astringents, zinc and lead salts, tannin and subnitrate of bismuth, have no antiseptic properties, and should not be used during the acute stage of the disease. Boracic acid, antipyrine, resorcin, salicylate of sodium, often influence the inflammation favorably, but are useless as germicides. He uses in the first stages a weak solution of nitrate of silver, about one to three thousand, four to six times a day, later, some milder agent.

Diday uses an injection of nitrate of silver solution, 1-20, and allows it to remain in the urethra from fifteen seconds to two minutes, according to the amount of pain. Picard believes that nitrate of silver will abort a gonorrhœa, and is harmless if given before pus appears; after that it may do harm.

O'Brien² uses injections of sea-water seven or eight times a day in the acute stage.

An injection given by Impamplimenti, consists of a one per cent. solution of creosote in an infusion of camomile, with a little boracic acid added.

Pyoktanin has been used by several observers with good results.

The ointment-carrying sound of Unna is recommended by several authors for chronic gonorrhœa. Szadek uses an ointment containing nitrate of silver one per cent., and balsam of Peru two per cent. Sperling and Bender nitrate of silver one per cent. in lanolin. The sound remains at first three, later fifteen minutes in the urethra. For the second stage Lewis uses an ointment with lanolin as a base, and a non-irritating antiseptic, such as resorcin, four per cent.

Allen³ calls attention to the use of the endoscope, through which a cotton-stick may be used, as a method of application to the urethral mucous membrane.

Internally, Lane⁴ obtained good results in sixty

per cent. of his cases in from two to seven days, with salol, in doses of from five to fifteen grains, three times a day. In chronic cases injections also must be employed. Dreyfous uses salol at the same time with the balsamic remedies.

Bird has obtained good results by the internal administration of calomel.

Stern⁵ recommends a thorough washing of the body in the neighborhood of the genitals, and the patient's clothes, with a one to two hundred solution of corrosive sublimate, to prevent an auto-inoculation, which he considers a common cause of recurrence of gonorrhœal symptoms, and of so-called chronic gonorrhœa.

Correspondence.

[From a Special Correspondent.]

LETTER FROM ITALY.

TURIN, October, 1890.

SOME ITALIAN ASYLUMS.

MR. EDITOR:—Any one who is at all acquainted with recent Italian medical literature, and with the many journals of nervous and mental disease published in Italy, is aware of the large amount of admirable work done in the field of psychiatry, experimental psychology and neuro-pathology by the Italian alienists and neurologists, but I must own that I was surprised to find their asylums so complete in all the requisites, not only for the comfort and care of the insane, but also for scientific study and experimental research in the field of neurology. The palatial asylums in this country, on which we pride ourselves, afford no such baths and douches for the administration of every variety of balneotherapy as are seen in all the asylums in Italy; and the space allotted, even in the smaller city asylums, to the pathological laboratory, where every facility for experimental and pathological work is given, is superior to that found even in many medical schools in this country.

One of the newest and finest asylums in Italy is that just outside the walls of the little town of Imola, half-way between Ravenna and Bologna. The medical director is Dr. Giuseppe Seppilli, who, although still a young man, is well-known from many important contributions to neurological literature, among them his joint labor with Luciani in the field of cerebral localization, and his admirable monograph on cerebral tumors in the great Italian cyclopaedia of nervous diseases — "Il Sistema Nervoso Centrale" — now in course of publication. There are in Imola two asylums, one for acute and curable cases, with about six hundred patients; and an asylum for incurables, with about four hundred patients, a little farther away on the other side of the town. The former, which I visited, was built some years ago from plans drawn up by the present business director — the asylum having two directors, medical and business, which, in this instance at least, seems to cause no friction. It consists of a group of independent buildings, arranged about a square, and connected by long porticos open on one side to the weather. Several courtyards give opportunity for out-door exercise and recreation for the different classes of patients, which can thus be kept separate. The classification employed is substantially that of Esquiro; separate buildings affording wards for the quiet, the demented, the epileptic and paralytic, the semi-agitated, the agitated, and the furious of each sex. In addition there is another building used as an infirmary, and, of course, the various buildings for the administrative department. The wards were large, with abundance of light and air. Heat — a problem less important than with us — is supplied, when necessary, by stoves. The patients, as a rule, sleep in dormitories, supplied with the regulation

hospital iron bed, with the wire-woven mattress, which seems to find as much favor in Italy as with us. "No restraint" is accepted only with modifications. Dr. Seppilli holds that absolute "no restraint" by mechanical means often means chemical restraint by hypnotics, and that a camisole is frequently less injurious than large doses of morphine. The amount of actual restraint, however, was slight, and consisted only in the use of the camisole or confinement in bed or in a separate room. One feature of the single rooms for excited patients which I saw in several asylums, notably in Bologna, struck me as possessing various advantages, especially in a mild climate. The rooms opened on one side on a corridor, and were closed by ordinary doors provided with the "Judas" for observation of the inmates. On the other side they opened on a court-yard, separate from any of the airing courts, by a wide door, which could be closed at will by a grating, by glass, or by heavy wooden shutters, thus providing for the admission of light and air, either combined or separately. In addition to the dormitories, there are, of course, day-rooms, rooms for reading, billiards, etc., where the patients can have facilities for such recreation and work as they are able to indulge in. The kitchen and store-rooms gave proof that the diet afforded was excellent, and the vineyards had afforded the patients a good supply of grapes. The bath-rooms, as is the custom, were fitted with the ordinary tubs, and also with every variety of douches, similar to those of La Salpêtrière. The administration building contained several rooms, supplied with all facilities for pathological and experimental work, and a reading-room containing files of most of the leading neurological journals.

A little farther from Bologna, in the opposite direction from Imola, lies the town of Reggio, in Emilia. Some two miles to the south of it, straight out on the old Emilian way, is the asylum of Reggio, founded, in 1536, as a refuge for the sick, but since 1822 used as an asylum for the insane. The director is Professor Tamburini, president of the Società Freniatrica Italiana last year, and the editor of the *Rivista Sperimentale di Frenatria*, one of the leading Italian alienists, who is soon, I understand, to go to Florence to take charge of the new asylum just opened there. The plan of this asylum is entirely different from that of Imola, the colony system prevailing, the buildings being scattered about over a large farm, which supplies the asylum with its products, and gives an opportunity for work for the patients. Lack of time prevented a visit to the more distant buildings, but I had an opportunity to see the administrative department and some of the female wards. At the asylum is published the *Rivista*, so in the administration building is a large room devoted to the editorial department of the journal and containing the files of its exchanges. Beyond it are several large and well-lighted rooms for the pathological department, under the care of Dr. Vassale, where, not only post-mortem researches are conducted, but experimental research is carried on. I examined various interesting specimens of spinal cords, one case of syringo-myelia, and several interesting specimens showing the changes in pellagra, mentioned in my last letter, and had an opportunity to observe the convulsions in a dog who had been deprived of his thyroid. In another room were various instruments for the examination of patients, among them the apparatus for testing the time reactions devised by the lamented Buccola, a former assistant here, whose early death removed one of the most brilliant workers in the field of psychology. The laundry was supplied with all modern requirements, rotary steam wringers, drying-rooms, and washing machines; the kitchen and larder gave evidence that the diet of the patients was abundant and well-cooked; and the *cantina*, with its long vault filled with hogheads of wine for the use of the patients, was an unusual addition to one accustomed to American ideas.

The sight of an interesting case of hysterical somnolence led me to inquire as to the present opinion in Italy in regard to hypnotism, especially as the work done by Tamburini and Seppilli on the subject has been thoroughly scientific and exhaustive, and must outweigh much of the

careless and fallacious observations of certain enthusiasts. As a therapeutic measure I found that it was held in slight esteem. Its applicability in insanity was, of course, regarded as *nil*, but the physicians at Reggio had observed that even in hysteria, although hypnotism would sometimes remove the particular hysterical symptom, paralysis, contracture or anesthesia, it not infrequently induced chronic mental disturbances which proved permanent. In Turin, later, I saw in the asylum a medical student, previously well, suffering from hystero-epilepsy brought on by repeated hypnotizing.

The asylums at Reggio and Imola are the asylums for the provinces in which they are situated, and are in part supported by the government. The average cost per patient is from one and a half to two francs a day. A portion of the patients, however, pay board; at Reggio, for instance, there are three classes of patients, the classification being based upon the amount paid, and the cost of maintenance being, of course, somewhat greater for the first class than for the second; the first class having larger rooms, by themselves, with better furniture and surroundings, while the third class, when the cases are suitable, sleep in dormitories. At Reggio the men who are able assist in the farm work, while the women are employed in sewing, knitting, weaving, etc. I saw several of them at work on the old-fashioned hand-looms, weaving cloth for garments for the patients.

Of the city asylums, I visited those of Bologna and Turin. The former, under the charge of Professor Roncato of the University, is in an old sixteenth-century convent, just within the city wall, and commanding a beautiful view of the hills and the church of Madonna di San Luca; I have already spoken of the arrangement of the isolated rooms, but otherwise there is nothing differing materially from other asylums. At Turin the arrangement of the epileptic wards was of some interest. The furniture in the day-rooms was carefully padded, to prevent injury to the patients in falling, and the sides of the beds were made of woven wire, like the mattresses, to prevent injury should the patient have a seizure in bed. I have already spoken of the study of the muscular strength in pellagra now in progress there, and I had the opportunity of seeing one or two cases of pellagraous insanity. In all the asylums I found complete equipment, thorough neatness, excellent care, and a zeal in scientific work which has added greatly to the world's knowledge, and which has shown that Italy is fully abreast of other countries in the domain of medical science.

P. C. K.

THE CLAIM THAT THE MERIT OF INTRODUCING ETHER BELONGS TO THE LATE DR. HENRY J. BIGELOW.

BOSTON, November 29, 1890.

MR. EDITOR:—When a distinguished man dies it is but natural that many things should be said in his praise which will not bear too rigid an examination, and it shows both good feeling and good taste for those who dissent to hold their peace. Nevertheless, if claims are made for the departed at the expense of others no longer here, it is not only the right, but the duty, of their descendants to see that justice is done.

At the recent meeting of the Society for Medical Improvement held in honor of the late Dr. Henry J. Bigelow, and in separate articles which appear in the last number of the JOURNAL, the claim is repeatedly made, more or less outspokenly, and there is a manifest intention to give the impression, that Dr. Bigelow was the surgeon who introduced Morton's discovery of ether. The speakers and writers were, for the most part, the particular friends of Dr. Bigelow, and it is but right and proper that they should manifest the gratitude which many of them owed him, but this must not be done to the prejudice of others. It is stated that Dr. Bigelow aided and abetted Morton in his experiments with ether inhalation in a way to lead one to infer that by so doing he had a share in the discovery, but the fact is that

this was after the successful public trial. Morton brought his discovery to Dr. John C. Warren, then senior surgeon of the hospital, as Wells had done before him. Dr. Bigelow himself wrote in his "History of the Discovery of Anesthesia": "Dr. Warren was the principal New England surgeon of the day and it was the obvious thing to do."

Great stress is laid on the fact that Dr. Bigelow was the first to announce to the world the discovery of modern anesthesia. Let us look at the circumstances. The first surgical operation under ether was performed at the hospital by Dr. Warren on October 16, 1846, and the second on the next day by Dr. Hayward at Dr. Warren's invitation. Each of these gentlemen gave Dr. Morton a certificate a day or two later to the effect that they had operated successfully with his invention. Then came a pause, owing to the natural aversion of the surgeons to the use of a secret remedy of unknown composition which they were not allowed to administer themselves. Matters were adjusted about November 6th. Dr. Bigelow, then a young man of twenty-seven, recently appointed to the hospital, announced the discovery before the Academy of Arts and Sciences on November 3d. Let it be noted that, so far, there had been but two operations at the hospital, neither a capital one, and none in private practice (Dr. J. Mason Warren performed the first successful one on November 12th); that with neither of these Dr. Bigelow was concerned; and that besides these he had seen only some dental operations by Dr. Morton. The only report of this paper in the Proceedings of the Academy is the following: "Dr. Henry J. Bigelow gave some account of a new process of inhalation employed by Dr. Morton, of Boston, to produce insensibility to pain during the performance of operations by the dentist and the surgeon."

The paper, enlarged by the addition of new cases, *none of them Dr. Bigelow's*, was read before the Society for Medical Improvement, November 9th, and published in this JOURNAL November 18th. On December 3d Dr. Warren published in this JOURNAL a sober, judicial report of what had been done. This may properly be called the first authoritative statement of the subject, after the certificates.

Of the many astonishing assertions made at the late meeting of the Improvement Society, the most so is that by Dr. R. M. Hodges, who, after alluding to "timidity or jealousy" on the part of Dr. Bigelow's seniors, declares that but for him "the primary honor of introducing the great discovery would probably have been diverted from the Massachusetts General Hospital, and from the city of Boston to some more progressive institution and a more enlightened community." It is rather late, forty-four years after the event, to bring such a charge; but if the well-known account of the first operation is not enough, a sufficient answer is at hand in the remarks by Dr. Oliver Wendell Holmes, before the Suffolk District Medical Society, on the occasion of the death of Dr. Warren in 1856: "He had reached the age when men have long ceased to be called upon for military duty; when those who have labored during their days of strength are expected to repose; and when the mind is thought to have lost its aptitude for innovating knowledge, and to live on its accumulated stores. Yet nothing could surpass the eagerness with which he watched and assisted in the development of the newly discovered powers of etherization. It is much for any name to be associated with the triumphs of that beneficent discovery; but when we remember the reproach cast upon Harvey's contemporaries, that none of them past middle age would accept his new doctrine of the circulation, we confess it to have been a noble sight when an old man was found among the foremost to proclaim the great fact — strangely unwelcome, as well as improbable, to some who should have been foremost to accept it — that pain was no longer the master, but the servant of the body." A year after the discovery of ether Dr. Warren published his book on "Etherization," giving as one of his reasons for so doing, "the slow progress of the practice of etherization in this country, beyond the vicinity of its first introduction, compared with its rapid extension on the other side of the Atlantic."

Let me say most sincerely, in conclusion, that nothing is further from my purpose than to disparage the services which Dr. Bigelow rendered to the cause of anesthesia by ether, both in its earlier and its later days. I well remember the help he gave me more than once in this matter when I was one of the editors of this JOURNAL. What I protest against is the claim that he was practically the only surgeon who has a right to the remembrance of posterity for the introduction of ether. This, I believe, is unjust to others, indeed to several, but above all to Dr. John C. Warren.

Dr. Bigelow died laden with well-won honors. He needs no laurels not his own. Very truly yours,

THOMAS DWIGHT, M.D.

DR. BIGELOW AND THE INTRODUCTION OF ETHER.

BOSTON, December 3, 1890.

MR. EDITOR: — In October, 1846, it was the fortune and great privilege of the writer, being then a student of the Harvard Medical College, to witness, at the Massachusetts General Hospital, the first capital operation ever performed under the influence of sulphuric ether, which was the greatest epoch in the science of medicine of all time.

Among the surgeons and students then present, I can well remember Dr. Morton, who administered the ether, and Dr. Charles T. Jackson, both of whom claimed the discovery. Also, Dr. John C. Warren, Dr. George Hayward, who performed the operation, Dr. Townsend, Dr. Cabot, and Dr. Henry J. Bigelow, and three or four students that I can call to mind, all of whom, surgeons and students, are now dead. Doubtless others are now living who were present, and I should be glad to know who they are.

Of all persons present, the form and face of the late Dr. Henry J. Bigelow, who, at twenty-eight years of age, had just returned from several years' residence in Paris, is fixed most strongly in my memory. He rivalled in beauty the Apollo, whose statue was always present in the old Amphitheatre under the dome. The operation was amputation at the thigh, for long-continued disease of the knee-joint. The recovery was unusually rapid, allaying the fears of some, then expressed, that so powerful an agent might have an unfavorable influence on recovery. It was then and there demonstrated that the most painful operation in surgery could be performed while the patient was in a deep and unconscious sleep.

Dr. Henry J. Bigelow probably did more than any other to make known to the world this great discovery which was to be tidings of great joy to all people.

The recent eulogies of the great surgeon and broad-minded genius, who did so much for the science of medicine and surgery and for the world, are eminently just, and touch a responsive chord in the breast of every one who knew him.

For near fifty years I have known him professionally and personally, always with admiration and gratitude, and feel his death as that of an old comrade in the army, whose gallantry, generalship and faithful service deserve immortality.

Very truly yours, PETER PINEO, M.D.

THE STUDY OF MUSHROOMS.

BOSTON, November 27, 1890.

MR. EDITOR: — An article on the study of Mushrooms published by you, under date of October 2d, has been brought to my notice. Had there been no reference to myself in its text, I should not have considered it my duty, as I do now, to declare that it is strangely incomplete. The only article of mine mentioned therein is the first and consequently the most inferior I have ever published. I therefore ask you to print the following references to later

and far more elaborate essays as reported on page 22 of the "Bibliography of North American Fungi," issued by the library of Harvard University, February, 1887.

Empoisonnement par les Champignons. Moniteur Scientifique, Paris, 1879.
Mushroom Toadstool Poisoning. [Copied from above.] Philadelphia, September 20, 1879. Medical and Surgical Reporter, D. G. Brinton, M.D.
Three Articles in Boston Medical and Surgical Journal of these dates, namely, August 28, 1879, November 6, 1879, September 20, 1883.
Annual Cyclopaedia. D. Appleton & Co. Vol. XXVI, 1886, page 540.

Dr. Brinton's numbers of the *Reporter* of December 12, and 19, 1885, contain an article by Charles McElvaine possessing great interest to medical men, and singularly confirmatory — by the detailed case there reported — of that which he had copied from the *Moniteur* six years previous.

My article written for "Appleton's" is couched in popular language, and in the opinion of those competent to judge, has been pronounced the most valuable ever published on the subject of esculent and poisonous fungi. It cannot be that the contributor to your columns was ignorant of the above references, as he was not only furnished with copies of them by me a year or two ago, but further, he has more recently been loaned two quarto volumes of correspondence extending back for fourteen years, from which

and my researches in the forests, my conclusions have been drawn.

Mr. W. G. Smith's work will be of still greater value, if in his new edition he should recognize the progress which has been made in the segregation of the Amanita family from other hurtful fungi. As now printed, his book is very far behind the two French works, whose titles I annex.

Les Champignons, par F. S. Cordier. Paris, J. Rothschild, 1876.
Des Champignons, par E. Boudier. Paris, J. B. Ballière et Fils, 1886.

The last-named is the Orfila Prize Essay, the most valuable contribution ever issued on the subject of which it treats; the work of Cordier is also far more valuable — providing a student is thoroughly acquainted with its idiom — than any work published in our language, and it was so noticed by me in the press at the time of its publication.

Your contributor has been kind enough to mention my work issued for popular instruction by L. Prang & Co., but critical enough to find fault with its nomenclature. If he had carefully studied and collated the various authorities — as I did years ago — he would agree with me that a uniform system of nomenclature is a desideratum, not yet attained.

Yours very truly,
 JULIUS A. PALMER, JR.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 22, 1890, TO NOVEMBER 28, 1890.

By direction of the Secretary of War, Captain CHARLES B. EWING, assistant surgeon, in addition to his present duties, is assigned to duty as examiner of recruits at St. Louis, Mo. S. O. 215, Part I, Headquarters of the Army, A. G. O., November 28, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 29, 1890.

M. H. CRAWFORD, passed assistant surgeon, ordered to the Recreying-ship "Independence."

E. H. MARSTELLER, passed assistant surgeon, ordered to the U. S. S. "Petrel."

FRANCIS S. NASH, passed assistant surgeon, resigned from the U. S. NAVY, to take effect November 23, 1890.

F. J. B. CORDEIRO, passed assistant surgeon, granted extension of leave for four months, with permission to leave the United States.

PHILIP LANSDALE (retired), medical director, granted one year's leave, with permission to leave the United States.

ADRIAN RICHARD ALFRED, commissioned an assistant surgeon in the United States Navy from November 24, 1890.

and Life Insurance," and Dr. J. B. Mattison, of Brooklyn, N. Y., on "Opium Addiction and its Relation to Life Insurance." Other leading physicians will participate in the discussion. The medical public are cordially invited.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, December 8, 1890, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Papers: Dr. J. Homans, "The Report of Two Cases of Pelvic Hematocele Treated by Incision per Vaginam"; Dr. M. H. Richardson, "Laparotomy for Cyst of the Pancreas."

Election of new members.

G. G. SEARS, M.D., *Secretary.*

AMERICAN PUBLIC HEALTH ASSOCIATION.—The eighteenth annual meeting will be held at Charleston, S. C., on December 16, 17, 18 and 19, 1890. Papers of great value and importance have been promised. Blank applications for membership may be had by addressing the Secretary, Dr. Irving A. Watson, Concord, N. H.; also any information relative to the Association will be cheerfully given.

CORRECTION.

In the JOURNAL of September 18th, page 282, in the article on the "Use of Skin from Puppies in Skin Grafting," the name of Mr. Alexander Miles was spelt Milro, the error having been copied from the *Annals of Surgery*.

BOOKS AND PAMPHLETS RECEIVED.

Differentiation in Rheumatic Diseases (so-called). By Hugh Lane, L.R.C.P., etc. London. Reprint. 1890.

INEBRIETY AND LIFE INSURANCE.

The American Association for the Study and Cure of Inebriety will hold the first of a series of monthly meetings, at the Hall of the New York Academy of Medicine, on 43rd Street, December 10th, at 8 P. M.

The subject of the evening will be presented by papers from Dr. T. D. Crothers, of Hartford, Conn., on "Alcoholic Inebriety

Original Articles.

APPENDICITIS.¹

BY GEORGE W. GAY, M.D.,
Surgeon to the Boston City Hospital.

A SOMEWHAT extensive experience in laparotomy for appendicitis and other forms of local peritoneal inflammation would lead me to make three general divisions of the cases, as regards their clinical features.

The first class would include the violent cases, in which the symptoms are alarming from their onset, and in which the patient is in extreme danger in the earliest stage of the affection, or, at the latest, on the second or third day.

The second division would include those cases in which the attack is less severe and the progress of events less rapid, but in which suppuration finally occurs at the end of one or two weeks, or later. While in many of these cases the pus will in time find exit for itself, yet a reasonable operation for its removal will save time, suffering, and a certain amount of danger.

And, finally, there are numerous instances in which the symptoms are comparatively mild from the first, in which there may or may not be a tumor, and in which little danger is to be apprehended. These cases terminate in resolution, but, like those in the preceding class, they are liable to recurrence.

As regards treatment, it may be said briefly, that cases of the first class demand early operation; those in the second division call for rest, opium, leeches and poultices, and finally incisions, while the milder cases can be safely managed by non-operative measures.

With your permission I will very briefly refer to a few cases, which will serve to illustrate the above classification, as well as some others of general peritonitis in which laparotomy was resorted to without any beneficial result.

FIRST CLASS.

A policeman, about forty years of age, a patient of Dr. E. J. Forster, was seized with a moderately severe pain in the belly a few hours after eating heartily of canned lobster. Dr. Forster saw him on the second day, and called consultation at once. The abdomen was moderately distended, no flatus having been passed. A space not over two inches in diameter, situated in the right iliac region, was exquisitely tender. Laparotomy was done the next day, the incision being made over the tender spot above mentioned. Fecid pus, adherent intestines, and an enlarged and perforated appendix were readily found. On passing a probe into the hole in the appendix a hard substance was detected, which, on being removed, appeared to be a piece of solder about a third of an inch long. The appendix, which was about half an inch in diameter, was ligatured and cut off. The wound was closed around a drainage-tube. There were no symptoms of collapse either before or after the incisions. The patient was apparently neither benefited nor harmed by the operation. The symptoms of general peritonitis went steadily forward, and death occurred in about thirty hours after the operation, or on the fifth day of the disease.

The progress of this case was much like that of a

¹ Read before the Roxbury Society for Medical Improvement, October 23, 1890.

boy, who was under my care many years ago, before treatment by incision was in vogue. The symptoms were violent pain in right side of belly, vomiting, constipation, delirium and death in six days. An autopsy revealed general peritonitis arising from a perforated appendix, containing several small concretions of inspissated feces.

A young man was sent to the hospital by Dr. Coffin, on the third day of his illness. Without any known cause he had been seized with severe pain in the right iliac region, followed by vomiting, fever and chills. The belly was moderately distended. There was no lump to be felt in the lower right corner, but it was extremely tender, and there was distinct dulness on percussion, and marked resistance to pressure. An incision was made at once at the place indicated by the tenderness. A moderate amount of fetid pus was evacuated, but no foreign body was found, nor was the appendix seen. The adhesions of the intestines were broken up to a moderate extent in our efforts to find the appendix, but the search was not prolonged over five minutes. A drainage-tube was inserted. The discharge had nearly ceased in twenty-four hours. The wound was closed in a week, and the man was well in three weeks, and two years later was at work upon the horse-car. He has thus far had no recurrence, so far as we know.

SECOND CLASS.

A gentleman, about forty years of age, was seized with symptoms of acute indigestion a few hours after eating moderately of popped corn. The pain increased gradually, but it was not attended by much vomiting, nor were there any symptoms of collapse. At the end of a week there was fever, tympanites, tender abdomen, restlessness, imperfectly controlled by opium, and a firm, indurated area in right iliac region extending above the crest of the ilium. The symptoms were steadily progressing in the wrong direction. An incision was made above the crest of the ilium in the loin, and carried down through the muscles and fascia into an abscess, which extended forward and downward into the iliac fossa. A small piece of foreign substance was washed out, which was, undoubtedly, fecal in its character, from the fact that a similar piece, obtained later, was shown by the microscope to be composed of fat and vegetable fibre. Convalescence was reasonably satisfactory. The wound was healed in seven weeks. It is now nearly three years since the operation, and the patient is apparently as well as ever. From the location of the cicatrix this patient runs very little risk of having a hernia.

A lad, sixteen years of age, a patient of Dr. Gerry, felt something give way in his left side while lifting. In three days he began to complain of belly ache. Peritonitis supervened, and at the end of sixteen days I saw him. The belly was flat, hard, moderately tender, and there was a lump the size of an orange in the left iliac region. A soft, elastic tumor was also easily detected in the rectum. An incision over the bunch above mentioned gave exit to a large quantity of flaky pus from the general peritoneal cavity. The "lump" felt outside was a mass of lymph, and the tumor in the rectum was a collection of pus. The belly was irrigated freely with hot carbolized water once a day. The abscess proper became walled off from the peritoneal cavity in a few days, and the further treatment was simple. The patient was in bed about three months.

He is now, four years later, well, and free from hernia. He has had no symptom whatever of trouble in the affected region. This was probably a case of traumatic peritonitis.

Another case, seen with Dr. Joseph Stedman, had its origin in errors of diet and sleeping upon the ground without sufficient protection. The earlier symptoms indicated enteritis, but in about two weeks there was severe general peritonitis, with a lump just above and to the left of the symphysis pubis. A tumor was also detected in the rectum. The constitutional symptoms were severe, and the indications for interference were plain. The patient made a good recovery in a few weeks after laparotomy was performed.

This young gentleman had another attack a year later, and the abscess broke spontaneously into the rectum, and he finally got well without operation. He has been threatened with a repetition of the affection upon several different occasions since, but has thus far escaped anything as serious as the first attacks.

In operating upon this patient, a peculiarity was met with, which in a previous case had led me to abandon the operation and let Nature make the opening, which she had already nearly accomplished. I refer to a tympanitic condition of the abscess. As there was no marked obstruction to the bowels, the opening was carefully made by the Hilton method, and it gave exit to gas and pus, but to no feces. An exploring needle used in one of these resonant abscesses gave exit to nothing. The evidence was purely negative, and under the circumstances it was worthless. It is to be borne in mind that tympanitic abscesses in the vicinity of the intestines are not a very uncommon occurrence. Sometimes crackling, like that of an emphysema, is to be felt underneath the skin.

Three cases of appendicitis terminating in fecal fistula in which no operative measures were resorted to, have come under my notice during the past few years. In two of these patients the symptoms were extremely severe, entitling them to be placed in the first class. They simply show that Nature can occasionally save even a most desperate case of appendicitis, but she does it in a way not at all desirable. The results obtained by the expectant treatment constitute very strong arguments in favor of incision. It is a fact that in many cases of perforation of the appendix bits of feces, or even several fecal discharges may come from the wound, yet the sooner the pus and the foreign matters are evacuated, the less danger there is of a permanent fecal fistula.

Moreover, so far as I have observed, fistula following a seasonable operation give very little trouble, as they soon close and remain closed. In one of the "expectant" cases feces escaped freely from the wound a year after the abscess broke. In another case the fistula opened occasionally for some years and gave exit to a small amount of intestinal fluids, but it finally became soundly healed. I have never seen a permanent fistula in the class of cases under consideration, which has followed an incision made at a seasonable time in the progress of the case, with possibly one exception. It is certainly less common after an artificial than after a spontaneous opening.

THIRD CLASS.

I need not weary you by detailing cases of the third class. They are by no means uncommon, and so far as I have seen them, they terminate in recovery.

Recurrence is quite frequent. The symptoms are slower in their development, less severe in character, and are benefited by appropriate management. Rest, leeches, poultices and opiates should constitute the main features of the treatment. Cathartics are to be avoided until all acute symptoms have subsided. I have seen two cases, if not more, in which a fatal result was hastened or perhaps caused by the injudicious use of cathartics. The bowels may be locked up two weeks or more if necessary under these circumstances with benefit, and then induced to move with safety by the use of small doses of castor-oil, aided, if necessary, by injections of sweet oil and other substances.

It is no unusual occurrence for cherries, grape-seeds, currents, etc., to produce a good deal of disturbance in their course through the intestinal tract. The geography of the appendix, and the locality of the pain vary so much in abdominal affections, that no great dependence can be placed upon the seat of the distress and tenderness in many instances. As a general rule, if there be no marked, localized tenderness, small doses of castor-oil are reasonably safe and efficient in those cases. If, on the other hand, a distinct localization exists, or if there be febrile disturbance, laxatives are to be used with great caution, if at all.

The futility of incisions in cases of general peritonitis without localization is well illustrated in a case seen with Dr. Edson. A boy about ten years old had a severe attack of this affection. It was a question as to whether the inflammation was more severe in the right iliac region. An incision was made in that locality giving exit to flaky, foul-smelling fluid, adhesions were broken up, free irrigation used, and the wound dressed antisceptically with drainage-tube. In twelve hours the discharge had nearly ceased, and the patient was worse. Ether was given, adhesions were separated, even more freely than before, and the wound dressed as formerly. The next morning the tube was nearly dry, tympanites increased and all the symptoms aggravated. After much deliberation it was determined to make one more effort to save the boy. Ether was administered for the third time, an incision was made in the median line, adhesions broken up in all directions, drainage-tubes introduced, and free irrigation with hot water resorted to. This procedure was no more successful than the others had been, and the patient died in less than twenty-four hours, having been in the greatest agony after the final operation, except when under the influence of ether. Morphia, even when given subcutaneously, afforded no relief.

A man entered the City Hospital having severe general peritonitis with no symptoms of localization and without collapse. An incision gave exit to a large amount of nasty pus. Very thorough irrigation was made with a warm solution of hydro-naphthol (1-2,000) two large drainage-tubes were inserted in different directions, and careful antiseptic precautions followed throughout the treatment. The discharge ceased in a few hours and repeated irrigation failed to remove anything. Death followed within forty-eight hours. At the autopsy very little fluid was found in the peritoneal cavity, but extensive adhesions existed in all directions, and the appendix was found to be gangrenous and firmly imbedded in the surrounding exudation. The operation in this case did no good, nor harm, but if operative measures cannot save these patients, it is obvious that nothing else will. Incision, irrigation,

careful and thorough antiseptis, stimulants and opium, and great care to prevent shock and prostration are the indications for treatment.

So far as my observation goes, cases of acute general peritonitis without symptoms of localization at any time are not benefited by abdominal section. Pus, flaky lymph, etc., are usually present in these cases, but it is not practicable to thoroughly cleanse the peritoneal cavity. Adhesions form about the opening in a few hours shutting off the general cavity of the peritoneum, obstructing drainage-tubes, and the disease takes its usual course.

The aspirator is not to be relied upon for the detection of fluid in these cases. Hilton's method of exploration is far better. It consists in making an incision through the skin, fascia and muscles; then substituting the director for the knife, it is carefully pushed forward in the direction indicated. The small opening thus made is then dilated to the desired extent with very little risk to any important vessels or other structures.

What, then, are the indications for operation in cases of appendicitis, or localized peritonitis? Any one, who has had any experience in these affections, can but admit, that it is very difficult, if not impossible, to lay down definite rules, which will cover all points in the subject under consideration. Much must necessarily be left to the judgment of the operator in deciding the question in each case. It goes without saying, that the violent cases coming under the first class in this paper, call for an early operation, that is, on the second or third day. The treatment may not save the patient, nevertheless, the indications for its adoption are imperative, and the surgeon can rest assured, that he will do little harm, even if he can do no good. It is the only treatment worth considering in those "fulminating" cases in which the victim is in extreme danger from the first onset of the disease.

It may be said in a general way, that a tumor located in any part of the abdominal cavity, inflammatory in its character, and accompanied by pain, tenderness, and more or less febrile disturbance, calls for operation. Cases which have passed the febrile stage, but, in which, the local deposit does not diminish at the end of three or four weeks, often require exploration; and this treatment is especially indicated, if the symptoms are aggravated by the patients getting up and moving about. I have recently operated upon four cases under these circumstances. A gangrenous appendix was removed from one of these patients, and pus existed in all.

It is to be remembered that suppuration may exist to a considerable extent without the presence of any febrile disturbance whatever. Several cases of this sort have come under my observation, in which an operation was justified by the persistence of the affection. On the other hand the mere presence of a lump does not necessarily indicate operative measures for its removal. Many of these masses of induration are removed by absorption. If they persist for three or four weeks without showing signs of resolution, surgical measures should receive careful consideration.

Cases of non-traumatic, general peritonitis, in which the symptoms have shown no tendency to localization throughout the whole course of the disease, offer the least encouragement for operative treatment. I have never seen a patient recover under these circumstances after an operation. I hope other surgeons have been more fortunate.

Finally, we have to do with quite a large class of cases in which the symptoms, even if severe, are very transitory. Convalescence is early established, and proceeds with more or less rapidity to recovery. These cases require rest, leeches, poultices or fomentations, and later, blisters and perhaps an occasional dose of castor oil. They generally recover after a longer or shorter time, and leave the patient as well as ever.

THROMBOSIS OF ARTERIA CENTRALIS RETINÆ; LARGE RETINO-CILIARY ARTERY; CENTRAL VISION UNIMPAIRED.¹

BY O. F. WADSWORTH, M.D.

IT has been suggested that the presence of a so-called retino-ciliary artery might, in the event of embolism or thrombosis of the arteria centralis, serve for the preservation of central vision, but no instance of the kind has, so far as I am aware, been reported. The following case is, I believe, an example.

Katie C., twenty-four years of age, unmarried, weaver, discovered on the morning of February 4, 1890, that the sight of her left eye was much affected. She had a headache at the time, but in other respects was and continued in her usual fair health. She had observed no special change in the sight until I saw her, a week later, February 11th.

The external appearance of both eyes was normal. Vision of either eye $\frac{1}{2}$. The right eye, except for a few dots of pigment on the anterior capsule, was quite normal. In the left eye, although central vision was perfect, the field was contracted to a small oval, measuring in its long, horizontal diameter some twenty degrees. The media were clear. The greater part of the disc and of the fundus for a wide extent around it was obscured by a uniform, whitish haze, such as is characteristically seen in embolism or thrombosis of the central artery. But in embolism or thrombosis of the arteria centralis it is characteristic that the haze appears most dense in the macular region, and here the macular region was wholly unaffected. Perhaps one-tenth or one-twelfth of the outer part of the disc, and an area of the retina, measuring at the edge of the disc about a third of the disc diameter in the vertical direction, gradually widening as it extended outward, and at the centre of the macula having a width of about one and one-third diameters, was entirely free from haze. This free area reached farther above than below the fovea, and the haze at its upper border was very well defined, at its lower border shading off imperceptibly. Except in this free area, the haze over a wide extent around the disc was sufficiently dense to hide or greatly obscure the vessels, only a few short portions of them on and close to the disc appearing with defined outlines; it completely hid the outline of the disc except for a short distance on the temporal side; towards the periphery it gradually faded.

A striking peculiarity was the presence at the edge of the haze, where it bordered the free area that extended outward from the disc, of several irregular wide bands of a more dense and brilliant white, recalling in tone the white, defined patches seen so frequently in albuminuric retinitis. These were not perfectly uniform in whiteness, but showed slight markings as if they might have been formed by coalescence of

¹ Read before the American Ophthalmological Society, July, 1890.

smaller patches. They were sharply defined against the free area on one side, and although the haze reached in undiminished intensity to their other side, yet their brilliancy of tone was such that the definition was hardly less pronounced on that side also. Two of these bands (the word is not very closely descriptive) extended outward from close to the edge of the disc something more than half a diameter; two others were situated at intervals at the upper edge of the free area; a fifth extended downward and outward from a point about a diameter outward and downward from the fovea. The latter three suggested in shape and markings a length of large intestine.

For a moment or two the appearance of the fundus was puzzling, but the explanation was soon found. A retinal artery of considerable size emerged from under the outer edges of the disc a little below its horizontal diameter, described a semicircle on the disc, and then ran for nearly a diameter straight towards the fovea, when it swung in a wide curve upward and outward to descend and branch something more than a diameter to the outer side of the fovea. From the point where it turned upward and outward on the retina, a small branch ran outward and downward a little below the fovea. Evidently the circulation in the macular region was kept up through this artery.

Two days later, February 13th, the haze was beginning to diminish. I spent some time in making a sketch of the fundus, and while I rested Dr. Cheney examined the eye again. He discovered in a branch of the inferior temporal vein, some distance below and a little to the outer side of the fovea, an irregular movement of the blood column. The branch in question ran nearly horizontally and joined another of the same size coming from above and outward. The color of the blood in the latter branch, as in the larger vein formed by the union of the two, was normal. In the horizontal branch the color was much darker, the blood column was broken into lighter and darker masses and these masses oscillated rhythmically to and fro, but at the same time advanced. Where the dark blood passed into the larger vein it flowed at first along its lower side, so that for a short distance the darker and lighter currents ran along side by side, the darker gradually becoming narrower until after a little it could no longer be distinguished. Searching the fundus still further, I found a similar but less marked oscillation of a broken blood column in a branch of the superior temporal vein outward and upward from the macula.

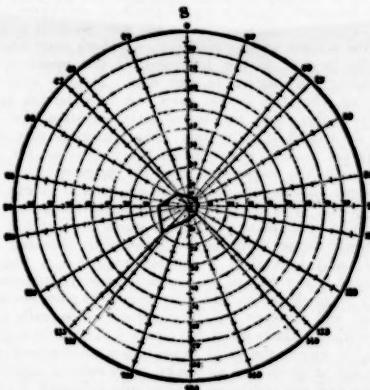

February 15th, the haze was less; the pulsation was still present in the two veins, but less pronounced.

February 18th, the haze had cleared so much that all the larger veins and arteries could be seen on the disc and beyond, apparently of full size: on the disc at least, all the larger vessels were now clearly defined. The dark colored venous branches in which pulsation had been seen were now so nearly of the same color as the veins into which they emptied, that no difference would have been remarked had they not been observed before; they showed no irregularity of current and had a well-marked light streak. Although the haze generally was much less, the "bands" were still well-marked, but not quite so bright as before. The central vision was still $\frac{1}{2}$, and the field apparently unchanged.

From this time the patient was lost sight of and the eventual result must therefore remain in doubt. Yet

the fact that for two weeks central vision continued perfect, makes it probable that it did not subsequently deteriorate. On the other hand, I am inclined to think that the retinal arteries, the retino-ciliary branch excepted, and veins did undergo more or less shrinkage.

That the only directly visible disturbance of circulation was observed in the veins might be held to point to an affection primarily venous rather than arterial. But the wide extent of the edema of the retina, impartially distributed in all directions except toward the macula, can hardly be explained otherwise than by an interference with the blood current in the main trunk, whether of vein or artery. And if the trunk of the vein were blocked there is no apparent reason why the district supplied by the retino-ciliary artery should have been in any way less affected than the parts supplied by the arteria centralis; and then, moreover, distention of the veins, which did not exist, should have been expected. Per contra, the plugging of the trunk of the arteria centralis while the retino-ciliary branch was pervious would rationally account for the peculiar distribution of the edema.

It remains to account for the apparently undiminished size of the arteries. A certain amount of shrinkage from the original size there may have been, for the haze had not wholly disappeared when the patient was last seen, although on the disc the vessels were clearly defined. That may be explained, perhaps, on the supposition that the circulation was not entirely interrupted at the first, and that afterward the plug was broken up or shrank, but too late to admit a recovery of function in the parts of the retina from which nutrition had been largely cut off.

I have preferred to call the lesion here thrombosis rather than embolism, because a very careful examination by Dr. W. W. Gannett failed to reveal any disease of the heart or large vessels, and because I believe the evidence indicates that thrombosis of the retinal arteries is the more common affection of the two.

— A new danger has been revealed by an enthusiastic bacteriologist. He says: "I have been examining street-car straps under the microscope lately, and I find them filled with thousands of bacteria, which must be excessively dangerous as transmitters of disease."

ON THE FATE OF THE HUMAN DECIDUA REFLEXA.

BY CHARLES SEGWICK MINOT, M.D.

THE decidua reflexa is a distinct membrane up to the end, it is said, of the fifth month of gestation, and after that period it can no longer be found. Exactly at what time it disappears, is not established by observation, though the fact of the disappearance has long been known. Nor have we had hitherto any definite knowledge as to how it disappears, although its gradual attenuation and increasing transparency during the first four or five months have been familiar to us since the publication of Coste's magnificent atlas. The view most generally accepted has been that it fused with the decidua vera, and that, accordingly, the layer of decidua nearest the chorion during the latter half of pregnancy represents the decidua reflexa.

I have had opportunity to study four well-preserved, normal pregnant uteri of two, three, five to six, and seven months' gestation, respectively. These show that at two months the decidua reflexa is undergoing hyaline degeneration, that at three months the degeneration is considerably more advanced, and that by the sixth and seventh month the reflexa can no longer be found. These observations justify the theory that the reflexa degenerates and is completely resolved.

I will review briefly the actual observations.

First, the reflexa at two months. It starts from the edge of the placental area with considerable thickness, which is rapidly lost, most of the reflexa being a thin membrane, and the thinnest point being opposite the placenta. The examination of sections show that the entire reflexa is undergoing degeneration, which is found to be the more advanced the more remote the part examined is from the placenta. The chorion laeve lies very near the reflexa, being separated only by chorionic villi, which are very much altered by degeneration, their ectoderm having become a hyaline tissue which stains darkly, and their mesoderm showing clearly the partial loss of its cellular organization. In the region half-way between the base and the apex of the dome of the reflexa, the tissue of the decidual membrane shows only vague traces of its original structure; only here and there can a distinct cell with its nucleus be made out, for most of the cells have broken down and fused into irregular masses without recognizable organization. Ramifying through the fused detritus there are two layers of so-called "fibrine"—or, in other words, of a hyaline substance, which, like the "canalized fibrine" of the chorion, stains very deeply with the ordinary histological dyes (carmine and logwood). The fibrine is much more developed upon the inner or chorionic than upon the outer side of the reflexa. It forms on the inner side a dense network, which, on the one hand, fuses with the degenerated ectoderm of the chorionic villi wherever the villi are in contact with the decidua; and, on the other hand, ramifies more than half-way through the decidua, the ramifications being easily followed owing to the hyaline character and deep staining of the "fibrine." Upon the outside the fibrine forms a thinner layer, and shows its network structure in many sections much less clearly.

In the uterus three months' pregnant I find essentially the same conditions except that the degeneration is farther advanced, since the traces of cellular structure in the reflexa are still more vague and the fibrine

is more developed. The membrane is much thinner than at two months; the thickness is about two-thirds of what it was. In the fresh specimen the membrane appeared much more transparent than before. In all the parts examined, I found leucocytes present, and in the region of the reflexa near the placenta they are very numerous and conspicuous; it is natural to conclude that they are concerned in the resorption of the degenerated tissue. In a section not far from the base of the reflexa the three layers are distinct as at two months, there being a thicker inner and a thinner outer fibrine layer, while between them is a stratum in which remains of cells are seen; occasionally is an appearance which suggests a surviving decidual cell, and nearer the placenta the phantoms of cells become distinctly cells and true decidual cells can be made out. The inner fibrine layer is much denser and its meshes smaller than in the two months' specimen, the trabeculae of fibrine having become thicker during the month elapsed.

The relations of the amnion and chorion to one another in a uterus of seven months I have already described and illustrated in detail in my article "Uterus and Embryo."¹ I will recall only that the chorion lies directly against the decidua; between the chorionic mesoderm and the decidual tissue, extends a layer of epithelioid cells, which I interpreted as the modified ectoderm of the chorion, a view which I still hold. Of a membrane between the chorion and the decidua there is no other trace.

Those who conceive that there is a fusion between the reflexa and the vera, are forced to seek for traces of the former membrane next the chorion. They may assume either that the epithelioid layer is the remnant of the decidua, which forces them to leave the fate of the chorionic epithelium unexplained, or that the upper stratum of the decidua is the reflexa which is fused with and acquired the same structure as the underlying vera. If my observations on the degeneration of the reflexa are correct, and correspond, as there is sufficient ground to believe they do, to normal conditions, then both assumptions as to the persistence of the reflexa involve the further and very improbable assumption that the degenerated tissue is removed and replaced by fully organized cellular decidua tissue. It is obviously more in accordance with our knowledge of degenerative changes to assume that the hyaline metamorphosis is necrotic, and is succeeded by the disintegration and removal of the tissue. This accounts in a satisfactory manner for the absence of the decidua reflexa during the sixth and seventh month. The relations of the membrane at this period have been well described and figured by an admirable observer, Dr. G. Leopold, whose views and one of whose drawings have been incorporated by Prof. O. Herting in his "Entwickelungsgeschichte."² Leopold holds that the epithelioid layer is the reflexa; but what has just been said suffices, I think, to show that this view is untenable.

That the membrana decidua reflexa should degenerate and disappear no longer seems strange, since recent investigations have shown that in many placental mammals there occurs an extensive pseudo-pathological destruction of the mucosa uteri during gestation; these changes which are best known in the rabbit,³ may vary considerably in character, and are exceed-

¹ Journal of Morphology, vol. II, 425-426, cuts 33, 34.² Third Edition, p. 216, 217; fig. 147.³ Cf. Minot, Biol. Centralbl., 1890.

ingly remarkable, both for their extent and for their numerous modifications, so that we need feel no surprise at the entire destruction of the decudua reflexa in man, nor at form of the destruction being unlike the forms heretofore found in other mammals.

As to the purpose or advantage of the sacrifices of maternal tissue, we are in the dark. The same is true of the causation of the degeneration, although we must regard it as the result of a reflex nervous activity. It is becoming more and more evident that the nerves have a profound influence upon organization, and it is no strained hypothesis which places the structure of the mucosa uteri under the immediate control of the nervous system.

A NEUROPLASTIC OPERATION.

DESIGNED FOR THE RESTORATION OF NERVE TRUNKS THAT HAVE BEEN DESTROYED BY INJURY OR DISEASE.

BY H. H. A. BEACH, M.D.,
Visiting Surgeon, Massachusetts General Hospital.

THROUGH the connections of a tumor with an important nerve, and from the fact that such a growth derives its origin from the nerve or its close vicinity, it occasionally happens that an excision of the tumor necessarily sacrifices a section of nerve. A similar destruction of nerve tissue may attend the crushing and tearing of soft parts incident to severe railroad and machinery accidents, thereby impairing the usefulness of a limb, to a serious degree. In the cases where a nerve so injured is large enough to permit the operation to be described, the latter offers a chance for the restoration of nerve function that can be gained in no other way. Although I have had no opportunity as yet to make a practical test of its value, I am encouraged in the belief that it may be of worth, through some experiences in the junction of nerves that have been severed but not otherwise injured. Others of the profession may have cases before me, that can be helped by its application, and upon that ground alone, though it is against my preference, I will not defer its publication.

Operation. — For convenience, the severed ends of the nerve may be described as three inches apart. Pick up the nerve with a tenaculum or needle, and transfix it with a silk suture. The latter is useful in place of forceps for regulating the tension of a nerve during its dissection, without bruising its tissue. Care must be taken not to exercise too much traction, or the suture will tear through the nerve. Open the nerve sheath for three and one-fourth inches in either direction from the wound by following one of the divided ends, or in both directions for one and three-quarters inches. Then, having measured the distances accurately, partially divide the nerve trunk, in a vertical direction to its axis, at the required point, and split the nerve to a point within one-third of an inch of its end; thus,

N is the other severed end, to which the flap is to be joined by fine sutures, the flap being sufficiently long to avoid tension; thus,

From the character of the injury, it is possible that, in some instances, it will be more convenient to take a flap on one side of the wound, from the superior half of the nerve, and on the other side, from the under half of the nerve. This change would not materially alter the technique of the operation, as shown by the following diagram:

Should any tension be produced by either method the flaps are of insufficient length.

The method adopted for joining the ends should be governed by the accessibility of the nerve trunks without excessive or unnecessary dissection. A pair of dividers will be found convenient for measuring distances.

The operation, which has not, so far as I am aware, been described or employed before, may be suitably termed "Neuroplastic," and will, I hope, meet the commendation of surgeons who may have occasion for its use.

REPORT ON PROGRESS IN DERMATOLOGY.

BY JOHN T. BOWEN, M.D.

LUPUS FROM INOCULATION.

THE dermatological clinic at Breslau that has produced so many scientific papers of late years, afforded an opportunity to Dr. Jadassohn, the assistant physician, to report two interesting cases of tubercular infection of the skin.¹

The etiological identity of lupus and tuberculosis is now recognized by all but a very few observers, yet much remains to be explained. The manner in which the tubercular infection takes place, the peculiar clinical features that distinguish lupus from other tubercular lesions, especially those upon the skin, are matters of which our knowledge is still very limited. The author speaks well when he says that it is only by the publication of carefully observed individual cases, that we can hope to obtain a basis for more systematic investigations.

CASE I. His first case is that of a butcher, twenty years of age, who had received, eighteen months previously, a cut on the end phalanx of his right forefinger while engaged in his occupation. The wound did not heal. Nearly a year after the injury there appeared a lesion upon the lower arm of the same side, and very soon afterward a nodule upon the upper arm, which opened spontaneously and evacuated a considerable quantity of pus. When seen at the hospital he exhibited an ulcer upon the forefinger with thin edges, somewhat undermined and in places dentated. The floor was shallow with soft granulations, between which were isolated collections of pus. The movement of the joint between the second and third phalanges was much limited. At the upper end of the forearm were three small ulcers lying in a line with one another, similar in character to the lesion of the

¹ Virchow's Archiv., Bd. 121, Hft. 2.

finger. On the upper arm were three similar patches, one of which, however, was not ulcerated and showed plainly beneath the thin epidermal covering one or two small nodules. It was found necessary, on account of the extensive loss of tissue, to disarticulate between the first and second phalanx, while the lesions upon the arm were freely excised. The histological examination offered the appearances of an infiltration process in which the specific elements of tuberculosis although present, were sparingly observed. The lesion of the upper arm showed microscopically a lymph-gland in the lowest layers of the cutis, separated from the adjoining tissue by a firm capsule. This gland presented a typical picture of epithelioid and giant-celled tubercle with central necrosis. Above the gland, in the corium lay nests of small round cells with an occasional Langhan's cell in the centre. After a prolonged search it was possible to demonstrate the bacilli of tuberculosis both in the ulcer of the finger and in the lymph-gland from the upper arm. The writer considers it most probable that the wound upon the finger offered a point of ingress to the tubercular virus which was then carried by the lymphatics to the lymph-gland, from which point the skin of the arm became infected secondarily. Positive proof of this is wanting, but so much is clear: that a tubercular ulcer of not especially characteristic appearance showed itself at the site of an external injury, and that this was followed by a typical lupus of the arm. The probability that the virus was transferred from the ulcer to the arm by external means (as by the fingers in scratching) is to be wholly excluded.

CASE II. A woman of thirty had had some letters and figures tattooed on her left arm nine years previously. Beneath them a wreath had been pricked in at about the same time by a man who had used his saliva for moistening the India ink. This man was, on good evidence, phthisical at the time of the tattooing, and died soon afterward at the hospital of tuberculosis of the lungs. At several points of the tattooing the wounds made by the punctures had never healed, and several typical lupus plaques with characteristic nodules were now apparent. The plaques were excised and showed histologically the typical lupus structure with the presence of bacilli very sparingly.

The writer then discusses the etiology of spontaneous lupus at some length. Three views are entertained: (1) That lupus is caused by an hematogenous infection, or in other words that the virus circulating in the blood is brought through its channels to the affected cutaneous area. This is the view warmly espoused by Baumgarten, who regards it as the usual, if not the only, mode of infection. (2) That the skin is affected per contiguитетem from structures lying below it, which have become tubercular. This mode of infection cannot be doubted, as so many cases of lupus developing upon fistulae and diseased glands are known. (3) That lupus is the result of direct inoculation of skin and mucous membrane.

The writer claims that all of these modes of infection can, and probably do, prevail, and takes issue with Baumgarten's statement that the usual way is by the channels of the blood. His second case he considers undoubted evidence of infection by direct inoculation, and is inclined from his clinical experience to consider this latter the more frequent mode. The variations in clinical appearances that the inoculation of tubercular virus shows upon the skin, seem to be

very great and are dependent on the difference in mode of infection, place of infection, and possibly also in the virulence of the bacilli. We are already able to distinguish clinically several different forms of tuberculosis, and it may be expected that we shall in the future be in a position to differentiate numerous transitional forms between the individual species.

[The greater interest is attached to the second case from the fact that few, if any, authentic instances of true lupus caused by direct inoculation of tubercular virus have been reported. The records of the past few years, however, afford numerous examples of tuberculosis verrucosa cutis (including the anatomical wart) and of doubtful looking ulcers, produced by direct contact of the secretions of phthisical subjects with the skin. With these forms of cutaneous tuberculosis a lupus is sometimes allied, but in most instances the probabilities favor the view that it was developed secondarily. A single example of the kind reported above cannot be considered as conclusive, as Baumgarten and the advocates of the hematogenous theory might reply that here, too, the lesion could be explained as the result of the action of the bacillus when conveyed by the blood current to a locus minoris resistitiae caused by the tattooing. No other symptoms or family history of tuberculosis could be elicited, however, and if a number of such instances can be collected, all doubt that "spontaneous" lupus is sometimes, at least, produced by the direct inoculation of tubercular material must vanish.—REP.]

ACUTE GANGRENE OF THE SKIN AND GANGRENOUS ZOSTER.

From time to time there have appeared descriptions of an acute form of gangrene of the skin, differing from Raynaud's disease in many particulars, and not always described under the same title. Sangster, Neumann and Leloir have all published cases of this nature, which have been interpreted in various ways, some authorities even considering them as having been produced artificially. The resemblance of these lesions to herpes zoster was alluded to by Neumann, and of late there have appeared several advocates of the view that they represent an atypical form of zoster gangrenosus.

Doutrelepont² relates the sequel of a case of this nature that he had described in 1886,³ and had had under almost constant observation since, and which he thinks should be placed in the same group with herpes zoster. A strong, healthy looking girl, twenty-one years old, who had previously had several convulsive attacks of an hysterical nature, pricked herself under the nail of the thumb with a needle. Seven days later the first appearances showed themselves in the form of small spots of gangrene on the skin of the first phalanx of the thumb, attacking then the back of the hand, arm and shoulder, and extending gradually over the whole body, and the mucous membranes as far as visible. The eruption appeared in the form of outbreaks of gangrenous patches, which appeared simultaneously on different parts of the body and were attended with a rise of temperature. The gangrenous patches were, at the outset, made up of groups of small, round spots, which were shown by histological examination to represent the beginning of vesicles, and in the farther course of the case, groups of vesicles were frequently

² Archiv. f. Derm. u Syph., 1890, s. 385.

³ Viertel. f. Derm. u Syph., 1886, s. 179.

seen on the skin, both detached, and at the periphery of the foci of gangrene. At one time the outbreak took the form of grouped vesicular lesions on the face, which could not be distinguished from a double zoster. The patient had frequent attacks of extreme excitement or of great depression and made three attempts upon her life. No disturbance of the sensibility of the skin could be detected except some hyperesthesia of the regions affected. Finally, she was seized with hemorrhages from the lungs, and died a few months later with the symptoms of a rapidly progressive phthisis, during the course of which occasional outbreaks of eruption were still observed on the skin and mucous membranes. The autopsy revealed a tuberculosis of the lungs, but threw no ray of light on the cutaneous affection, although a careful examination of the brain and cord was made.

Kaposi¹ related four cases which he classifies as atypical zoster gangrenosus. They present many points of resemblance with Doutrelepoint's² and those previously described as multiple gangrene of the skin. They were characterized by groups of vesicles with gangrenous change in the centre, differing from an ordinary gangrenous zoster (*a*) in their bilateral distribution, (*b*) in not following the course of a spinal nerve or that of the trigeminal, and (*c*) in their recurrence in successive outbreaks. They were exhibited mostly in young, hysterical women, in whom paresthesia is noted, in one case even complete left hemianesthesia. He regards the affection as a vasomotor or tropho-neurotic disturbance, of hysterical nature, and proposes to classify it as zoster gangrenosus hystericus.

SKIN-GRAFTING.

At a meeting of the New York Academy of Medicine, held October 2, 1890,³ Dr. Charles McBurney read a paper on "Thiersch's Method of Skin-Grafting," which had proved most successful in twenty-four cases of deep loss of tissue in his hospital practice. In the succeeding discussion Dr. P. A. Morrow, who had had no personal experience with Thiersch's operation, related an interesting case of skin-grafting in the field more especially occupied by the dermatologist. The subject was a man who had become almost hypochondriacal on account of a scar on his scalp which had become exposed by the fall of his hair. Dr. Morrow took grafts with the cutaneous punch, very much smaller and thicker than those used in Thiersch's method (the grafts here consist of thin shavings four or five inches long and one inch wide), from the opposite side of the patient's own scalp and inserted them at once into holes of the same size made by the same instrument in the scar-tissue. Union was complete within a week. "Four grafts were made and he waited several weeks to see if the hair would grow. It did. He then made transplantsations from another patient's scalp and these also grew and bore hair luxuriantly. The grafts were fully one-quarter of an inch thick. There was no suppuration, no untoward result. He had employed the same method in one or two cases of epithelioma; and while there was no indication of breaking down, there had not been sufficient time to justify conclusions." He thought that lupus, moles and warts, might possibly be treated by this method also.

Dr. Girard, a speaker who followed, stated that in

one case he had placed grafts from the skin of a negro on a white man, with the result that they remained for some time black, gradually, however, taking on the white appearance of the surrounding tissue.

(To be continued.)

Reports of Societies.

NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED Meeting November 17, 1890. The Vice-President, S. B. WYLIE MCLEOD, M.D., in the chair. DR. J. LEWIS SMITH read a paper on

APPENDICITIS, TYPHILITIS AND PERITYPHILITIS IN CHILDREN.

After some preliminary remarks on the structure and relations of the parts affected, he spoke of the period of childhood at which these inflammations were most liable to occur. Matterstock had collated 72 cases, and of these two were under the age of two years, 10 between the second and fifth years, 25 between the fifth and tenth years, and 35 between the tenth and fifteenth years.

In treating of the etiology, he said that the most common cause was the lodgement and impaction in the cecum or appendix, or both, of fecal matter or hard, indigestible bodies, which produce inflammation, and sometimes perforation by their pressure. In 49 cases of fatal perityphilitis embraced in Matterstock's statistics perforation had occurred in 37; from which it might be inferred that in the majority of cases of perityphilitis resulting from appendicitis, perforation of the appendix had occurred. In the analysis of 152 cases collated by Fitz, the result was very similar to that noted by Matterstock. The fecal concretions found in the appendix were single or multiple, and of different degrees of hardness.

Anatomical Characters. — In children the initial lesions, with few exceptions, occur in the appendix. Atrophy or necrosis of its epithelium takes place from pressure of the foreign substance. Then the intestinal microbes invade the exposed sub-epithelial tissue, causing septic inflammation, which extends through the muscular coat to the sub-peritoneal tissue and to the peritoneum, causing a local peritonitis. Or, it ceases before reaching the peritoneum, producing gangrene or ulceration of the underlying tissues, and, as they contract in healing, the lumen of the appendix may be obliterated and its shape changed. Sometimes the appendix is nearly or quite obliterated, its place being occupied by cicatricial tissue; or, its proximal end may be obliterated while its distal end remains open. A retention cyst then results, which may subsequently be inflamed, and may at some point be destroyed by gangrene or ulceration, so that its contents escape, causing peritonitis. Occasionally similar changes occur in the cecum. In the mild and favorable cases of perityphilitis a fibrinous exudation occurs over the inflamed parts, so as to limit the extension of the disease and prevent the escape of pus or fecal matter.

Balzer states that perityphilitic abscess is much less frequent in children than in adults. The location of such an abscess depends on the place of perforation. It is said that in most instances the centre of the abscess is behind or alongside of the cecum, and if it

¹ Archiv. f. Derm. u Syph., 1889, s. 561.

² New York Medical Record, October 25, 1890.

extend upward, its walls consist of intestine and the posterior and lateral parieties of the abdomen. The abscess, left to itself, may open in any direction. Evacuation of the pus per rectum has been regarded as favorable from the time of Dupuytren. But the result is not always favorable when the abscess breaks into the intestine; for, after the pus has been evacuated, fecal matter may escape through the opening, carrying with it microbes which may poison the system and set up septic fever. Extension of the inflammation from the perforated appendix to and around the contiguous blood-vessels may cause disastrous results.

While perforation of the appendix commonly results in localized peritonitis, a more serious and ordinarily fatal result sometimes follows, namely, the occurrence of acute diffuse peritonitis. This may take place immediately after the perforation. Frequently, however, an abscess forms, perhaps of little extent, around the appendix, and it may continue for weeks or months without producing any dangerous symptoms. Finally it bursts, and its contents escape into the general peritoneal cavity, producing an acute peritonitis, which rapidly extends over the peritoneal surface. A large proportion of the cases of perforation of the appendix, if left to themselves, terminate, after a time, in this manner, in peritonitis, which, from its extent and severity, is usually fatal.

Owing to the length of the paper, Dr. Smith omitted the portion describing the symptoms, and went on to speak of the diagnosis. Recurring pain or tenderness in the right inguinal or lumbar region, at intervals of a few weeks, he said, should excite suspicion of the presence of a foreign substance in the appendix. Sometimes the accumulation of fecal matter in the cæcum can be determined by palpation. The diagnosis from invagination is not difficult, since the latter occurs chiefly in infancy, is attended by a tumor more centrally located, and is often accompanied with bloody stools and fecal vomiting. Perityphilitis has sometimes been mistaken for hip disease; but the swelling in the latter is lower down, and in perityphilitic induration the characteristic signs of disease of the hip-joint are absent. Dr. Smith also referred to Senn's hydrogen gas test for perforation, and to the diagnosis between perityphilitis and psoas abscess.

The prognosis varied greatly in different cases. If the inflammation were of little extent and encapsulated, and sepsis did not occur, the prognosis was good. On the other hand, if the perforation of the cæcum or appendix were of considerable size, with the escape of much feculent matter, the inflammation, which resulted in the peritoneum or retro-peritoneal tissue, with, perhaps, consecutive septic inflammation in adjacent organs or tissues, was almost certain to terminate fatally. It was evident that the statistics relating to the result, as given by different writers, varied according to the extent and severity of the disease in the cases which they had collated. Having mentioned the relative number of deaths and recoveries published by various authors, he said that, according to Matterstock, age influences the result in a measure, since of 12 patients under the age of six years, 11 died; of 24 between the ages of six and ten, 15 died; and of 34 between the ages of ten and fifteen, 23 died. Diffuse peritonitis was usually fatal, while evacuation of the abscess into the cæcum or rectum generally justified a favorable prognosis. Evacuation of pus through the abdominal

walls, if it took place at an early date, was also regarded as favorable. Laparotomy and evacuation of the pus through the abdominal walls, if performed at the proper time and with antiseptic precautions, increased the chances of recovery. In those mild cases in which the inflammation was of slight extent and the patient was soon convalescent, a sudden aggravation of symptoms sometimes occurred from breaking loose of the inflammatory products, and the case ended fatally.

Coming to the treatment, he spoke first of the matter of prophylaxis, and then of curative treatment. As to the latter, he referred particularly to the plan of Professor Henoch, of Berlin, who keeps the intestines perfectly quiet by opium, and only gives castor-oil or calomel when prolonged constipation and palpitation indicate the presence of a large fecal accumulation in the cæcum. Otherwise he abstains from purgatives. He applies a few leeches, without after bleeding; if there be much tenderness, gives an emulsion of oil with the aqueous extract of opium every two hours, and uses constantly the ice-bag over the cæcum. When with this the pain and tenderness cease, it is found that defecation usually occurs spontaneously or can be produced by a simple enema or a dose of oil. Henoch has made the following remarkable statement, which, were it not for his well-known accuracy and high professional standing, might be thought to be an exaggeration: "When this treatment was begun early enough, recovery ensued in almost all cases, and if a swelling had been formed by the exudation, its transition into suppuration was prevented even in children who, in the course of a few years, had been repeatedly admitted to the hospital on account of relapses."

Dr. SMITH thought that Henoch's treatment was probably the best that could be adopted before the stage of suppuration. The use of laxatives, even of laxative enemata, he said, should be postponed until the tenderness and other inflammatory symptoms had, to a considerable extent, abated by the use of opium and the ice-bag. If, then, the presence of fecal masses were ascertained by palpation, a large clyster of warm water containing one ounce each of glycerine and sweet oil might be given, or perhaps, as recommended by Henoch, a dose by the mouth of castor-oil or calomel. Even at the commencement of the treatment Dr. Smith thought it proper to employ such a clyster as that mentioned if there were a history of constipation and if on palpation the cæcum appeared to be distended with fecal matter. The diet should consist of liquids which leave little residuum, such as the beef peptones and peptonized milk. Carboлизed water might be allowed to relieve thirst or nausea. If the case result favorably without surgical interference, the child should lead a quiet life, avoiding violent exercise for a considerable time, on account of the danger of relapse.

If the inflammation continued, and a perityphilitic abscess formed, this required opening. In 1882 Dr. R. F. Noyes collated the records of 119 cases in which an operation was performed, only about sixteen per cent. of which proved fatal. The late Dr. H. B. Sande strongly objected to the use of the exploratory needle at an early stage of the inflammation, since it might penetrate the healthy peritoneal cavity and pierce the intestine, and if the instrument entered the abscess the foul substance adhering to it would probably infect the peritoneum and cause diffuse peritonitis. Morton

stated that the aspirator needle should never be used, and Ransohoff also objected to it. G. Buck, Weir, Noyes and Bull advised, if the presence of pus were determined by the needle, to leave the latter *in situ* to serve as a guide in making the incision.

After referring to the various incisions practised by different surgeons, he said that laparotomy had been performed many times during the last ten years, and cases had been published showing very favorable results. Still, it was not to be forgotten that the favorable cases were much more likely to be reported than the unfavorable ones. Having described successful cases reported by Drs. Sands and Homans, he went on to say that such cases show what may be accomplished by surgical treatment even in cases where diffuse peritonitis has resulted. Of course, however, when peritonitis not limited by adhesions occurred, death would result in a considerable proportion of cases under any treatment whatever.

Removal of the perforated and diseased appendix, where it could be readily brought into view, was now generally recommended by surgical writers, since the diseased appendix was a source of irritation, and by the subsequent escape of fecal matter it might cause a renewal of the inflammation. But, in a large proportion of cases, the appendix lay at the bottom of the cavity, surrounded by adhesions, so that it could not be removed without considerable cutting and tearing of the parts surrounding it, and perhaps producing an opening through which inflammatory products might escape into the peritoneal cavity. In regard to the surgical treatment of perityphlitis and the perityphilitic abscess, however, he thought the surgeon was more competent to express an opinion than the physician.

DISCUSSION.

DR. E. G. JANEWAY said he only wished to direct attention to a few practical points, and especially to the question how far liable we were to make mistakes in diagnosis. He then proceeded to enumerate some of the conditions which were likely to be sometimes mistaken for appendicitis or perityphlitis, and *vice versa*. Among these were the following:

Neuralgias affecting the right iliac region and adjacent parts. In making the differential diagnosis it was important to ascertain whether the tenderness was located superficially or in the deeper tissues.

Renal colic. The pressure produced by appendicitis was sometimes liable to cause pain in the region of the right kidney, and this was especially the case if the abscess were situated down between the rectum and the bladder. Here it was of service to make deep pressure in the seat of the appendix.

Fecal impaction. He had met with two cases of this in children where the question of appendicitis arose.

Inflammation of the mucous membrane in certain rare cases, without any impaction or induration. The way in which the symptoms came on, however, if the case were investigated carefully, would generally show that we had to deal merely with a case of catarrhal enteritis, especially affecting the colon. The diagnosis could also be established by the prompt subsidence of the trouble.

Carcinoma of the cæcum. This, of course, was only met with in adults, and was a rare condition.

Pelvic cellulitis and peritonitis in young girls as well as women. Many such cases were doubtful where

the physician was debarred from making a vaginal examination.

Reflected pains, as from pleurisy and pneumonia. The earlier stages of certain cases of typhoid fever. Lumbar abscess from caries of the vertebrae. Subphrenic pneumo-hydrothorax.

While the diagnosis was usually very easy, in some instances it was extremely difficult.

As to the matter of operation, he thought that there was not a sufficiently strong line drawn between the cases in which general peritonitis occurs at the outset, and those in which the trouble is strictly localized. In the former class the patients almost invariably die badly. A question of far more importance was this; If we have appendicitis and peri-appendicitis with induration, is peritonitis likely to result? It was often a difficult matter to decide whether to operate or not. He supposed, however, that it was probably the wisest course to open the abdomen in all cases where appendicitis is followed by peritonitis. In regard to abscess, the abscess should be opened at the earliest moment after a purulent accumulation is discovered. As to exploration with the hypodermic needle, it seemed to him that such a procedure was absolutely injurious unless practised with special precautions. It should only be resorted to, he believed, with the child under ether, and as a prelude to incision. To make such an exploration and then not do anything for, say, twenty-four hours, was a course that could not be too strongly condemned.

DR. CHARLES MCBURNETT said he was sorry to see that Dr. Smith still adhered to the terms perityphlitis and paratyphlitis. It was liable to lead to confusion by giving rise to the idea that there were quite a number of diseases which produced the condition in question, when, as a matter of fact, the appendix was almost invariably the seat of the original trouble; the cases in which this was not so being extremely rare. He agreed with Dr. Janeway that the most interesting and important question to be considered was the one of arriving at a correct diagnosis at the earliest possible moment. In his opinion the physician and the surgeon should study each case together from the very beginning of the disease. The surgeon was very commonly called in at too late a time, when operation could only result in failure, and as an illustration he narrated a case in which he was asked to operate after the attack had lasted six days, general septic peritonitis had set in, and the patient was already in a state of collapse.

The early localized signs were of great importance, and if we hoped to save our cases it was generally necessary that we should decide whether to operate or not within the first twenty-four hours. He had no desire to operate in cases which did not require surgical interference, and therefore he was especially interested in the matter of early diagnosis in the different varieties of cases that were met with. The operation, (by which he meant the opening of the abdomen in order to make a diagnosis) was certainly not a very severe or dangerous one. One very noticeable fact was that even in a large number of cases where a deliberate laparotomy was performed and a considerable amount of manipulation was required, he did not know of a single instance in which septic peritonitis had resulted from the operation. The mortality from the operation was very slight, and the percentage of death, as shown by the statistics, was certainly very much

less in those cases operated on at the proper time than in those in which either no operation was performed, or it was resorted to at too late a period. We are often told to wait till signs of septic peritonitis had occurred; but what course could be more dangerous than this, when the very object of operating was to prevent peritonitis. As to the signs of impending perforation, which we were also told to wait for, he did not know what these signs were, and should very much like to be informed.

As to some of the results obtained from operating in the early stages, Dr. Lewis Stimson had reported five cases, all of which recovered. His own cases amounted to twenty, and all had recovered but one. The fatal result in this case was caused by paresis of the entire intestines, and he was convinced that this had been due to too long delay in operating. Such results were certainly better than those given in the statistic quoted by Dr. Smith. If the patients which were not operated on did not have septic peritonitis, they were liable to suffer in other ways. The appendicitis was apt to go on to abscess, and he knew of two cases in which when relapses occurred, there was extensive burrowing of pus. If the appendix were removed by operation, the patient was saved all future trouble of this kind. The thing that he most feared in connection with appendicitis was the allowing of a case which ought to be operated on early, to go on too long without interference.

DR. C. A. LEALE narrated a case of abscess in which he had operated successfully under discouraging circumstances. He thought the use of the exploring needle could not be too emphatically condemned. In addition to other evils, it was apt to increase the peristaltic action of the intestines, and sepsis was liable to result. Surgeons sometimes said it was too late to operate, but he thought it was never too late to operate. As an illustration he referred to a case which occurred many years ago, in which Dr. Willard Parker and several other surgeons were called in consultation, and the result of the consultation was that an operation would be hopeless, and should not therefore be attempted. Afterwards the family sent for Dr. Parker alone, and asked him to operate. He did so, and as a result of this procedure the patient was alive to-day. If there was one chance in a hundred for the patient, he thought that he ought to be offered this chance.

DR. ÖBERNDORFER, having asked Dr. McBurney upon what signs he would rely in deciding the question of whether to operate or not, the latter replied that this was a matter in regard to which it was practically impossible as yet to lay down any definite rules. In general he would say, however, that if he found a patient who had pain in the right iliac region, but with no fever, vomiting or special interference with any function, and who looked well and was able to move about in bed with comparative ease, he would feel satisfied to let such a patient go on to the next day. If, however, the next morning he found that the tenderness had increased to an exquisite degree, that there was inability to move the part, that there was a well-defined point of extreme sensitiveness, and that the temperature was over 100°, he said he should tell such a patient that by an operation for the removal of the cause of his trouble, he could almost certainly cure him, and prevent the recurrence of anything of the kind in the future; while, if the operation was not done, he would be likely to die of septic peritonitis,

and if this did not occur an abscess would probably result, and he would be liable to dangerous relapses from time to time.

There were other cases which were very grave from the first. There would naturally be no tumor thus early, but extraordinary tension of the abdominal muscles on the right side, would be found. There would be rapidly increasing tenderness and marked constitutional disturbance. Such cases he would not leave a single hour unoperated on. Dr. McBurney said he laid considerable stress on the amount of constitutional disturbance. The temperature, however, was often not at all high, and in some of the worst cases it was not above normal.

DR. SMITH, in closing the discussion, spoke first of the difficulty of making an early diagnosis in many instances. The seat of harm, as Dr. Janeway had remarked, was often deceptive, and he had met with one case in which it was principally located in the upper part of the lumbar region, and another where the pain was at the site of the right kidney. As to the desirability of calling in a surgeon on the first day, he was not entirely prepared to accept Dr. McBurney's opinion, and very few families, he thought, would be willing to consent to such a course. The surgeon would be almost sure to advise laparotomy, and when an authority so eminent as Hencoe had made the statement that when the opium and ice-bag treatment was begun early enough, recovery ensued in almost all cases, he did not think that such a measure was called for as a rule in the early stages.

INOCULATIONS FOR PULMONARY TUBERCULOSIS.

DR. H. J. BOLDT made a few remarks on this subject, his object being to call attention to the work in this direction, which had been accomplished by a member elect of this Association, Dr. J. Hilgard Tyndale. For many years he had been pursuing experimental investigations upon the subject, and for the past year and a half he had met with excellent results from the inoculation of bovine virus diluted in a saline solution. Among the results noted in tuberculous patients were the following: The bacilli decreased in the sputa, hectic disappeared, cough diminished very rapidly, the weight increased and the health generally improved. As in the case of Koch's inoculations, the constitutional symptoms after the inoculation were quite severe. Dr. Boldt felt sure that Dr. Tyndale would be very glad to explain his process, and to exhibit some of his cases to any members of the Association who might be interested in the matter.

SOUTHERN SURGICAL AND GYNÆCOLOGICAL ASSOCIATION.¹

SECOND DAY.—AFTERNOON SESSION.

DR. W. O. ROBERTS, of Louisville, read a paper on REMOVAL OF STONE FROM FEMALE BLADDER THROUGH THE URETHRA, WITH CASES.

This paper was devoted simply to his individual experience in the extraction through the urethra of stone from the bladder of the female. The cases thus treated were six in number; the ages of the patients ranged from fifteen to fifty-six years. Four were married, but

¹ Third Annual Meeting, held at Atlanta, Ga., November 11-13, 1890. Concluded from page 536 of the Journal.

only two had borne children. The stones were phosphatic in four cases, uric acid in one, and an incrusted, fringed body in another. In one, a very hysterical patient, the stone had for its nucleus a piece of soft wood. In one the patient had a vesico-vaginal fistula, which had been closed by an operation some months prior to the occurrence of the symptoms of stone. In another the bladder had been opened by a surgeon in doing an ovariotomy upon the patient a year before the stone was discovered.

In four of the cases the stones were single, in one there were two, and in one nine. In this case the patient had passed at various times a number of small stones, from two to seven at a given micturition. These stones varied in size from that of a grain of wheat to a grain of coffee. In two years she had collected 184 stones, a number not representing all she had passed.

The extraction was done in every case under chloroform, the patient being profoundly anesthetized. The urethral dilatation was begun with forceps, and completed by means of the fingers. The little finger being first introduced, the ring finger next, and finally the index finger. The fingers were well oiled. In Case I the stone was found to be almost an inch and a half in diameter. In Case II the stone was found in the urethra, and proved to be a piece of soft wood heavily incrusted with urinary salts. In Case III the stone was spherical, and had a diameter of about one-half inch. In Case IV the stone was ovoid, its long diameter being an inch, the shorter three-fourths of an inch. In Case V there were nine stones, the smallest measuring circumambiently two and one-fourth inches; weight, eighty-four grains.

Dr. WILLIAM PERRIN NICOLSON, of Atlanta, Ga., presented a paper entitled

WET ANTISEPTIC DRESSINGS IN INJURIES OF THE HAND.

The especial point that was urged in the paper was the doctrine formulated by Verneuil—never to use a scalpel in a hand injury. The old teaching, that when a finger was crushed, you should go far enough behind the injury to secure a sound flap, and amputate, was pernicious in the extreme, and had cost thousands of fingers that would have been restored to usefulness. Only such parts as were actually destroyed and pulped should be removed, and all the tissues to come away could be amputated with the scissors. Projecting pieces of bone could be removed with pliers, until reduced to the level of the fleshy parts. In compound fractures the parts should be coapted as well as possible, and the line of separation be determined by nature, and under strict antiseptic dressings. Such a slough was harmless. Another point to which attention was forcibly called was the utilization of blood-clot in filling up ragged injuries, and by its substitution the restoration of lost parts. When a finger was crushed off, the end should be trimmed with scissors, and the clot utilized in building up a tissue over the bone. In reference to dressings Dr. Nicolson said that he had tried almost all varieties, and had finally obtained the most satisfactory results from keeping the parts constantly bathed in a non-poisonous antiseptic solution.

In dealing with these wounds they were first cleansed as well as possible, and then bathed in a sublimate solution. Over all wounds a piece of aseptic rubber tissue or oiled silk was placed, then iodoform and sub-

lime gauze, and finally over all a covering of rubber tissue, into which, at some convenient point, a small opening was made. The patient was then given a bottle of antiseptic solution, to be carried in his pocket if moving about, and instructed to pour, at frequent intervals, enough into this opening to saturate the dressings. He uses almost exclusively listerine, combined with a small amount of carbolic acid, in the proportion of half an ounce of the former and half a drachm of the latter, in a six-ounce mixture. If there was much pain, a small amount of aqueous extract of opium was added. These dressings were not disturbed until the third day, when they were removed under strict antisepsis, to preserve the integrity of the blood-clot. Wet dressings were substituted at the end of about a week by the ordinary antiseptic dressings, kept moist by external covering of rubber tissue. Should sloughing occur, it is kept wet for a longer time with the antiseptic. Under this treatment pain was reduced to the minimum. Suppuration never occurred, and the separation of sloughs was facilitated by the warm moisture.

Dr. J. T. WILSON, of Sherman, Tex., read a paper on

UTERINE MOLES AND THEIR TREATMENT.

In the few cases that had come under his observation, they had been more troublesome and elicited more anxiety than most writers indicate they should, and the hemorrhage in some of the cases was alarming; then, too, there were some points noticed in his cases which he failed to find described in text-books.

He had never met with a case that was lying loose in the uterus, but all were more or less adherent to its walls and most of them to the posterior wall. They all required after-treatment, because all except one case had endometritis and endocervicitis; two had severe cervical lacerations and erosions; most of them had a greater flow than usual at the subsequent menstrual periods until the inflammatory condition was relieved; none of them were in perfect health; none had any history of a cancerous cachexia, nor of syphilitic taint; one was tuberculous. His experience had taught him to believe that if these cases do not receive treatment at a proper time there are two grave dangers to be apprehended, namely, hemorrhage and septic poisoning.

In the treatment, if the cervix is sufficiently dilated and hemorrhage troublesome, the mass should be promptly removed. If this cannot be done, a hot, antiseptic vaginal douche should be given, followed by a careful and efficient tampon, with the internal administration of ergot and anodynes, if required, directing quiet, rest and simple diet. In from twelve to sixteen hours the tampon should be removed, and the foreign body extracted as completely as practicable; this will require a good stout pair of forceps. He had used the ordinary dressing forceps and placental forceps for the purpose. An excellent instrument in some cases is Emmet's curette forceps. The surface should be well curetted with a wire curette, the uterus thoroughly washed out with a hot solution of bichloride of mercury and carbolic acid or tincture of iodine well applied to the surface. If much bleeding ensues—and this is not usual—the application of persulphate or perchloride of iron gives good results. In from three to five days the uterus may need curetting again and another intra-uterine douche; then the application of iodine about twice a week.

THIRD DAY.—MORNING SESSION.

DR. G. FRANK LYDSTON, of Chicago, read a very elaborate paper entitled

A REVIEW OF THE TREATMENT OF VARICOCELE,
WITH CASES.

For practical purposes the various methods may be divided into (1) acupressure, (2) subcutaneous deligation, (3) open deligation, (4) deligation with resection of veins, (5) deligation with resection of scrotum, (6) resection of scrotum.

The employment of acupressure was an evidence of a lack of faith in modern antisepsis. It reminded him of the Dutchman's method of cutting off his dog's tail, an inch at a time, so that it would not hurt him so much. Gradual obliteration of veins had all the dangers of immediate deligation in a marked degree and none of its advantages. There is little choice between deligation without disturbance of the veins and deligation with resection of the veins, excepting the remotely greater danger of sepsis in the latter. Gould's method of division by cautery he believes to be the most dangerous operation yet devised. The dangers of the open method are, in a less degree, those of subcutaneous deligation. If open ligation be determined upon, the operation should be done as high up as possible in the straight portion of the veins and a single ligature applied to the vein. Deligation with resection of the scrotum he considers to be the ideal operation, in the majority of cases which require surgical interference. His plan is as follows: An incision is made parallel with the spermatic cord just below the external ring. This incision should be about one inch in length. The cord is hooked out with aneurism needle, the veins separated and tied, the ligature is cut through and the cord dropped. Sutures and antiseptic dressings complete the operation. The scrotum is now amputated by the improved Henry operation. Resection of the scrotum he considers the simplest and safest operation for varicoceles of moderate size. In the more marked forms the affection invariably recurs to a greater or less extent. He does not, therefore, consider the so-called Henry operation a radical cure in the true sense of the word. The author reported a large number of cases operated upon by various methods. The author had noticed hydrocele as a result of subcutaneous deligation in two cases. The doctor reported one very interesting case in which the scrotum was continually bathed in bloody perspiration and in which the seminal ejaculations were heavily tinged with blood.

DR. GEORGE A. BAXTER, of Chattanooga, read a paper on

SILICATE OF SODA, SOME NEW METHODS OF USE
IN SURGERY,

in which he said the jacket of baked silicate of soda which he would present to the Association possessed all the qualities to be found in the plaster, firmness and support, and weighs only one pound and six ounces. It is neater in appearance and finish, can be perforated like leather for ventilation, which plaster cannot. It is even lighter than leather without its costly process of construction, and has the same advantage over the woven-wire jacket with the additional advantage over both these latter and all others of this class, that it can be constructed by any surgeon at any time or in any place. Dr. Baxter suspends his patients and puts

roughly a plaster jacket around them, and cuts this as soon as it has hardened enough to retain its shape, thereby lessening materially the time of suspension, binds the cut edges together where it has been cut down directly in front, with cords, and then places a core of paper in the centre. This paper core is used for two reasons, to lighten the cast and take as little plaster as possible, and to dry it the more readily by heating the inside. This done, the plaster is poured around the core and inside the cast, which gives a mould of the body in extension and counter-extension, exact in every respect. Around this is made the silicate jacket after the manner of the plaster roller bandage, weaving one-half inch metal strips in the meshes of the bandage at a distance of four inches apart around the whole cast, an inside lining of a knit shirt having been first placed over the cast. The whole is then placed over a coal oil stove, and allowed to dry, which it does in from one-half to two hours. This process of heating not only dries the silicate but bakes it, and renders it impervious to the action of water or perspiration, and gives it sufficient strength to allow of its being perforated for ventilation. It is now cut from the mold with a straight incision down the centre, two pieces of leather, to which button hooks or eyelets have been previously attached, sewed up and down the front on each side, then the whole can be laced up solid or loosened or taken off at will.

DR. EDWIN RICKETTS, of Cincinnati, O., contributed a paper entitled

SURGERY OF THE GALL-BLADDER,

in which he said, to Langenback was due the credit of totally extirpating the gall-bladder, and to J. Marion Sims we owed a debt of gratitude for establishing the operation of cholecystotomy.

Dr. Ricketts reported seven cases of gall-stones.

CASE I. Mrs. —, aged thirty-eight, married, consulted him in 1880 for a tumor in her right side in the region of the gall-bladder. Said she had passed by the bowel, following a severe attack of hepatic colic, a number of gall stones. She was emaciated and suffered from what she claimed was neuralgia of the stomach. She was slightly jaundiced and bowels constipated. Upon examination of the abdomen the tumor was well-marked and nodulated, above which was the liver surface smooth. He made the diagnosis of gall-stone and urged an operation. The patient's physician, however, urged the expectant plan of treatment which was accepted by the patient. She then went to the country and in less than three months had an attack of hepatic colic, followed by peritonitis, dying inside of three days.

CASE III. Ellen —, colored, aged thirty, consulted him for a markedly distended gall-bladder which made its appearance after a hard day's work over the wash tub. She had been sick for ten days with fever, temperature reaching 103°, rapid pulse, clayish stools, with occasional attacks of hepatic colic, though not severe. He opened the gall-bladder, turning out one pint of fluid which consisted of bile, mucus and pus, stitching the gall-bladder up against the peritoneum. After three days catarrhal plugs were washed out of the common duct through the abdominal incision in which had been deposited a glass drainage-tube. The fistulous tract is still open, discharging periodically, but with no bad results to the patient.

In Case IV, a diagnosis of cancer of the liver was

made by the attending physician. The gall-bladder was opened and the stone turned out and weighed 128 grains, and the common duct was filled with catarrhal deposits.

CASE V. After incising the gall-bladder there escaped first about one drachm of pus, after which Dr. Rickette turned out twenty-eight stones. A diagnosis of cancer of the liver in this case was made by the attending physicians.

THIRD DAY.—AFTERNOON SESSION.

DR. W. HAMPTON CALDWELL, of Lexington, Ky., read a paper on

RECTAL MEDICATION,

in which he said that several years ago he was convinced of the utility and safety of rectal administration of medicine, and had ever since regarded it as a most important plan of treatment. Since we accept the theory of the local origin or manifestation of the majority of diseases, this idea of rectal administration of medicine, was more readily accepted as scientific in its applications than at any time heretofore. The rectal suppository, consisting of coco butter, incorporated with the various therapeutical agents, affords the most efficient and pleasant mode of administration in our possession. Rectal suppositories satisfy all requirements as a local or constitutional remedy; they are neat, convenient, and in almost every instance preferred by the patient to the administration of the same drug by the mouth. In the administration of anodynes, it is certainly a superior method of administration to all others, as the sensitive stomach is no longer a barrier or excuse in the administration of even the most disagreeable medical agent, for we well know that in many instances that this organ is either tolerant to opiates or the patient has an invincible objection to taking them, the impossibilities of the rectal administration being thrown off, is one great advantage over all other methods of administration. The effects of rectal medication embrace a wide range of action, including anodyne, antiseptic, alterant and astringent. In severe pain they certainly afford the best and safest source by which our patient's suffering can be relieved, as the action upon the rectal surface of a diffusible anodyne is quite rapid, and produces an effect about as soon as when administered by the stomach. In all inflammatory or painful affections of the abdominal or pelvic organs, this plan of administration has succeeded better than all others with the author.

DR. THAD. A. REAMY, of Cincinnati, Ohio, reported a case in which he removed a stone weighing 365 grains, by vaginal cystotomy, from the bladder of a child six years of age, with injury of the ureter. Operations done for closing the bladder were difficult, but ultimately successful. He exhibited the stone, and made some comments on the case.

He felt after the stone was removed that it would have been better to have made supra-pubic cystotomy. Had he known the size of the stone, he would probably have done that operation. But in view of the fact that it was partly encysted, that the bladder walls were much inflamed and thickened; also the fact that in the child the parietal peritoneum dips much lower down in front of the bladder than in the adult, it became a serious question whether this course would have been better than the one pursued.

It was not clear whether the ureter was damaged

in the removal of the stone, or was exposed by the sloughing which occurred much later on. He was inclined to favor the former view; and that the discharge of urine into the tissues of the bladder wall in the line of suture, was to no small degree responsible for some of the failures in closing the bladder. However, until the last operation the most critical examination failed to discover the ureter.

Though Parvin, Campbell and others had turned an exposed ureter into the bladder, the speaker was not aware that it had heretofore been done in a subject so young. The vagina being so small rendered the manipulation difficult in the extreme.

DR. JAMES A. GOGGANS, of Alexandria City, Alabama, read a paper on

THE SURGICAL TREATMENT OF EMPYEMA.

He said during the last eighteen months he had treated six cases of empyema which developed in the wake of pneumonia, all of which had made perfect recoveries. These patients varied in age from three to thirty-five years.

Surgical treatment was the one which had been the most successfully employed. Spontaneous cures, he said, were rare—so rare that surgical interference was the rule. There were many methods of operating for the removal of pus from the pleural cavity, but they may be classified under two general headings: (1) The closed method, which consists in removing the pus by simple puncture with some kind of trocar or modern aspirator and allowing the puncture to heal at once. (2) The open method, which consists in making an incision more or less free with the introduction of some kind of drainage-tubes to maintain the perfect evacuation of the fluid, and admit of medicated washings, and to promote free ingress and egress of air that has been passed through an antiseptic dressing. The surgical treatment then being an absolute necessity, we cannot overestimate the importance of making the diagnosis certain by resorting to exploratory puncture with the hypodermic syringe. We can assure the patient and friends that no evil results can come from this procedure, and that the prognosis positively depends upon this means of settling the diagnosis.

Officers for 1891: President, Dr. L. S. McMurtry, Louisville, Ky.; First Vice-President, Dr. McF. Gaston, Atlanta, Ga.; Second Vice-President, Dr. J. T. Wilson, Sherman, Texas; Secretary, Dr. W. E. B. Davis, Birmingham, Ala.; Treasurer, Dr. Hardin P. Cochrane, Birmingham, Ala.

Place of meeting, Richmond, Virginia, second Tuesday in November, 1891.

THE NEW YORK NEUROLOGICAL SOCIETY.

MEETING of November 4, 1890, the President, DR. L. C. GRAY, in the chair.

ASTASIA AND ABASIA.

A patient was presented by DR. G. M. HAMMOND exhibiting the symptoms laid down as characteristic of this unusual affection. The patient, a young woman, had never been the subject of any serious illness excepting Pott's disease, which had come on during childhood. Over a year ago, the speaker had attended her through an attack of nervous prostra-

tion. During her illness she had suffered from aphonia; the difficulty in standing and walking was not discovered until she was able to leave her bed. On regaining her strength sufficiently to walk around, it was observed that she invariably walked by first advancing the left leg and then drawing the right one up to it. When she attempted to walk naturally, immediately that the right foot touched the ground her body would revolve rapidly to the right, when after making a revolution and a half she would sink to the floor. Physical examination of the limbs revealed nothing abnormal. The patient while seated or lying down could move both legs normally, with the right leg, however, more mental effort was required to make the movements. The patellar tendon reflex was normal on both sides. There was no ankle clonus, no anesthesia, hyperesthesia or any other disorder of sensibility in any part of the body with the exception of slight loss of the muscular sense in the right leg. The electrical reactions, both qualitative and quantitative, were normal. The field of vision and the color-sense were found normal. The senses of hearing, touch, pain and temperature were tested without anything abnormal being discovered. There was some resistance to passive flexion and extension of the right leg.

Those symptoms then of difficulty in standing and of inco-ordination and ataxia of movement for the act of walking, but not for other muscular acts, corresponded accurately to that condition described by Bloeg under the title of "astasia and abasia." Bloeg was of the opinion that astasia and abasia was a condition pathologically similar to agraphia. The speaker did not see anything in these cases to substantiate this view. People afflicted with the disease under consideration could make the motions of walking perfectly well if they were allowed to lie down, but it had never been claimed that an individual suffering from agraphia could write any better in one position than he could in another. The condition, it seemed to the speaker, depended upon a loss of the power of adjusting muscular contractions so as to retain an exact equipoise or equilibrium. This was, of course, a defect of the muscular sense. There was no known tract in the spinal cord, disease of which, would be followed by these symptoms. Bloeg had attempted to make a distinct neurosis of this class of cases, and had claimed that a differential diagnosis between hysteria and astasia and abasia could readily be made. In the latter disease there were no hysterical stigmata, he claimed, no constant paralyses or constant contractures. But the latter were by no means characteristic of all cases of hysteria, and when it was considered that every case of astasia or abasia had been accompanied by some other symptom or symptoms, such as, for example, hyperesthesia, anesthesia, aphonia, contraction of the visual field and temporary color-blindness, all of which frequently accompanied hysteria, and since the disease under consideration was purely functional in character, no gross macroscopical or microscopical lesion ever having been discovered in them, it would not be difficult to believe that astasia and abasia was merely an uncommon type of an hysterical affection.

Dr. C. L. DANA said that if it were possible to exclude any organic trouble as a factor in the case there seemed nothing left but to give the condition the name which Dr. Hammond had done. It was by

no means that this so-called disease deserved a separate clinical position, and they were by no means aware of all the vagaries of the trouble. He thought that the diagnosis might be accepted as a provisionally correct one.

DR. LOUISE F. BRYSON said she had recently been reading a case reported in a French journal of what was known as "left- and right-sided disease," in which the patient always had to walk to the right. Physiologically the muscles on the right side were stronger than those of the left, and perhaps the case was one of exaggerated function of the muscles of the right side.

DR. G. W. JACOBY said that in a recent number of the *Berliner klinische Wochenschrift*, Dr. Binswanger had stated his belief that the whole trouble resulted from a psychical condition as the same phenomena were found in other mental states. He had not seen a case exactly like this but others which reminded him very much of it. He was inclined to consider the condition, as a psychic manifestation. Women after long confinement in bed would sometimes when attempting to walk, find themselves too weak to do so and immediately conclude that they had lost the power. While lying down or sitting they would have entire control of their limbs, but when they essayed walking then came the fear. It was a psychic disturbance of equilibrium. He thought that Binswanger had done as much to clear away doubt in this class of cases as others had done to confuse.

THE PRESIDENT said he had never seen anything like this case. The cases of hysterical paraparesis which he had seen were typical forms of paraplegia. He had also read the two cases described by Russel Reynolds who had called them "paralysis of idea." He did not think it was well to designate this case as one of hysteria on account of the presence of some spots of anesthesia, because it had been shown that this occurred in a great many different nervous disorders, both functional and organic. It seemed better to accept the case as a clinical entity, and hold any opinion in reserve as to the cause of the manifestations.

SYRINGOMYELIA?

DR. S. E. SHAW presented a patient to the society suffering with, as he had diagnosed, syringomyelia. The patient, a single woman, thirty years of age, had always good health until about six years ago, when a weakness of her left hand was noticed. This condition had steadily increased up to the present time. For the past three years she had had a constant aching in the left arm, shoulder, and side of the neck, and lately, on that side of the head. For two years there had been a numb spot on the inner side of the left arm. She had constant sensations of burning on the left side of the face and neck, with flashes of heat and cold. There was a small spot on the back of the head where this burning sensation was greater than anywhere else. She presented an atrophy of the small muscles of the left hand which had been in existence for six years and was gradually growing worse. There was also slight atrophy in all the muscles of the arm, shoulder and face of the left side. In the area of the numb spot the tactile sensibility was impaired. The thermic sense was greatly diminished over the entire left side, and in the right lower extremity as well. The reflexes were exaggerated. While the examination of the patient had not been as careful as it might have

been, the speaker thought that it was sufficient for the purpose of making a diagnosis.

DR. B. SACHS thought the personal equation was a powerful factor in this case. It certainly had been so that evening. The case did not seem to him to be one of syringomyelia. The atrophy was not marked enough, particularly about the shoulder. The sensory symptoms were not so distinct as in a typical case. So far as he could judge the case seemed one of amyotrophic lateral sclerosis, though further examination or observation might lead him to a different conclusion.

DR. A. M. STARR said that there were several features about this case which reminded him of one which had come under his observation. He had not brought these points out because he did not know that they belonged to syringomyelia. One of these peculiarities was the noise made in the throat, a sound as of alarm. This had been present in his patient, who was by no means an hysterical girl. He had regarded it as a muscular contraction of the larynx during inspiration. His patient would make the noise whether she was quietly conversing in his office or was before a class of students. This feature was to be taken into consideration. He thought that the stationary condition of the atrophy in this case indicated the existence of syringomyelia rather than that of amyotrophic lateral sclerosis. He had demonstrated pretty conclusively the changes in pain-sense by sticking the point of a needle in the patient's arm without her knowing it. There was no mistake about this, for he had put the needle in a quarter of an inch. Then there was the history of a loss of temperature sense. The patient had noticed in putting her hands in hot water, that there was a difference between the two sides. Therefore, bearing in mind the non-progressive condition of the atrophy, the existence of changes in the temperature and pain senses, he supposed they were warranted in making a diagnosis of syringomyelia at the present date.

DR. SACHS thought the question depended upon the actual condition of the sensory derangements in this case, and of course the examination had been but sensory.

DR. W. R. BIRDSALL thought that here the results of examination were so at variance it would be hardly worth while to attempt any expression of opinion in the way of diagnosis. It had been his impression from the description of cases of syringomyelia of which he had read, and in which an autopsy had been held as confirmatory evidence, that the histories had given the pain and temperature sense as having been both affected. He should say that the case before them was at least typical in this respect. As to this disease it was a remarkable fact that, during the past year, of the cases in which syringomyelia had been diagnosed during life there was no autopsy, while in those autopsies which had revealed the existence of the disease, its presence had not been suspected during life.

DR. DANA said that last spring he had a patient in his hospital service who had presented many similar symptoms. There had been atrophy in the muscles supplied by the ulnar nerve and in the small muscles of the hand. There was also anesthesia involving the temperature and pain senses. The atrophy had slightly involved the opposite side. There was also a belt of anesthesia over the lower portion of the trunk and extending to the thighs. There was no disturbance to the sensory functions. The girl had gradually developed symptoms of bulbar paralysis without any sen-

sory symptoms accompanying. He had been obliged to regard this as a typical case of progressive muscular atrophy. He had seen a case of this disease in which the sensory symptoms were present. If the symptoms of bulbar paralysis were developed in the case before them, it would, he thought, turn out to be a case of progressive muscular atrophy. As to amyotrophic lateral sclerosis, it was simply another name for the same disease.

The PRESIDENT said the only way to make a diagnosis of syringomyelia was to make an autopsy. The value of the loss of thermic sense in a patient as a diagnostic point, was somewhat vitiated by the fact that the relations of this sense to other organic spinal diseases were unknown. He thought they would be unable to establish the fact satisfactorily that this was a case of syringomyelia until the woman died.

CASE OF SPINA BIFIDA WITH SUPPURATIVE MENINGITIS AND EPENDYMITIS OF BACTERIAL ORIGIN.

DR. L. E. HOLT and DR. I. VANGIESON reported a case of spina bifida in an infant, in which the entrance of bacteria into the wall of the spinal sac, had apparently caused a suppurative spinal meningitis and ependymitis. The child had died three weeks after birth, without having any very serious symptoms, beyond those of paraplegia, marked irritability and failing nutrition, there were no physical signs of hydrocephalus. The centre of the spinal sac had the appearance of a granulating surface and was covered with a sero-purulent discharge. At the autopsy the ventricles of the brain were found to be greatly dilated and to contain three ounces and a half of thin pus. The pons and cerebellum were partially covered with a yellowish exudation which also coated a portion of the spinal cord and the whole of the interior of the spinal sac. The viscera were normal. Microscopical examination had shown the presence of great numbers of small cocci in chains, in the wall of the spinal sac and in its internal necrotic fibrinous coating; in the central canal and meninges of the spinal cord; in the exudation on the surface of the cord; in the exudation on the pons and cerebellum, and finally in the walls of the lateral ventricles. Although the cocci were not identified by cultures, their grouping and division and a careful comparison of them with other known species of micrococci seemed to indicate that they were streptococci pyogenes. The authors called attention to the fact that the skin of the spinal sac in spina bifida cases, was often quite thin, and had a raw exposed central surface which would permit of the entrance of pyogenic bacteria into the wall of the sac, and this would explain the occurrence of the complicating purulent and fatal lesions of the central nervous systems. Judging from their own case, the writers also thought that in operative procedures on the sac, bacteria had been introduced when purulent central neural inflammation had occurred afterwards, and advised the most careful antisepsis in dressing the wall of the sac, especially when the central cicatrix had an exposed surface.

DR. L. E. HOLT said he had seen one other of these cases of hydrocephalus in which the disease had existed without any symptoms during life. He thought there were probably a great many more than was usually supposed. He had been surprised to find that the ventricles contained several ounces of fluid. He had seen several cases of basilar meningitis in which only a moderate amount of distention of the ventricles was

found. In two of these cases the entire contents of the lateral ventricles would not have exceeded an ounce.

CEREBRAL COMPRESSION.

DR. E. D. FISHER read a paper with this title. He said that while he had nothing new to present, he thought that he could settle definitely the question of the influence of compression on the cerebral mass within the skull, and whether the cerebral substance was, *per se*, compressible without interference with its capillary circulation or function. Bergmann and Adam Knoiez (?) hold the views that the brain substance was uncompressible, the only conditions of change possible in the cerebral volume being those dependent on the displacement or variation in the cerebro-spinal fluid or the cerebral circulation, these standing in converse relation to each other. The question of the compressibility of the brain depended on which of the elements comprising the brain was most liable to compression, as the blood-pressure was higher than that of the cerebral fluids it was possible that the tissue fluids were first affected. Much depended also as to whether we regarded the liquor cerebri as a secretion or as a transudation from the blood-vessels, as in the latter case we would have to consider arterial tension as a very important factor in cerebral compression. The vascular centre was not only situated within the medulla but probably also within the brain, that is, the corpus striatum or optic thalamus. The brain possessed a mechanism of its own for increasing its blood-supply independent of increased cardiac action. Experimentally it had been proven that cold acted deeply within the brain. Its good effect was very marked in the headaches of the anemics, the ice-bag being an efficient remedy. The cold probably acted by increasing the blood-current rapidity in the capillaries and by causing spastic contraction of the arteries. In these cases the amount of the blood passed through the brain by increasing the rapidity made up in the quantity for the quality, thereby maintaining the nutrition.

The extent of a cerebral hemorrhage depended on the arterial pressure or tension, the intra-cerebral pressure, and also on the resistance of the brain-substance, the latter, of course, depending on the site of the hemorrhage. By spastic contraction of the arteries of the brain we really had active hyperemia, the decreased volume of skull contents causing increased capillary circulation. By paralytic dilatation of the arteries we have passive hyperemia, which was, in fact, anemia, the blood being no longer in a proper state to carry on the nutrition of the brain as the increased volume of the brain caused retardation of the capillary circulation and probably also interfered with the venous circulation. The speaker's experiments had been made by exposing the pia mater and observing the changes made in the blood-vessels. Extension of the sciatic nerve produced increased volume of the brain. Compression of the carotids caused marked loss of volume. Asphyxia caused expansion of the brain. Chloral caused anemia of the brain with marked contraction. Chloroform contracted, ether at first contracting and subsequently expanding the brain. Strychnia caused marked expansion, as did digitalis and small doses of alcohol. Caffeine and the acids caused expansion while the alkalies produced the reverse result. Drawing from his experiments the speaker concluded that the blood-supply of the brain

varied directly with the blood-pressure in the systemic arteries and that the extensibility of the walls of the cerebral vessels allowed of great variation in calibre. The vaso-constrictor centres were excited directly by disturbance with the nutrition of the nervous system, as in anemia, asphyxia and so forth. Finally that the essential product of cerebral metabolism contained in the lymph spaces, bathed the walls of the arterioles and could cause variations in the calibre of the vessels, that this mechanism reacted on the brain and that by this means the vascular supply could be varied locally according to local varieties of functional activity.

DR. JACOBI said that the demonstration that the nerve-tissue could be compressed in its molecules and anatomical elements had been claimed by one author. Another had maintained the non-compressibility of these elements, but had further stated that the effect of hemorrhage was due to anemia of the brain. This was as a theory substantiated by comparing the clinical symptoms in such hemorrhage with the symptoms caused by the injection of lycopodium powder into the cerebral vessels and producing thrombi. He then referred to certain experiments which had demonstrated the displacement of the cerebral spinal fluid. In one case in which rice was injected into the aqueduct of Sylvius was found to be ruptured and the lateral ventricles flattened together. This experimenter had inferred that the very suddenness with which the compression was exercised had caused the violent displacement of the cerebro-spinal fluid and consequent rupture. The same observer had also estimated very minutely the amount required to oppose the arterial tension and had claimed that if, at any time, an effusion took place on the surface of the brain to entirely balance this, death must instantly result. Dr. Fisher had pointed out the necessity of maintaining arterial tension rather than depressing it, upon this very theory. It had been suggested that in cerebral hemorrhage the head should be hung down to mechanically send blood to the head and thus oppose the effusion which was taking place from the ruptured vessels. He did not know whether this had ever been put into practice.

— The New York State Civil Service Commission recently adopted a resolution, which has been approved by the Governor, changing the classification of the positions of superintendents and assistant physicians in the eight State hospitals from the non-competitive to the competitive schedule. In accordance with this resolution the following qualifications will be required of all physicians who wish to enter the medical service in State hospitals: A physician seeking the place of junior assistant physician must be a graduate of a legally incorporated medical college and must have had at least one year's experience in a general hospital or three years' experience in the general practice of medicine; promotions may be made between the grades of junior and first assistant physicians without examination; candidates for the place of first assistant physician must be at least twenty-five years of age, and must have had at least three years' actual experience in a State or city hospital for the insane; applicants for the place of superintendent must be at least thirty years old and must have had at least five years' experience in the profession in a State or city hospital for the insane, and once having passed an examination for superintendency the candidate shall be eligible for appointment for at least three years.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, DECEMBER 11, 1890.

A Journal of Medicine, Surgery, and allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Rentmittances should be made by money-order, draft or registered letter, payable to

AN ARMY SURGEON'S TOUR OF DUTY WITH STATE TROOPS.

THE Report of the Surgeon-General of the United States Army contains, as usual, some very interesting material. An account of the field operations of the troops during the previous summer, so far as these operations concerned the medical corps, covers several pages. This account is made up of the several reports of the medical directors of various departments and other medical officers.

One of the most prominent of these reports, in point of general interest, is the account of a tour of duty by Assistant-Surgeon Brechemin with the Illinois State National Guard in 1889. Captain Brechemin spent over three weeks at the State Encampment, and met four State regiments. The camp-ground comprises one hundred and sixty acres about one and three-quarters miles from the State-house at Springfield, and possesses every advantage which could possibly be desired in the matter of shade, ample water-supply, opportunities for bathing and natural drainage. The ration furnished is a generous one. In addition to the regular army ration the State issues lard, fresh fish, eggs, butter, milk, baking powder, prunes, extracts of lemon and vanilla, onions, fresh beans, fresh tomatoes, cabbage, canned corn, tomatoes and peaches. The average cost of the ration is about thirty-three cents, and caterers are apparently unknown.

As at present conducted, the medical staff of a regiment is appointed by its colonel — a faulty method, justly condemned by the report, and one which we believe did not prevail in Illinois during the late rebellion, though in other States its shortcomings were abundantly shown.

One of the first defects noticed was the ignorance of company officers of their duties in relation to the medical department. Apparently no instruction was given the men as to the meaning of surgeon's call. In many cases men were excused by commanders on account of sickness and reported to the post-adjudant as sick on the company's morning report without being sent to the surgeon. First sergeants were not instructed, as

a rule, to conduct the sick of their companies to the hospital at surgeon's call.

One regiment arrived at camp without any medical officer, hospital steward or hospital corps, and of the total number of medical officers and hospital stewards over one-half did not report for duty at all, or were present only a part of the week during which their regiment was in camp.

Soon after the arrival at camp a detail of one man from each company was made for the position of private of the hospital corps. One hour was spent each morning in litter and ambulance drills, instruction in first aid to the wounded, improvised methods of carrying wounded men, etc. The squads with litter, were detailed in turn to attend the different regimental formations, drills, guard-mounting and dress-parade. invariably the privates of the hospital corps showed zeal and intelligence in learning the drill; its practical value was appreciated by officers and men, and illustrations of its usefulness were of frequent occurrence. Captain Brechemin speaks with satisfaction of the quickness and aptness of the men; but he found the litters faulty and flimsy in construction, and the State owns no ambulance. He recommends a rigid inspection by the brigade surgeons of the medical department of each regiment belonging to his brigade during its encampment, and that a full and detailed report of each inspection should be submitted to the Surgeon-General so that any deficiencies noted may be acted on by him.

This report is another example of the growing desire to assimilate the national guard and the regular army, and it shows the defects and advantages of the medical corps of the militia of one of the important States. It is curious to note that certain defects in the medical department which existed in most State organizations in the *ante-bellum* days, and which were the cause not only of discomfort but of loss of life, are still perpetuated. The request for the detail of a medical officer from the army — no such detail would have been made without a request — shows a most laudable desire to produce during times of peace a medical department which shall be prepared for actual service. Doubtless such a detail would be of service in other States beside Illinois.

PROFESSOR KOCH'S TREATMENT OF TUBERCULOSIS.

DURING the past week very little new, authentic information has been received on the subject of Koch's method of treating tuberculosis. It is evident that there is little hope of a publication of the process of preparing the fluid for some time to come, and the clinical reports of cases treated are still very incomplete. There has been little important information on the subject that is not contained in the article by Koch in the *Deutsche Medicinische Wochenschrift* of November 14th.

The therapeutic action of the fluid seems to be different from anything which has, up to this time, been

employed in medicine. It does not directly kill the bacilli, neither does it act as a preventive inoculation after the manner of cow-pox vaccination, but apparently tissue containing tubercle bacilli becomes violently inflamed, and finally suppurates, and perhaps separates from the healthy underlying tissue, carrying the bacilli, still alive, with it. This induced inflammation is attended with constitutional disturbance more or less dependent upon the amount of tissue involved, and may be sufficient to cause death, especially where large portions of the lungs are affected. Haemoptysis may occur, or the lung may swell to the exclusion of air. There seems to be no reason to believe that cavities are favorably influenced except by the removal of the bacilli. It is remarkable that the constitutional symptoms are almost identical in character with those met with in abscess formation.

The excitement in Berlin is intense. The city is full of physicians trying to find out something, and trying to get a specimen of the so-called lymph. Although about a thousand cases are under treatment in the Berlin hospitals, the amount of the fluid obtainable seems to be very small, and very little has left the city.

The material used by Professor Koch in his inoculations,¹ is a viscid fluid, the color of a dilute solution of iodine, of a slightly syrupy consistence. It is prepared for use by adding one hundred grammes of sterilized water, the maximum dose of injection being one gramme. No reaction appears locally, but at the

Should the lymph continue in demand, this is a question on which there may be differences of opinion as well as numerous rumors, and we shall have occasion to refer to it again.

INOCULATION FOR DIPHTHERIA AND TETANUS.

FOR some time reports have been in circulation that in connection with the inoculation method of Koch for tuberculosis, a similar process would be applicable to other diseases.

Sir Joseph Lister is reported to have made a speech at King's College, on his return from Berlin, in which he said that within a month the world would be startled by two new discoveries. He said Dr. Koch's consumption-cure hinted at and involved the cure and prevention of two of the most terrible contagious diseases known. He had witnessed experiments on guinea-pigs in which they were inoculated with a new, simple chemical substance which any one would be able to prepare, and were totally unaffected when germs of these diseases were injected.

This was supposed to refer to investigations of Dr. Behring, assistant in the Hygienic Institute and Dr. Katsato of Tokio. An article by them appears in the *Deutsche Medicinische Wochenschrift* of last week, and an abstract has been telegraphed to the *Medical Record*, which published it December 6th, which says experimentation these observers claim mals suffering from either diphtheria e inoculation of the serum from the already infected. It is claimed by a experiments, (1) that the blood of from tetanus possesses the property > tetanus poison; (2) that this pro l by the non-cellular serum obtained (3) that this property is of so cont it also remains active in the organa, so that notable therapeutic effects the transfusion of blood or serum; of destroying the tetanus virus is od of those animals which are not tetanus, and if the tetanus virus is -protected animals, it can be so de after the death of the animals, in the other fluids of the body. A nts are described. he authors express a hope that the strated in these experiments may, in to the treatment of diphtheria and

After going to press we received the following cable from Dr. Harold Ernst in Berlin, under date of December 10th:

"The secret of making Koch's material has been turned over to, and kept by the German Government only until a thorough trial can be made. The effect in lupus and surgical tuberculosis is most striking, because the results can be seen. The most wonderful property is the selective affinity for tuberculous nidus, often making latent centres active. Pulmonary tuberculosis will have to be under observation for a long time still before permanent result is determined. The action of the material is certainly as wonderful as that of any known medicine."

and incompetent persons that they are in a position to dispense the new treatment.

The therapeutic action of the fluid seems to be different from anything which has, up to this time, been

employed in medicine. It does not directly kill the bacilli, neither does it act as a preventive inoculation after the manner of cow-pox vaccination, but apparently tissue containing tubercle bacilli becomes violently inflamed, and finally suppurates, and perhaps separates from the healthy underlying tissue, carrying the bacilli, still alive, with it. This induced inflammation is attended with constitutional disturbance more or less dependent upon the amount of tissue involved, and may be sufficient to cause death, especially where large portions of the lungs are affected. Hemoptysis may occur, or the lung may swell to the exclusion of air. There seems to be no reason to believe that cavities are favorably influenced except by the removal of the bacilli. It is remarkable that the constitutional symptoms are almost identical in character with those met with in abscess formation.

The excitement in Berlin is intense. The city is full of physicians trying to find out something, and trying to get a specimen of the so-called lymph. Although about a thousand cases are under treatment in the Berlin hospitals, the amount of the fluid obtainable seems to be very small, and very little has left the city.

The material used by Professor Koch in his inoculations,¹ is a viscid fluid, the color of a dilute solution of iodine, of a slightly syrupy consistence. It is prepared for use by adding one hundred grammes of sterilized water, the maximum dose of injection being one gramme. No reaction appears locally, but at the end of four hours severe constitutional effects are manifest in the appearance of rigors with malaise, followed by a temperature which may reach 106° F., with a corresponding increase in the pulse-beat from 120 to 160. Vomiting may occur. Sometimes the reaction is attended with alarming symptoms, very great prostration (requiring the use of stimulants) and severe dyspnea. When the tuberculous deposit is superficial, there is in and around it great tumefaction. The constitutional symptoms are usually of short duration. Subsequent injections are not attended with systemic disturbances. Over the surface and in the neighborhood of tuberculous swellings, scabs appear which, on being separated, leave healthy granulating surfaces. Cases in that stage are said to be cured, inasmuch as they show no constitutional reaction.

A report has been in circulation that the German Government intends to purchase from Koch, and to keep secret, the method of manufacture of the fluid, except that, later, properly commissioned deputations of other governments may be taught the art with the understanding that the secret shall go no farther. Such a step, though possibly guaranteeing the uniformity of the lymph, would give the manufacture too much the air of a proprietary medicine, and, from that point of view, is to be deprecated, although the adoption of some similar step might prove to be a necessity, in order to hold in check announcements of unscrupulous and incompetent persons that they are in a position to dispense the new treatment.

Should the lymph continue in demand, this is a question on which there may be differences of opinion as well as numerous rumors, and we shall have occasion to refer to it again.

INOCULATION FOR DIPHTHERIA AND TETANUS.

FOR some time reports have been in circulation that in connection with the inoculation method of Koch for tuberculosis, a similar process would be applicable to other diseases.

Sir Joseph Lister is reported to have made a speech at King's College, on his return from Berlin, in which he said that within a month the world would be startled by two new discoveries. He said Dr. Koch's consumption-cure hinted at and involved the cure and prevention of two of the most terrible contagious diseases known. He had witnessed experiments on guinea-pig in which they were inoculated with a new, simple chemical substance which any one would be able to prepare, and were totally unaffected when germs of these diseases were injected.

This was supposed to refer to investigations of Dr. Behring, assistant in the Hygienic Institute and Dr. Katsatos of Tokio. An article by them appears in the *Deutsche Medicinische Wochenschrift* of last week, and an abstract has been telegraphed to the *Medical Record*, which published it December 6th, which says that after long experimentation these observers claim to have cured animals suffering from either diphtheria or tetanus by the inoculation of the serum from the blood of animals already infected. It is claimed by a large number of experiments, (1) that the blood of rabbits protected from tetanus possesses the property of destroying the tetanus poison; (2) that this property is possessed by the non-cellular serum obtained from the blood; (3) that this property is of so constant a nature that it also remains active in the organism of other animals, so that notable therapeutic effects are produced by the transfusion of blood or serum; (4) the property of destroying the tetanus virus is absent in the blood of those animals which are not protected against tetanus, and if the tetanus virus is injected into non-protected animals, it can be so demonstrated, even after the death of the animals, in the blood and in the other fluids of the body. A series of experiments are described.

In conclusion the authors express a hope that the principles demonstrated in these experiments may, in time, be applied to the treatment of diphtheria and tetanus in man.

MEDICAL NOTES.

— A bill has been introduced in the Georgia legislature to prohibit physicians and drug clerks who are addicted to the use of whiskey or opium from practising their profession. For the first conviction of being drunk a fine of two hundred dollars is imposed, and for the second the license to practice is revoked.

¹ New York Medical Record, December 6, 1890.

— Mr. Lodge has embodied some of the suggestions of Surgeon-General Hammond concerning restrictions on immigration, in a bill which he will introduce before long. This bill aims to exclude all undesirable persons, and devises means and provides the proper officers to carry this prohibition into effect. It also adopts the precautionary measures recommended by Dr. Hammond by providing that no immigrant shall be brought here who has not a certificate of fitness from the United States consul nearest his home. This certificate must be in detail and cover not only the proposed immigrant's financial ability, but also his physical condition and moral character.

— A device called a "pill-taker" recently introduced in England, consists of a light horseshoe-shaped piece of metal, which grips the edge of the wine-glass and supports a little cup-shaped arrangement of bars in which the pill is placed. The victim has then but to take a drink, and the pill is washed down the gullet with an ease and a certainty calculated to surprise the novice in the act of pill-swallowing.

— A perplexing suit involving professional secrecy has been before the Paris Society of Public Medicine. A suburban practitioner, called in to attend a patient suffering from scarlet fever, advised the landlord to disinfect the house. This was done, and the landlord sued the patient to recover the cost. The patient thereupon sued the doctor for breach of professional secrecy, and it is thought that he will win his case.

— Dr. Prentiss at a meeting of the International Medical Congress at Berlin, related the case of a lady, aged twenty-five, who had thin blonde hair, and who suffered from uræmic symptoms depending on an affection of the kidneys. Frequent injections of pilocarpine were given. In one month the hair had become changed to a chestnut color, and after two months it was found to be a deep black, the hair, moreover, being much fuller and thicker than before.

— A daily paper from a town in Illinois says: "There is upon the face of the earth no more pleasant place than the interior of the office of Dr. J. P. Slaughter. It has recently been built and is located some distance from the main highway, affording the traveller only a bird's-eye view of its gigantic proportions. The style of the architecture is the Moresque of the twelfth century. The interior contains a parlor, vestibule and druggist's room, in all resembling a Gothic cathedral. The eye of the visitor wanders over this expanse, bewildered by its extent and the impossibility of grasping its vast dimensions. It is surmounted by a graceful dome rising a few feet above the roof, and terminating in a colossal ball which supports a figure of the doctor standing with outstretched arms, as if extending a welcome to all the world. At the corners are highly decorated arcades with promenades looking outward over the surrounding country, and inward over the beautiful gardens, ornamented with fountains and statuary. The druggist's room is open at all hours, and is presided over by Sam Parrish. A flight of blue marble steps leads up to the front en-

trance from the terrace, at the centre of which is an open kiosque about twelve feet in diameter. At the entrance the visitor passes through a self-registering turn-stile."

NEW ENGLAND.

— The Massachusetts Home for Intemperate Women has its new home in working order, and there are ample and suitable arrangements for the accommodation of private patients who require such facilities as the Home can offer. Such patients may receive treatment, medical or surgical, by their own physicians if they so desire.

— The Massachusetts State Board of Health recently made complaint against the manufacturers of a face lotion which was sold under the name of "Madame A. Ruppert's World-Renowned Face Bleach," and "Madame M. Yale's Excelsior Bleach," and contained a dangerously large amount of bichloride of mercury. The case was brought up in the criminal session of the Municipal Court, where the two defendants pleaded guilty, and were fined ten dollars apiece.

— The Brockton Hospital Company has been incorporated under the laws of Massachusetts. The company is formed in the language of the certificate of organization, "for the purpose of establishing and maintaining a hospital in the city of Brockton for the surgical and medical treatment and nursing of sick and wounded who may not have the means or opportunity to obtain relief and care in other ways, and of any others who may desire such treatment." The organization has no capital stock, but the members of the company severally agree to pay for the uses of the hospital the sum of ten dollars annually for the next five years.

NEW YORK.

— At a meeting of the Section on Hygiene, Public Health and State Medicine of the New York Academy of Medicine, held December 5th, Dr. Simon Baruch read a paper entitled, "A Study of the Public Baths, together with an Inexpensive Method for their Hygienic Utilization." In it he urged the desirability of establishing in the tenement districts of the city a system of shower baths, which he believed to be the most effective, as well as the most economical.

— Succi is now in the last third of his attempted fast of forty-five days, and although he plainly shows the effects of the great strain upon his system, his condition remains very fair under the circumstances. On December 5th his weight was 112½ pounds.

— A theatre for the amusement of the patients, with workshops in the basement for their use, has been fitted up at the New York City Asylum for the Insane (females) on Blackwell's Island, by the Commissioners of Charities and Correction, at an expense of \$4,000; and it was recently opened by a musical and miscellaneous entertainment which greatly delighted the five hundred patients who made up the audience. The building devoted to the purpose was one formerly used as part of the asylum.

Miscellany.

THE MEDICAL REGISTER FOR NEW ENGLAND.

We have been told from reliable sources that circular blanks will soon be sent out to gather information for a new edition of "The Medical Register for New England." The Medical Register is well-known to a large part of the subscribers of this paper. It is a well-recognized fact that it aims to be a thoroughly practical working book, to be found on the tables of physicians who have the most active interest in their profession as it exists to-day in New England.

The book contains all that can be found out, or that any one need know, of all the national, State and local societies, either general or special; of the medical schools and kindred institutions, the hospitals and dispensaries, and various institutions to which we must refer our patients; and of those thousand miscellanies which we are glad to have at our fingers' ends, but can never quite reach. Perhaps, still more valuable are the biographical records of members of the State societies; — by which one can speedily learn the length, breadth and standing of every member therein recorded.

The present duty which impresses itself on our minds as pertaining to the periodical labor of one of our fellow-members in Boston in his relations with his fellows here and elsewhere is that *they owe him the duty of co-operation*. The work of collecting the information necessary for such a book, the know-how and know-where to find it, the putting it together and seeing it through the press, is a labor of no small moment. This labor on the part of the author can be much lessened and the final result much improved by the joint action of members of the profession. To this end each one individually ought to give attention, not only to his own individual record, but as an officer or member of a society or as a worker in a hospital or a school should feel an interest in this joint work for the united good.

Let us see how this will work. Dr. Eyeopener or Dr. Taubbilfer, in one of the cities, is asked to consult with a self-styled physician from the most retired part of New England. Is he a reputable physician or not? Let the Medical Register decide. Again, Dr. Blank of the metropolis wishes to send a patient away to Cranberry Centre among the Granite Hills. Shall he send to Dr. X. Y. Z., who, so far as any record goes, is an entirely unknown quantity, — or to Dr. A. B. C., whose record gives him an M.D. from a reputable college, within recent years, and, with a membership in societies and authorship of professional papers which show that he is abreast of the times and thinking over conscientiously the problems which trouble the best of us.

These are but two points. We must all co-operate; individually, by sending *our own records in full*, so that others may know us as we may wish to be known; as officers of societies, so that as they are better known the better men may be drawn into them; as officers of medical schools and similar bodies for the same reason; as officers of hospitals and kindred places. What more frequent question? How can I get a child into the Children's Hospital in Boston? Does Dr. B., of Beeville, take mental cases as well as nervous? Or what hospitals give special attention to this, that or the other disease?

Again, these are our points, they all show that works of the character of a Medical Register, which invokes so much labor in the making, is justly entitled to the attention of each man for five minutes of his time with his personal record; to secretaries and others with their accounts; and, by and by, — if our societies themselves do not subscribe in the interest of all their members, — to the personal subscriptions of each one of us.

MANIPULATION OF THE NASAL MUCOUS MEMBRANE.

DR. VON CEDERSCHIÖLD¹ has for some years employed a kind of manipulation, which he considers is of the nature of massage, in various affections of the nasal and pharyngeal mucous membrane. He first tried this kind of treatment on himself while suffering from chronic pharyngeal catarrh following diphtheria, and since then has had opportunities of using it on about a hundred cases in Stockholm. The instrument for the nares consists of a double spiral of silver wire about five inches in length, provided with a small wooden handle at one end and a loop or eye at the other. This loop serves to fasten one end of a strip of batiste — a material of which infants' frocks are made — which is wound round the spiral so as to cover it completely before the process is commenced. The instrument is gently introduced into the nostril, and moved to and fro. For the pharynx a sponge-holder is used, carrying a plect of cotton-wool, which, as well as the metal parts, is carefully covered over with batiste. Gentle but rapid friction movements are made with this over the mucous membrane of the pharynx or naso-pharyngeal space. Not content with manipulating these regions, Dr. von Cederschiöld has actually invaded the interior of the Eustachian tube. For this purpose he employs a spiral similar to that used for the nares, but much finer — fine enough, that is to say, to be introduced into the tube through an ordinary Eustachian catheter.

A TRUE HERMAPHRODITE.

In a letter to the *New York Medical Journal*, November 22, 1890, Dr. C. W. Fitch reports a case which was brought to his notice by the commandant of police of San Salvador, Salvador, C. A., while he was in charge of the sanitary service of said government.

J. H., a house servant of masculine features and movements, aged twenty-eight, height five feet seven inches, weight one hundred and thirty-nine pounds, was arrested by the police for violation of the law governing prostitution, which compels prostitutes to register with the Direction-General of Police and pass a weekly examination by a surgeon detailed for that purpose. On examination, both female and male organs of generation were found in a remarkably well-developed condition. The labia majora were of normal size, but flattened on their anterior surface. The labia minora and the hymen were absent. The vagina was spacious, four inches and a quarter long anteriorly and six inches posteriorly. The os uteri was torn on the left side. There was profuse leucorrhœa. Seven years before, she had given birth to a normal female infant. In place of the clitoris there was a penis which when in

¹ The Lancet, November 15, 1890.

erection measured five inches and a quarter long by three inches and five eighths in circumference. The glans penis and the urethra were perfectly formed. The scutum, which was two inches and an eighth long, contained two testicles about an inch in length and two inches and a half in circumference. The mons veneris was sparsely covered with short, straight, black hair. Both sets of organs were perfect in their functions, semen being ejected from the penis and the ovaries being capable of producing eggs. Scanty menstruation occurred every three weeks, and lasted but two days. Sexual gratification was said to be equally distributed between the two sets of organs.

Up to about seven years before, masculine clothes had been worn, but when pregnancy became apparent the local authorities compelled a change to female attire.

THE TREATMENT OF FURUNCULOSIS.

DR. HOFRAU¹ stated, at the annual meeting of German physicians, that he had employed in the treatment of furunculosis an ointment composed of equal parts of oxide of zinc and vaseline, with four per cent. of boric acid. In circumscribed furunculosis the application was rubbed in and around the parts affected three times a day. The ointment was applied over the whole body in cases where the affection was universal. Sublimate baths were also employed if they could be borne by the patient. A case of universal furunculosis was perfectly healed by the treatment in seven weeks. Poultices were employed in treating large furuncles.

SPERMIN.

In consequence of Brown-Séquard's well-known statements as to the rejuvenating power of hypodermic injections of semen, says the *British Medical Journal*, October 18, 1890, renewed attention was given to an alkaloid found in the seminal fluid. The alkaloid was named spermin, and the hydrochloride of spermin has been administered hypodermically by Professor Poehl, in a large number of cases with alleged beneficial effect. He states that it acted as a general stimulant in many forms of chronic disease, and his results have been confirmed by a number of other Russian observers. Dr. Paul Werner² devotes a long article to an exhaustive criticism of these results, and shows that most of the cases reported were of such a nature that improvement often takes place spontaneously without other treatment than rest and the improved hygienic conditions consequent on coming into hospital. In no case was the benefit derived of a striking or unusual character. In other cases (as with Brown-Séquard himself, according to Dr. Werner) the tonic effect was strictly psychical, the temporary increase of strength being due to the excitement of the experiments and a confident hope of their results. The author illustrates his argument by pointing out that similar results have been obtained by many forms of charlatanism. At the Tenth International Medical Congress, Professor Poehl read a paper on spermin before the Section of Pharmacology. Several members, however, disagreed entirely with what he said,

and Professors Schmiedeberg and Kobert both stated that they had found spermin to be an inert substance, and that it could in no sense be regarded as a stimulant.³ Spermin⁴ has been known under various names since 1851 — as Charcot's or Charcot-Neumann crystals, as the asthma crystals of Leyden, and as Schreiner's crystals. In 1865 Boettcher found them in semen, and they have been obtained from the spleen, the blood, the spinal cord, white of egg, sputum, and old anatomical preparations. In 1888 Ladenburg and Abel established their identity with ethylenimine. The alkaloid resembles other ptomaines chemically, and when fresh has the odor of fresh semen, the same odor sometimes found in sputum being also no doubt due to its presence.

OBITUARY. JEDEDIAH H. BAXTER, M.D., SURGEON-GENERAL, U. S. A.

DR. J. H. BAXTER, Surgeon-General of the United States Army, died at Washington, December 4th. He had been stricken with paralysis a few days before, and, except for a few moments, did not regain consciousness. Dr. Baxter was born at Derby Line, Vt., May 11, 1837. He was educated in the University of Vermont, graduating with credit both from the academic and medical departments. He entered and graduated from the Law School of Columbia University, and, later, though not having practised law for many years, was admitted to the bar of the Supreme Court of the United States. At the breaking out of the war he was in Massachusetts practising medicine. In June, 1861, he entered the service as surgeon of the Twelfth Massachusetts Volunteers, the Webster Regiment. In April, 1862, Dr. Baxter was promoted to brigade-surgeon volunteers. He was with the Army of the Potomac during its hardest service. Later he was surgeon in charge of Camp Bell, the United States General Hospital at Washington. He was in charge of this hospital from the time it was opened till January, 1864. Then, at the request of General Fry, Provost-Marshal-General, Surgeon Baxter was detailed on his staff, and became the chief medical officer of his bureau. This position gave Surgeon Baxter an opportunity to collect the records of the physical examination of more than 100,000 men who were examined for enlistment. From these records he compiled a valuable work on "Vital Statistics," which is still a well-known book of reference. After serving throughout the war, Surgeon Baxter, when the army was reorganized, was appointed assistant medical purveyor, with the rank of lieutenant-colonel. In 1872 President Grant promoted him to the chief medical purveyorship of the army, with the rank of colonel, and he held that position until the 16th of last August, when President Harrison appointed him surgeon-general, with the rank of brigadier-general, although not in regular order of promotion.

It will be remembered that Dr. Baxter was one of the attendants upon President Garfield, after he was assassinated by Guiteau. He had many political acquaintances in Washington, not a few of whom enjoyed the hospitality of his summer home on the Restigouche River in Canada, where he was much devoted to the sport of salmon fishing.

PEROXIDE OF HYDROGEN.

It is only recently that the value of peroxide of hydrogen as an antiseptic has begun to be recognized to the extent that it deserves. In past times it has frequently been impure, or so old that it had lost its properties. An editorial article in the *University Medica Magazine* for December, calls attention to the fact that the drug is now gradually and steadily growing in favor on account of its merits.

As ordinarily found in the shops, peroxide of hydrogen is a 3.2 per cent. solution, yielding fifteen times its bulk of oxygen. This solution is far more potent than is water charged with fifteen times its volume of oxygen, since in the peroxide preparation the gas is given off in its nascent state and is peculiarly powerful in its chemical affinities.

There is abundant evidence as to the value of peroxide both from the clinical and the unexperimental standpoint. The number of those who have reported excellent results from its use is very large, and to this must be added the testimony of the bacteriologists,

who find in this drug a potent and almost immediate germicide. It is devoid of septic properties, its worst effect being, when used in a too concentrated form, to cause some local pain and irritation. It is applicable to all cases where there is pus, and when the discharge is foul and profuse is unequalled in the effect it produces. Its use in a great variety of sloughing and suppurative cases has given results better than those obtained from any other germicide, bichloride of mercury not excepted. To a granulating surface it can be applied by means of an atomizer; in the case of a suppurating fistula or cavity it may be injected by means of a syringe. Immediately after its application to a suppurating surface, an active effervescence goes on, and every particle of pus which it reaches is destroyed. The microbes also are vitalized, so that a large surface can sometimes be rendered aseptic by one or two thorough applications. Even if this result is not reached, the discharge is very much diminished. The use of peroxide of hydrogen as a disinfectant of water has already been noticed on page 477 of the JOURNAL.

REPORTED MORTALITY FOR THE WEEK ENDING NOVEMBER 29, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 29, 1890, TO DECEMBER 5, 1890.

By direction of the Secretary of War, leave of absence for six months is granted Captain WILLIAM E. HOPKINS, assistant surgeon, S. O. 278, Par. 2, A. G. O., Washington, D. C., November 29, 1890.

By direction of the Secretary of War, Captain JAMES E. PHILCHER, assistant surgeon, now on leave of absence, will report in person to the commanding general, Division of the Atlantic, for temporary duty at Fort Columbus, New York Harbor, during the absence on leave of Captain WILLIAM E. HOPKINS, assistant surgeon, S. O. 278, Par. 3, A. G. O., Washington, D. C., November 28, 1890.

By direction of the Secretary of War, First Lieutenant EUGENE L. SWIFT, assistant surgeon, is removed from further duty and station at Fort McDowell, Arizona Territory, assigned to Fort Thomas, Arizona Territory, where he is now on temporary duty. S. O. 282, Par. 16, A. G. O., Washington, D. C., December 3, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 6, 1890.

L. W. ATLEE, assistant surgeon, ordered to examination preliminary to promotion.

H. M. MARTIN, surgeon, placed on retired list December 4, 1890.

A. R. ALFRED, assistant surgeon, ordered to the Naval Hospital, Norfolk, Va.

J. M. WHITFIELD, assistant surgeon, from Hospital Norfolk, and to the U. S. S. "Chicago."

A. M. D. MCCORMICK, assistant surgeon, detached from U. S. S. "Chicago," and wait orders.

J. F. KEENEY, assistant surgeon, ordered to the U. S. S. "Minnesota."

H. N. T. HARRIS, assistant surgeon, detached from the U. S. S. "Minnesota," and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING DECEMBER 6, 1890.

FESSENDEN, C. S. D., surgeon. Leave of absence extended seven days. December 4, 1890.

BAILLACHE, P. H., surgeon. Granted leave of absence for twenty days. November 28, 1890.

HUTTON, W. H. H., surgeon. To proceed to Solomon's Island, Md., on special duty. November 29, 1890.

SAUTELLE, H. W., surgeon. Granted leave of absence for ten days. December 2, 1890.

PETRAKOFF, C. T., post assistant surgeon. Granted leave of absence for ten days. December 1, 1890.

HUSSEY, S. H., assistant surgeon. When relieved to proceed to New Orleans, La., for duty. November 24, 1890.

GROENEVELT, J. F., assistant surgeon. When relieved to rejoin station. November 24, 1890.

COOPER, L. E., assistant surgeon. Ordered to temporary duty at Boston, Mass., November 24, 1890.

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—The Section for Clinical Medicine, Pathology and Hygiene will meet at 138 Boylston Place, on Wednesday, December 17th, at 7.45 o'clock.

Speaker, Dr. W. N. Bullard, "The Care of Chronic Pauper Epileptics." Dr. L. M. Baker, of Baldwinville; Dr. Edward Cowles, Superintendent of McLean Asylum, Somerville; Dr. Walter E. Fernald, Superintendent of Massachusetts School for the Feeble-minded; Dr. Everett Flood, Superintendent of Hospital Cottages for Children, Baldwinville, Mass.; Dr. Geo. F. jelly, Boston; Dr. A. R. Moulton, Massachusetts State Board of Health, Lunacy and Charity; Dr. Geo. H. Rose, Superintendent of City Hospital, Boston, and others are expected to take part in the discussion.

ALBERT N. BLODGETT, M.D., Sec'y., 138 Boylston St.

E. G. CUTLER, M.D., Chairman.

THE MATTISON PRIZE.

OPJUM ADDICTION AS RELATED TO RENAL DISEASE.—With the object of advancing scientific study and settling a now mooted question, Dr. J. B. Mattison, of Brooklyn, offers a prize of \$400 for the best paper on "Opium Addiction as Related to Renal Disease," based upon these queries:

Will the habitual use of opium, in any form, produce organic renal disease? If so, what lesion is most likely? What is the rationale?

The contest is to be open for two years, from December 1, 1890, to either sex, and any school or language. The prize paper is to belong to the American Association for the Cure of Inebriety, and be published in a New York medical journal, *Brooklyn Medical Journal* and *Journal of Inebriety*. Other papers promising to be published in some leading medical journal as their author's own work.

All papers are to be in possession of the Chairman of Award Committee on or before January 1, 1893.

The Committee of Award will consist of Dr. Alfred L. Loomis, President of New York Academy of Medicine, Chairman; Drs. H. F. Formad, Philadelphia; Ezra H. Wilson, Brooklyn; Geo. F. Shady and Jos. H. Raymond, editor *Brooklyn Medical Journal*.

OBITUARY. SAMUEL SWETT, M.D.

Dr. Samuel Swett, for eighteen years a well-known retired physician of Jamaica Plain, died last week. He was born at Cambridge in 1810. After studying one year at Harvard College, he finished his education at the Harvard Medical School and at the Medical School in Philadelphia, and subsequently became house-surgeon at the Massachusetts General Hospital, Boston. Four years ago he was also surgeon of the Independent Corps of Cadets. Dr. Swett had spent a portion of his earlier years abroad, and was probably the last survivor of that colony of young physicians in Paris of whom Oliver Wendell Holmes has lately written in "Over the Teacups."

DEATH.

Died in Boston, Mass., December 10, 1890, O. W. Doe, M.D., M.M.S.S., aged forty-seven years.

BOOKS AND PAMPHLETS RECEIVED.

Report of the Surgeon-General of the Army to the Secretary of War, for the Year ending June 30, 1890.

Original Articles.

AN UNSUCCESSFUL CASE OF DIGITAL DILATATION OF THE PYLORUS FOR CICATRICAL STENOSIS.

BY E. G. CUTLER, M.D., AND M. H. RICHARDSON, M.D.

HISTORY OF THE CASE.

D. H. L., a horse-shoer, aged fifty-two, married, called on me April 3, 1890, and gave the following history: He had suffered frequently from attacks of dyspepsia and acid eructations for the past twelve years. During one of these attacks in recent years he had vomited blood in considerable quantity and had suffered from epigastric tenderness. For a year he had suffered from dyspepsia, off and on, with occasional vomiting and constipation. Of late the vomiting had recurred every two or three days, preceded by considerable pain and gastric distension. The vomitus was usually in great quantity, and would afford relief to pain for a day or two, when the symptoms would gradually return, and after becoming quite severe, relief would only be obtained by profuse emesis. The vomitus was frothy, sour-smelling, and consisted of partially digested food and slime.

At the time of the visit he was quite emaciated, the skin was dry and harsh, the eyes deep-sunken, the breath foul, and the tongue covered with a thick, brownish coat. He said that in about an hour after taking food, pain would be felt to the right of the epigastrium, which would increase in severity, till at last he would force himself to vomit a little, when relief would soon follow, the pain gradually dying away; and every two or three days there was profuse emesis. The bowels had been constipated for some time. The pulse was small and about seventy-six to the minute; examination of the heart and lungs was negative. The abdomen was sunken in at the epigastrium, and quite distended at, and just below, the umbilicus. There was at this part of the abdomen a half-moon-shaped distension, dull on percussion, which fluctuated to the touch, gave the succussion sensation to the hand and ear, and altered its shape and location on changes of position. No tumor could be felt anywhere in the abdomen. The stomach tube was passed, and about three pints of sour-smelling, frothy fluid, of the consistency of thin paste was removed, together with a large number of seeds from a preserve eaten some days before. This gastric fluid, on testing, was found to contain free hydrochloric acid in quantity estimated to be about normal, also some lactic, acetic, and butyric acids and mucus. On blowing up the empty stomach with air, it was found to reach nearly to the pubes, and to give a tympanitic resonance everywhere except in the right hypochondriac and right epigastric regions. The distended stomach nearly filled the abdominal cavity. Three quarts of water were readily taken into the stomach by the patient through the tube. The stomach having been thoroughly washed out and disinfected, the diet was restricted to milk, water, eggs, meat, fish, oysters, and a little bread.

Two days later the patient was seen again. He had felt much better for the treatment, and had neither vomited nor suffered pain, but his mouth and lips had been quite sore from the irritating character of the fluid which had been vomited during the washing pro-

cess. A test meal was given, and he was found to have plenty of hydrochloric acid in the gastric juice. The time of absorption from the stomach was found to be a little longer than normal, and certain pills given at the previous visit were washed out, showing the delay in the onward passage of the gastric contents. He was again washed out and told to report in three days.

The gastric absorption, motor activity, and chemical character of the gastric juice were investigated for a fortnight, with always the same result. The symptoms, therefore, together with the results of examination, showed conclusively that there was pyloric obstruction and gastric dilatation. The previous history, the chemical examination of the gastric juice, and the absence of tumor, pain, and cachexia, led to the belief that the stenosis was probably cicatrical, due to a healed gastric ulcer.

At this time he was seen in consultation by Dr. A. T. Cabot, who concurred in the diagnosis, and advised digital dilatation of the pylorus. After taking three weeks to consider the matter, and meantime having become more feeble and emaciated, he entered the Massachusetts General Hospital for operation. The washing out relieved the patient at first so that he could go for three days, and later for five days, without trouble. The dilatation of the stomach decreased somewhat under treatment, and when he lay on the right side there could be felt, in the right lumbar region, a soft, flexible, painless mass, about the size of the two thumbs, which could be rolled under the fingers, be moved several inches in any direction, and which was believed to be the pyloric end of the greater curvature of the stomach, hypertrophied and dislocated. After the first few days nutrient enemas were given, three to four times a day, in addition to the other treatment. In spite of all that was done, the patient steadily lost flesh at the rate of about three pounds a week, so that surgical interference alone offered any chance of relief. Dr. Cabot having meantime broken his arm, Dr. M. H. Richardson assumed charge of the case.

E. G. C.

OPERATION AND SUBSEQUENT HISTORY.

Two days before the operation the patient was fed by nutrient enemas; nothing whatever was taken by the stomach. The bowels were thoroughly cleaned out with castor oil and enemas. On the 8th of May, the day previous to the operation, the abdomen was scrubbed with soap and water, washed with ether, and then covered with a bichloride dressing. On May 9th the patient had a small enema of brandy and milk at 7 o'clock. Stomach thoroughly washed out at 9.30. Rectum again cleaned out with enemas, and the patient given a final enema of one ounce of brandy.

Operation.—Patient transferred to the abdominal amphitheatre at 10.30. Patient having been etherized carefully, an incision four inches in length was made between the ensiform cartilage and the umbilicus, terminating at the latter point. The pyloric end of the stomach was quickly exposed and drawn four inches out through the abdominal incision, where it was held by an assistant. At this point the condition of the patient suddenly became alarming; the pulse was feeble, and he ceased to breathe. Artificial respiration was resorted to and brandy given hypodermically. He soon improved, and after a few minutes the operation was continued. During the rest of the operation no

¹ Read at the Meeting of the Surgical Section of the Suffolk District Medical Society, November 5, 1890.

ether was given. The stomach being fully exposed, an incision was made between the greater and lesser curvatures, about three inches from the pylorus. This was felt to be thickened very considerably. The vessels on the peritoneal surface were congested, the mucous membrane was thickened. There was considerable oozing from the cut in the mucous membrane, but no free hemorrhage. The finger was then passed into the stomach while its walls were held tense by fingers of an assistant, sponges being packed about the wound. At first the finger could not be introduced into the pylorus. There was a thick, contracting ring almost cartilaginous to the feel. Prolonged attempts at digital divulsion in about twenty minutes were followed by enlargement of the orifice sufficient to admit two fingers with the greatest ease. On attempting to increase the orifice to a diameter greater than that of two fingers, a very firm, constricting band was felt which made a deep furrow in the dilating finger. This fact was noted by Dr. Cabot, who introduced his fingers and called attention especially to the constricting band. There was no hemorrhage after the divulsion. The condition of the pylorus was very satisfactory. The orifice had been dilated without much difficulty to a size quite sufficient entirely to relieve all symptoms of obstruction. The opening in the wall of the stomach was then closed, the mucous membrane being brought together with a continued silk suture, and the peritoneal coat with the interrupted Lambert sutures of fine silk. Hemorrhage into the stomach was slight, as shown by the subsequent vomitus, which consisted mainly of bile and mucus. The abdominal incision was closed with eight silver-wire sutures, and a large, dry, absorbent cotton dressing applied. The whole operation lasted fifty-five minutes. The patient rallied slowly, but at 4 p. m. was in a very fair condition. Complained of much epigastric pain, but was relieved by sulphate of morphia, one-sixth of a grain hypodermically. Given an enema of three ounces of peptonized milk, one ounce of brandy, and one raw egg at 6 p. m. Slept comfortably subsequently.

May 10th. Patient has been in a very feeble condition through the day. Has vomited small amounts of bile and coagulated blood three times. Pulse irregular in rhythm and volume, rate from 100 to 120; evening temperature 98.6°; respiration 16 to 20. He has had nutrient enemas of peptonized milk, and egg and brandy, every four hours. Peptonized milk three ounces, one raw egg, and one ounce of brandy, with occasionally a little digitalis added. Frequent hypodermic injections of brandy. Has required one-sixth of a grain of morphia twice to-day for pain and vomiting. This evening at 8, patient is feeling fairly comfortable, with pulse at 106. No abdominal distension.

May 11th. Condition little changed since last night. Began to take champagne, one drachm every half-hour, at 3 p. m. Slightly stronger at 8 p. m. Nutrient enemas continued.

May 12th. Patient has failed steadily all day, in spite of constant stimulation with brandy, atropia and nitro-glycerine by hypodermic injection and by rectum. Small doses of champagne have caused nausea. There has been frequent vomiting of mucus, but no blood. No distension of abdomen or abdominal pain. In intervals of nausea, lasting sometimes two or three hours, patient very comfortable. In the evening patient moribund.

May 13th. Stimulants kept up last night, but patient failed to respond. No pulse at wrist after 8 o'clock. At 10, patient perfectly rational. Died quietly at 2.20 a. m. No examination was allowed.

The condition of extreme emaciation into which this patient had come, from prolonged mal-nutrition, was probably the cause indirectly of a fatal termination in this case. It has been my experience in quite a number of laparotomies where the condition of the patient was one of great anemia from prolonged disease that death quite frequently follows a rapid exploratory incision. In my experience the mortality is large in exploratory operations for advanced disease, whether malignant or not. I do not think that death in this case was caused by peritonitis or by any other preventable condition, though such may have been the case. There was no leakage of the contents of the stomach into the peritoneal cavity, and the operation proceeded quickly and smoothly, without any unfortunate complications either at the time of the operation or after.

The stomach seems to heal more surely and safely after incision through its walls than any other of the abdominal viscera, and there was no reason why this should not have done the same had the man's condition been sufficiently good to allow it.

The most important local element in this case was the condition of the pylorus. The appearance and the feel of the constriction was like the non-malignant organic strictures in other parts of the alimentary canal accessible to the finger. There was a good deal of thickening and induration. There was an annular stricture which was so firm and resistant as to make a deep crease in the divulsing fingers. The divulsion of the stricture was accompanied with more or less laceration of the tissues, and was nothing more or less than a violent tearing of fibrous bands. It seems to me, therefore, that this operation for cicatricial stenosis of the pylorus, as for strictures elsewhere, must be palliative. I do not see any reason why a stricture of the pylorus should differ from a stricture anywhere else in the alimentary tract. We all know that strictures of the esophagus, the rectum, and of the urethra contract after divulsion, and it does not seem to me reasonable that a stricture of the pylorus should differ materially in this respect. The experience of others show that the stenosis of the pylorus recurs after divulsion. In some patients the operation has been repeated. A more reasonable procedure seems to me, therefore, to be found in establishing an anastomosis between the stomach and the small intestine — gastro-enterostomy. Experience in this line of treatment, however, is yet insufficient to justify any certain, fixed line of treatment in this very important class of cases.

M. H. R.

— About fifteen years ago the Queen of Holland was in London, staying at Claridge's Hotel. A great friend of hers, a Dutch baroness, was very ill at the Hague, and the queen asked Mr. Spencer Wells (not then a baronet) to go over and see the lady. The day after his return to London the queen walked round to Upper Grosvenor Street to ask after her friend, and the servant came into the consulting-room saying, "Please, sir, there is a lady in the waiting-room who wants to see you. I suppose she must be mad. She says she is the Queen of Holland."

PERFORATING GASTRIC ULCER; CIRCUMSCRIBED PERITONITIS; DEATH ON THE FIFTEENTH DAY.¹

BY REGINALD H. FITZ, M.D.

The following case is reported for the purpose of illustrating the possible benefits to be derived from a laparotomy immediately after the perforating of a gastric ulcer, as well as at a later period in the course of the consequent peritonitis.

A female cook, forty-one years old, was admitted to the Massachusetts General Hospital at the time of the visit, and came under my care. She was evidently suffering intensely from abdominal pain. The abdomen was moderately swollen, tense and tympanitic, and there was a complete absence of hepatic dulness in front. There was slight, general tenderness, while there was no marked, localized sensitiveness. A rectal examination was negative, and the uterus was freely movable, not tender to the touch. The pulse was 70, of fair strength, and the temperature was 100° F. The respiration was 25.

It appeared, on inquiry, that eighteen hours before entering the hospital, she was suddenly seized with a severe pain in the left epigastric region. She was cooking a piece of steak at the time, and had eaten nothing during the afternoon excepting a bit of cheese. The pain soon became general, and she was seen by Dr. J. J. Minot, who was able to relieve her distress by means of two doses of morphia subcutaneously, in all less than a half grain. At this time the abdominal walls were flat and rigid. During the night a small quantity of yellow fluid was vomited. He saw her again in the morning, at which time the abdomen was swollen, the pain was persisting, and he advised her removal to the hospital.

The patient was questioned as to any previous symptoms which might be connected with this sudden seizure. She acknowledged that during the preceding month she had noticed occasional attacks of epigastric pain running into the back, unaffected by food, also eructations and water-brash. She had not sought herself sufficiently ill to seek for medical advice.

The sudden onset of an intense, epigastric pain, with symptoms of an incipient peritonitis and a disappearance of hepatic dulness, in a person apparently well, and with slight evidence of an antecedent gastric dyspepsia, suggested as the most probable explanation—a perforating gastric ulcer. The possibility of the occurrence of an acute pancreatitis was thought of, but the collapse usually associated with this condition was not present, and the development of the peritoneal symptoms was unusually rapid. My colleagues, Drs. Cutler and Porter agreed in this opinion, and an immediate laparotomy was advised. The patient refused permission, although appreciating the gravity of her situation and feeling that she was to die.

For a week nothing was taken into the mouth excepting bits of ice; nutrient, rectal enemas were given every six hours. She was kept free from pain by small doses of morphia, from a third to a half-grain daily. For several days during the second week she required no opium whatever.

On the fifth day intercostal tenderness in the splenic region was recognized. At this time three copious dejections took place, a large amount of gas escaped

by the rectum, and the abdomen became softer and less sensitive except in the epigastrium. The area of hepatic dulness was now apparent, though narrow, in the axillary region.

At the beginning of the second week some milk was taken by the mouth. The epigastrium became conspicuously swollen and tympanic, neither excessively tender nor fluctuating, and eventually transmitted the aortic pulsations. During this period the question of a laparotomy was again presented, on two separate occasions, with a view to the drainage of the supposed peritoneal abscess, but the patient refused her consent.

During the last three days of life the strength rapidly failed, but the patient was comfortable, at times even happy, in an exalted delirium, and died on the fifteenth day.

The temperature was about 100° F. during the first week, and between 100° F. and 101° F. during the greater part of the second week. The pulse was in the vicinity of 100 until two days before death when it rapidly rose. The respiration was between 25 and 30 during the greater part of her illness.

On opening the abdomen, the space between the suspensory ligament and spleen, the diaphragm and the left lobe of the liver was shut off from the rest of the peritoneal cavity by fibrinous adhesions. It contained some two pints of thin, opaque, yellow fluid, and a considerable quantity of gas, forming the tumor observed during life. The peritoneum enclosing this space was covered with a moderately firm, fibrinous membrane. Elsewhere the peritoneum was normal in appearance, with the exception of a few delicate adhesions between the omentum and the abdominal wall. The stomach was contracted, and contained but little fluid. Its anterior wall, near the smaller curvature, was adherent to the lower surface of the left lobe of the liver, near the anterior edge. The adhesions were fibrous. At the inner surface of the stomach, corresponding to the adherent portion, was sharply defined ulcer, not as large as the little finger-nail, of elliptical shape, the edges somewhat puckered. This ulcer was in the anterior wall near the lesser curvature, and midway along its course. After separating the adherent stomach from the liver a minute perforation was found in the base of the ulcer.

It is evident from the anatomical appearances, the early hour at which a laparotomy was advised, and the strength of the patient at the time, that a favorable result was likely to have followed the immediate operation.

Unfortunately in most cases of perforating gastric ulcer an operation for relief is likely to be merely exploratory, or attended with such difficulties as to prove of no avail and to greatly shorten life. Hence in any given case it cannot be fairly urged with any considerable degree of hopefulness. The possibility of meeting with the conditions as above stated should offer a greater degree of encouragement than would be possible without such an experience.

There can be no question that the drainage of the circumscribed, peritoneal cavity would have been of the greatest advantage to the patient, and would have been likely to have considerably prolonged life. It is by no means certain that it may not have been followed by a complete cure of the ulcer. The patient's opposition to the late operation was quite as strong as to the immediate laparotomy.

HYDROCELE IN CHILDREN, WITH A REPORT OF CASES.¹

BY ROBERT W. LOVETT, M.D.

HYDROCELE in young children is an affection which differs in so many respects from the ordinary hydrocele of adults, that it seems to merit separate consideration, and especially since in the last few years new light has been thrown upon certain points in its etiology and clinical history.

In speaking of the affection, I have used the terms infantile and congenital hydrocele not in any technical sense, as is done by some writers, but as signifying only the hydrocele of young infants.

At birth the testis should have descended to the bottom of the scrotum, carrying with it a pouch of peritoneum, which is cut off from the abdominal cavity to form the tunica vaginalis. Between the abdominal rings and the tunica vaginalis there should be no passage, only the remains of the obliterated peritoneal pouch, which should exist as a fibrous cord.

A failure of all or part of this tract to close results in the escape of the abdominal fluid into the tunica vaginalis, which distends it and forms a hydrocele. That this failure to close is more common than had been supposed is demonstrated by the figures of Zuckerkandl,² who found that in 100 new-born children the neck of the peritoneal process had failed to close in 37, 20 of them being on both sides. The opening was often small and difficult to find, but it could be clearly demonstrated to exist.

There are five possibilities in the causation of infantile hydrocele, resulting from five different anatomical conditions, and resulting in as many different varieties of hydrocele, all of which are to be distinguished clinically.

(1) The entire process of peritoneum may remain widely open from the abdomen to the bottom of the scrotum. This is called by many writers *congenital* hydrocele. (2) The funicular process of peritoneum alone may remain open, forming a *funicular* hydrocele, which does not descend to the bottom of the scrotum. (3) The funicular process of the peritoneum may be shut off above and below, but distended with fluid, forming an *encysted hydrocele of the cord*. (4) *Infantile* hydrocele is the name applied by some English writers to the condition where the tunica vaginalis and funicular process are distended with fluid, but the internal ring is closed. (5) Common *vaginal* or *scrotal* hydrocele is the condition in which, as in adult hydrocele, the fluid accumulation is confined to the tunica vaginalis.

There are few figures bearing on the frequency of infantile hydrocele. In 247 new-born children, at the Dresden Clinic, Wechselman³ found 37 cases of hydrocele. The proportion is surprisingly large, and not in accord with the statements of other writers. He explains it, however, on the ground that many of the hydroceles were so small that they would have escaped any but the closest observation.

The cases which I have the pleasure of presenting this evening are chiefly from the surgical clinic of the Children's Hospital; and, although they are not enough in number to serve as the basis of much generalization, they are nearly as large a group as any series

¹ Read at the Surgical Section of the Suffolk District Medical Society.

² Arch. f. Chir., xx, p. 216.

³ Arch. f. Klin. Chir., 1887, xxxvi, p. 627.

reported among young children, and they have been investigated largely as to the results of treatment. Of the 30 cases which I have been able to tabulate, all of which occurred previous to October 1889, five were cases of encysted hydrocele of the cord, and the remainder were situated in the tunica vaginalis, being examples of the ordinary infantile or scrotal hydrocele, with the exception of one case, which was a well-marked instance of funicular hydrocele, where the fluid did not reach the bottom of the scrotum.

The children were very young when they were seen. Two-thirds of them being in their first four months, five cases were in the second year, and over that age there were only three cases, all of which were five years old. These latter had been affected with hydrocele only a few weeks, so that they cannot be classed as congenital cases. Among Wechselman's cases, where 247 children were observed twice a day during the first two weeks of life, it was found in the 37 cases where hydrocele occurred that it appeared from the second to the fourteenth day in a large proportion of all the cases; neither in the series of cases reported to-night were the congenital cases all noticed at birth. Fifteen of them were clearly described by the mothers as beginning then, but many of the others were described as beginning in the first few weeks of life. At the same time there were several cases where the hydrocele apparently began in the first few months, and in most of them no clearly marked traumatism could be assigned. Such cases were the three already alluded to, where the hydrocele began at the age of five; in the other instances, it began sometime in the first year.

It has ordinarily been stated that the hydrocele of infants is easily reducible, the fluid running back into the abdominal cavity when the child is laid on his back and the scrotum manipulated. In these 25 cases of vaginal hydrocele the notes were defective in three cases, and of the remaining 22 cases, 19 were not reducible by any ordinary manipulation. That is to say, no connection with the abdominal cavity could be demonstrated, as the children were examined in the Out-patient Department. There may have been a valve-like opening which permitted the fluid to flow into the scrotum, and not out of it; or, perhaps, prolonged recumbency would have obliterated the hydrocele, but to the ordinary tests the fluid was not reducible in 19 out of 22 cases of infantile hydrocele.

It was, therefore, a relief to find that Wechselman⁴ found in 37 hydroceles of new-born children only 14 which were reducible, while 23 did not communicate, so far as could be ascertained, with the abdomen. Bryant,⁵ in 124 cases of children and adolescents, found only five which communicated; while Mechior,⁶ in 282 similar cases, found only 21 which were reducible.

It is this class of cases of irreducible hydrocele which is of particular interest. When the funicular process of the peritoneum is open, it is easy to see the reason for the hydrocele. But when to all intents and purposes the funicular process is closed and the tunica vaginalis is a shut sac, it is more difficult to account for the presence of fluid in the scrotum.

It is evident that irreducible hydroceles may exist even in intrauterine life, as is shown by cases of

⁴ Arch. für Klin. Chir., 36, 1887, p. 631.

⁵ Guy's Hosp. Rep., 3 s., vol. II, p. 75.

⁶ Annali Universali di Medicina, 1886, April, May and June, p. 235.

Schreiger,⁷ Tavignot,⁸ von Ammon⁹ and particularly Legende,¹⁰ who found in a child, which died almost immediately after birth a hydrocele the size of a hazelnut where the peritoneal process was completely obliterated.

Taking then the existence of irreducible hydrocele in intrauterine life and in new-born children for an accepted fact, one is at a loss to account for it by the former theory that infantile hydrocele is due to a leaking of peritoneal fluid into the tunica vaginalis. It may be that the funicular process remains open unduly long and suddenly closes, leaving fluid in the tunica vaginalis. It may be that the accumulation of fluid results from traumatism at birth or afterward; or, finally, it may be due to an idiopathic, possibly an infectious inflammation of the tunica vaginalis. It has been demonstrated that obstruction to the circulation in the cord does not cause hydrocele.¹¹

The question of the causation of the affection must be left in this very unsatisfactory condition. Probably traumatism will in future be assigned a more prominent place among the causative factors.

Of course, it is not safe to assume in these cases that no connection with the abdomen exists, if one is contemplating the use of any irritating injection into the tunica vaginalis, but the matter is of interest from a diagnostic point of view.

Although the hydrocele of adults affects the right and left side in an equal proportion, when large numbers of cases are considered in children, the right side is much more frequently affected and double hydrocele is proportionally much more common. Of the 30 cases reported, nine were double, 12 affected the right side, six the left side, while in three the affection was unilateral but the side was not noted.

The coexistence of hernia was a point of decided interest. It would be supposed that patency of the inguinal canal which was sufficient to cause hydrocele would predispose to hernia, but curiously enough in these 30 cases, many of them being double and some extremely large, only three cases of coexisting hernia were noted, one a slight funicular hernia, and the other two well-marked cases of infantile hernia.

Cases of hernia with slight accompanying hydrocele have not been included in this report.

The size of these infantile hydroceles has varied very much, at times they have been small and flaccid, but more often tense and entirely filling the scrotum. It has not always been easy to say whether the accumulation was confined to the tunica vaginalis proper, or extended to the internal ring, nor is it a matter of very much importance. In the case of one child, two months old, with a double hydrocele, half an ounce of fluid was drawn from each side of the scrotum, and this, perhaps, was as severe a case as any coming under observation, although several were equally severe. This made a tumor the size of a small orange.

The diagnosis is, of course, simple, and is dwelt upon at some length in all the text-books. There is no impulse on crying except in cases where the canal is open, and in these the fluid is easily reduced without the characteristic gurgling of hernia. Where the inguinal canal is closed, it is easy to demonstrate the pyriform shape of the tumor and impulse is absent.

⁷ Von Walther and von Ammon's *Journal für Chir.*, xxxv, 121.

⁸ *Journal für Kinderkrankheiten*, Bd. I, p. 121.

⁹ *Angenborene Chir. Kinderkrankheiten*, p. 66.

¹⁰ *Journal für Kinderkrankheiten*, xxii, p. 220.

¹¹ *Langenbeck's Arch.*, xxiv, 1879, 369.

The swelling is, of course, translucent, but this is not an easy fact to ascertain in the case of small children. The coexistence of hernia often renders the diagnosis obscure. In encysted hydrocele of the cord a hard, elastic, and non-reducible swelling is felt in the inguinal canal, which varies from the size of the normal testicle to that of a cherry. It is most likely to be confused with a retained testis but the presence of both testes in the scrotum, of course disposes of that possibility and except for the very rare occurrence of tumors of the cord, such a swelling is not to be mistaken for anything else than an encysted hydrocele.

The prognosis is said to be much more favorable than in the hydroceles of adults. Certainly the results of treatment in these 30 cases would lead one to look for a speedily favorable result in cases which did not communicate with the abdomen. When, however, the tunica vaginalis is merely a prolongation of the peritoneal cavity, and the hydrocele is reducible, and especially if hernia coexists to continually distend the testicle, the outlook is not so favorable as in those cases where the tunica vaginalis is shut off.

The treatment of the affection is, of course, the important practical interest in the discussion of these cases. I attempted to find out the results in these 30 cases, and by the kindness of my assistants at the hospital I have been able to learn the results in 21 cases. Many were from out-of-town and have neglected to answer letters, while others have disappeared from their former residences and were not to be traced by any amount of inquiry. All these cases were treated at the hospital previous to October, 1889, so that at least a full year has elapsed in every case.

Of the 30 cases it has been possible to obtain the results of treatment in 21.

Of the five cases of encysted hydroceles of the cord, four have been heard from and all were cured. One was tapped and cured by one withdrawal of the fluid. The other three were treated by counter irritation and expectancy, and yielded readily in a few days or weeks. None of these cases were congenital, and the affection had been of short duration in each case.

Of the 25 cases of scrotal hydroceles it is possible to report the results in 17 cases. Ten were tapped with a hypodermic needle or a small trocar, and the sac completely evacuated with every antiseptic precaution. Nine of these cases were cured, while one remains in the same condition at the end of two years. This was a case of double reducible hydrocele, widely open into the abdomen with a slight complicating hernia on one side. The child was tapped several times, and an attempt made to keep the fluid back by the use of a double worsted truss. No benefit whatever resulted from the treatment. The cases which were cured were tapped once or several times as occasion demanded and the sac in most cases refilled temporarily after tapping. Seven cases were treated without tapping, and the patients were kept merely under observation or given some mild counter-irritant to use. Four of these cases recovered, while three are not improved. Of these three cases that are not improved, two were reducible hydroceles, communicating freely with the abdomen (and in the case of the third no mention is made in the notes as to the patency of the abdominal ring.)

In these cases an attempt was also made to retain the fluid by the use of the worsted truss, but it was unsuccessful.

In so far as any conclusions may be drawn from so small a group of cases it seems safe to infer that hydroceles which do not communicate with the abdomen, that is, irreducible hydroceles, can be cured by simple tapping, and moreover, that there is a strong inherent tendency for them to recover under the simplest expectant treatment.

But if communication with the abdomen exists, the problem becomes more difficult and they do not seem to be amenable to this simple treatment or to expectant methods, and, finally, that encysted hydrocele of the cord has a strong inclination to recovery under the simplest methods. With regard, then, to simple irreducible hydrocele, which does not communicate with the abdomen, it seems unnecessary to go further in the discussion of the treatment. Many writers have advocated the injection of irritant fluids after the withdrawal of the contents of the sac, but that seems needless and risky. Cases of death have been reported following such injections and simple tapping seems to answer every purpose. At the French Society of Surgery the injection of chloride of ammonia was advocated by Gaillard, who reported successful cases from its use, and the injection of iodine, alcohol, chloride of zinc, and carbolic acid has been advocated by other writers. By such an authority as König the use of irritant injections in infantile hydrocele is condemned under all circumstances.

The proceeding of puncturing the sac with a needle in several places to allow the fluid to escape into the subcutaneous tissue seems to present no advantage over the tapping of the sac and is more painful.

With regard to the treatment of reducible hydrocele the question is more difficult. Possibly in later years these cases reported as unimproved to-night, may have been cured by the growth of the children and the strengthening of their tissues.

A favorite mode of treatment for these, much advocated in the books, is the use of a spring truss which shall excite enough irritation around the inguinal canal to cause the closure of the sac, but certainly in the case mentioned above, the worsted truss accomplished nothing, and the use of a spring truss in a small child is associated with much discomfort and almost inevitably with excoriation of the skin which is constantly wet under the pad. The use of an irritant injection in these cases must certainly be attended with a great deal of risk, inasmuch as it causes inflammation of a portion of the peritoneal cavity which may become general.

With regard to the operative treatment of these cases the writer has had no experience whatever. French surgeons who have been the most active in the discussion of infantile hydrocele, unite in deprecating early operation. Gaillard would never operate before the age of five or six, while St. Germain advises operation at the age of three, when the tumor is as large as a hen's egg. In general, however, the question of operation is deferred still longer.

The operative treatment consists in passing a subcutaneous ligature around the neck of the sac to obliterate the connection with the abdomen, or the sac is laid open and after the closure of the funicular process, allowed to granulate up as in the operation for adult hydrocele.

In conclusion, if these cases have served to show anything it has been to demonstrate that all cases of infantile hydrocele are not present at birth, but begin

later in many instances. That the majority of cases of infantile hydrocele cannot be demonstrated to communicate with the abdominal cavity, and that, finally, with a strong intrinsic tendency toward recovery, the disappearance of the affection is much hastened by the antiseptic withdrawal of the fluid contents of the tunica vaginalis where communication with the abdomen cannot be demonstrated.

CONGENITAL DEFORMITY OF THE NOSE.

BY E. H. BRADFORD, M.D.

The following case is unusual, and as such deserves to be recorded. It is one of a congenital defect in the shape of the nose, consisting of a depression in the median line of the nose, a broadening at its base, and a superabundance of skin, which gave a peculiarly disagreeable appearance to the face.

An examination by Dr. Langmaid and Dr. Leland of the internal condition of the nose failed to discover any abnormality. The child had been perfectly healthy, and there was no history of catarrh or any trouble of the nose during infancy or at birth. The deformity, apparently, was due entirely to a congenital malformation of the bones, the cartilage, and the skin.

There is no history of deformity of the sort among the parents or relatives of the child, and there is no cause known for this occurrence at the birth of the child, which was perfectly normal.

On palpation there seemed to be an unusual amount of loose skin over the nose. The color of the skin was normal, except that in the median line, and a little to the left, in the depression, the skin was whiter than elsewhere, looking the color of cicatricial tissue, though there was no other evidence of a cicatrix. The nostrils were wide, and the tip of the nose was slightly raised. The nasal bones seemed normal in length, but were abnormally widened. On feeling the cartilage over the bridge of the nose, in one spot the cartilage seemed softer than normal, as if there was a hole in the cartilage. The cartilage was, perhaps, thinner at this spot than is normal. This place was from an eighth to a quarter of an inch in diameter. In other respects the nose was normal, except in shape. It seemed to have a concavity in the median line, and about the middle of the nose, seen on profile. The alae of the nostrils spread more than is normal. The nose, however, was firm in resistance to any lateral pressure, and the septum of the nose seemed to be normal.

The eyes seemed wider apart than is usual, and the eye-brows had a slope to the inner side, characteristic of the Chinese.

The child was in perfectly good health, was three years old, and had no trouble in breathing through the nostril; and, in fact, appeared to be in no way incommoded by this deformity.

¹ Read at the Meeting of the Surgical Section of the Suffolk District Medical Society, November 5, 1890.

The operation showed, after dissection of the flap, that there was no actual deficiency in the cartilage over the bridge of the nose. In one place there seemed to be a lack of great resistance, but there was no palpable defect. The incision was enlarged so as to reach to the root of the nose, and the nasal bones were found to be perfectly sound and normal, though widened somewhat. An examination by means of a probe of the inner side of the nasal cavity, showed that there was no obstruction there. Tampons of iodoform gauze were placed inside of the nostrils, and the operation carried on, with the patient held in an upright position, so that the bleeding should not fall into the mouth. After the flaps were held widely apart, a slight incision was made through the middle line of the cartilage down to the mucous membrane, but not through the mucous membrane. An osteotome was applied to the side of each of the nasal bones, near the insertion on the superior maxillary; and, by a blow of the hammer, these bones were divided nearly through, so that with pressure they could be broken at the point of incision, care being taken that the lachrymal duct should not be interfered with. After these were loosened, by slight lateral pressure the cartilage could be pinched up so the bridge of the nose was higher than before, and in a normal position. A button suture was passed directly through the nose, from one side to the other, passing through the skin and the septum. The superabundant skin was removed along the median line, and iodoform dusted along the line of the incision, and the whole covered with collodion, the skin having been previously sewed up by a buried suture of fine catgut. At the end of three days the button suture was removed; at the end of ten days the collodion dropped off, and the wound was found entirely healed. The deformity was almost entirely corrected. The depression was removed, the widening at the tip of the nose and at the bridge of the nose was corrected, though at the base of the nose and between the eyes undue width still remained.

REPORT ON DISEASES OF CHILDREN.

BY T. M. ROTCH, M.D.

CIRRHOSIS OF THE LIVER IN CHILDHOOD.¹

In Canada Howard has recorded two cases; Germany presents eighteen; England forty-four; France fifteen; the United States eight; Ireland four; and India one. This recapitulation will serve to show how very rare is the disease: Flint, in a personal communication to Howard, remarks upon its exceeding rarity in the United States. Edwards presents a study of cirrhosis in the *Archives of Pediatrics*, July, 1890, with a report of one case and a tabulated résumé of the literature. The slight effect that alcohol has in these cases is illustrated by the fact that its habitual use is mentioned only eleven times, its absence being noted in fifty cases, and no mention being made of it at all in thirty-three instances. Six times it is recorded as probable. The infectious fevers play a more important rôle in the etiology of the disease; the hepatic derangements of fevers may, and often do, persist after they have subsided, and this is said, independent of syphilitic contamination or alcoholic abuse, to produce chronic interstitial hepatitis.

¹ American Journal of Medical Sciences, October, 1890.

Hebrard has recorded one case of interstitial hepatitis following measles, with microscopic studies presenting infiltration by newly-formed connective tissue, distention of veins and arteries, and much fatty degeneration; Klein has examined eight examples of acute interstitial hepatitis in scarlet fever cases. The case reported by Edwards would seem to be an example of cirrhosis following the infectious fevers, as the child (aged ten) was not syphilitic and was non-alcoholic, but had suffered most severely from measles and scarlatina.

Howard has collated six cases in which cirrhosis seemed to be part of a general fibroid change, and one case in which Gull and Sutton's arterio-capillary change could be considered as a causative agent. Tuberculosis may cause an hepatic cirrhosis. Of late years faulty digestion and the alkaloidal products of albuminous decomposition—the ptomaines—have been regarded as a possible cause of interstitial hepatitis, although the matter is as yet *sub judice*.

Regarding the disease as it occurs in childhood, it may be either atrophic or hypertrophic, and not unusually the so-called mixed cirrhosis is met with; some observers regard the latter as rather the usual form in childhood. The age of greatest frequency is from nine to twelve years; males are more affected than females, in the proportion of almost two to one. The symptomatology differs but little from the adult; the symptoms at first are apt to be confounded with simple congestion. Digestive troubles exist, abdominal pain, slightly augmented by pressure, alternating diarrhoea with constipation, increase in the size of the liver, slight ascites, dilatation of the subcutaneous abdominal veins, and slight jaundice or a subicteroid tint of the face. Stigmata, composed of collections of dilated minute venules may be observed on the face; their presence should suggest an examination of the liver, with special reference to the probable existence of cirrhosis.

A large proportion of the cases of infantile cirrhosis present irregularities in the temperature curves. The case that we are considering presented a temperature which, within a month, fluctuated between 100° and 97.6° F. It was quite as apt to be subnormal as elevated. The prognosis and treatment are as in the adult. Within the last eighteen months cases have been reported that appear to show that the prognosis is not as hopelessly fatal as we have formerly considered it.

MASTOID DISEASE IN CONNECTION WITH EAR-TROUBLE.²

According to the author disease of the mastoid process is, in general, an affection accompanying either an acute or chronic disease in the middle ear, in which a definite and thorough line of treatment is called for. Unfortunately, such a plan is not always pursued, and the patients must be the worse to a corresponding degree. Since in most cases the chief cause of the disease consists in the retention of pus in the ear, it becomes of first importance to allow it to escape freely. The indications, therefore, are paracentesis of the drum membrane at the proper time, dilatation of an existing perforative opening, the use of Politzer's method, so that permeability may be established through the auditory canal as well as through the Eustachian tube. In

² Archiv. f. Kinderh., xi. 4. Snell: Archives of Pediatrics, Nov. 1890.

a case which was narrated and in which this treatment was followed, as the pus was evacuated the dizziness and pains from which the patient had suffered four years, disappeared, and complete healing resulted.

Another case was a girl fifteen years old, who had suffered for two years from a frequently recurring affection of the ear with violent pains, including pain in the neck. When the pus was evacuated the pain ceased, and began again when the pus no longer flowed. At the mastoid process and on the neck there was evident only a slightly red and sensitive tumor. The external auditory canal was swollen; there was permeability of the Eustachian tube and perforation of the drum membrane. Under the use of cataplasmas and leeches, cleansing of the ear with warm boracic acid solution, and the Pulitzer inflation, the swelling disappeared and the pain ceased. In addition to the means which have been recommended, applications of iodine or of belladonna may be used. The swelling in some cases is excessive, extending over the head and neck. And the pain is sometimes attended with delirium, fever, etc. If these measures which have been referred to are insufficient, the suppuration extending into the drum cavity and the mastoid cells, the swelling increasing and the ear-muscles standing out from the head, while the sensitiveness becomes even more acute, then must operative measures be undertaken. An incision (Wilde's) may be made behind the ear, and the mastoid process may be perforated to give exit to the accumulated pus and prevent closure of the wound, through which a portion of diseased bone will probably come eventually. The incision should be made as far forward as possible, just behind the insertion of the auricle. The wound should then be dilated with a sound or a knife to find out the condition of the bone.

THROMBOSIS OF THE CEREBRAL SINUSES FOLLOWING OTORRHEA.⁸

The patient was four years of age, had had no previous illness until three months before, when a slight discharge was noticed from the left ear. Following this the child had measles. From that time he lost flesh and strength. Just previous to coming under observation he had several severe convulsions, had been stupid, and had not spoken or taken notice of his friends. On examination, he was emaciated, tongue foul, teeth covered with sordes, bowels constipated. He was semi-conscious, and occasionally had slight convulsions, in which the left arm was chiefly affected. There was no drawing of the face; the pupils were equal; there was no squinting. No retraction of head and no tenderness.

The patellar and plantar reflexes were present, equal and normal. There was no anesthesia or analgesia. Tache cerebrale could easily be shown. There was a purulent discharge from the left ear. The urine contained a trace of albumen. Following this there were several convulsions and a steady rise of temperature for two days. Then there was a surprising return of consciousness. Examination of the chest showed dulness and crepititation over base of left lung. One week after admission the mouth was noticed to be drawn to the left. Trembling of the left hand resembled the oscillations of paralysis agitans rather than the wide-jerking movements of chorea. When the

child was lying undisturbed these tremulous motions ceased, but became exaggerated when the limb was raised, and were then accompanied by tremulous movements of the face. Death occurred three weeks from the date of admission. The post-mortem showed thrombosis of the cerebral sinuses. There were numerous small abscesses in the lungs apparently from infarctions. The longitudinal and lateral sinus contained well-marked decolorized thrombi. In the latter they were soft; in the former firm. There was pus in the left tympanum and in the mastoid sinuses. There was no perforation of the membrana tympani, and there was no necrosis of the petrous bone.

CHLORODYNE POISONING THROUGH THE MOTHER'S MILK.⁴

A case is reported in the *Australasian Medical Gazette* recently of a woman who had given birth to twins, and was suckling them both. One evening she took a dose of chlorodyne, for relief of pain, and soon after taking the drug suckled the infants. The children were found the following morning profoundly narcotized, and died before evening. [The dose of chlorodyne taken is unfortunately not reported.]

DILATATION OF THE HEART AT THE TIME OF PUBERTY, AND ITS COMMON OCCURRENCE IN GIRLS.⁵

The author desires to direct attention to a certain group of symptoms which not unfrequently occur at the time of puberty, and to a plausible explanation of the same. He has in recent years observed eight cases (including a boy of fourteen, five girls between ten and fourteen, one girl at sixteen, and one at eighteen), in which these symptoms were prominent. Most of them had grown tall very rapidly, and in none of the girls was menstruation normal. The symptoms consist in debility, want of energy, palpitations, dyspnea after exertion, and disagreeable sensations in the region of the heart. In most of the cases there was weak pulse, diffuse heart impulse, with a weak first sound, and an accentuated second pulmonary tone. In two of the cases there were functional systolic murmurs. There was hardly enough dilatation in most of the cases to suspect insufficiency of the mitral valve.

These phenomena may be made to disappear entirely within a few months, by the use of appropriate treatment, which should consist of regular physical exercise without over-exertion, a nap for at least two hours every day, and the internal use of iron. The food should be abundant and nutritious. The explanation of these phenomena is to be found in the great changes which take place in the heart and great vessels at the time of puberty, as shown by the measurements which were made by Beneke. During the first years of life the heart gains eighty per cent. in volume; while between the seventh and fourteenth years it is only eight per cent. At puberty it again gains eighty to one hundred per cent. in volume. If the changes incidental to puberty take place in one year, the heart doubles its volume in that time; if in two years, the increase in volume occupies two years of time; if in five years, the increase in volume would be only twenty per cent. yearly; in a word, the development of puberty is accompanied by a *pari passu* increase in the volume of the heart. The conclusion from the foregoing is that when the heart is not in condition to develop rapidly,

⁸ Lancet, January 18, 1890. Tirard: Archives of Pediatrics, August, 1890.

⁴ American Journal of Medical Sciences, September, 1890.

⁵ Archiv. f. Kinderh., xi, 4. Pitt: Archives of Pediatrics, November, 1890.

the phenomena of puberty must be protracted. The consequences of the great efforts which are placed upon the heart at this period are manifested in the common occurrence of a slight degree of dilatation and in deficiency of heart-energy, which is especially noteworthy in individuals who grow rapidly at the time of puberty. In such persons, the changes of puberty are often prolonged or are incomplete, which is a direct consequence of the unsatisfactory increase of the blood-pressure. Symptoms of heart weakness are not generally found in children who have passed the experience of puberty quickly. Girls are more apt to suffer than boys, because between the ages of eleven and twelve they are weaker than boys. Between the ages of thirteen and fourteen they overtake the boys in point of physical vigor, while between fourteen and fifteen the boys again gain the ascendancy, continuing to grow, while the majority of girls do not.

(To be continued.)

REPORT ON PROGRESS IN DERMATOLOGY.¹

BY JOHN T. BOWEN, M.D.

FEIGNED SKIN DISEASES.

APROPOS of two cases of feigned skin disease recently under his charge at the hospital, Mr. T. Calcott Fox² took occasion to make this the subject of a clinical lecture in which many interesting cases were discussed.

Urticaria. — A very precocious girl, ten years of age, of an "excitable temperament and theatrical demeanor," had had for three weeks recurrent outbreaks of patches of an urticarial character, with a considerable amount of excoriation. These patches were all on the front of the body and face, and were few in number. The arrangement of the patches was such as one might expect if they had been produced by scratching. The child was detected in the act of producing a lesion, to which she called attention. It was found that wheals could be easily produced upon the skin; and the discovery of this had probably given her the idea of malingering, in order to attract attention.

Erythema Multiforme. — Cases are cited where marginated erythematous eruptions were caused by mustard paste and powdered cantharides. It is not very uncommon to find vesicating patches caused by the action of nitric and other strong acids, and in these cases the fluid exudation should be tested by litmus paper. In another class of cases there is added to the erythematous and vesicular appearances a gangrenous character, which may be produced by escharotics, as in the case of a servant girl, eighteen years of age, who presented several gangrenous patches on the chest. The writer expresses the opinion that some of the cases reported as multiple gangrene were, in reality, simulated affections. In extreme instances the gangrenous sloughs have, when separated, laid bare the tendons.

Excoriated Patches from Rubbing and Scratching. — Oval patches, wider than the finger, with broken edges are produced and are easily recognized. The neurotic excoriations of Erasmus Wilson, included some of these cases.

Eczema. — It is a singular fact that eczema appears to be very seldom feigned.

¹ Concluded from page 564 of the Journal.

² Illustrated Medical News, November 2, 1889.

Intractable Ulcerations. — Produced by picking and escharotics. An interesting case is related of a servant girl, nineteen years of age, who appeared on account of a bite from a dog received on the back of the left hand. The wound not healing for three months, she was admitted to the hospital, where the ulcer was scraped. The wound nearly healed, but in the course of a few months the ulcers recurred. The same thing happened again until a suspicion of the real nature of the malady being aroused, threats of an operation produced a speedy cure. Positive proof in this case seems to be wanting.

ERYSIPelas TREATED WITH ALCOHOL.

It having been claimed that ninety per cent. alcohol is, among other substances, a sure means of destruction for the erysipelas cocci, Behrend³ was led to make trial of this remedy by external applications, with the most gratifying results. As physician to a woman's prison, which constantly contained large numbers of women subject to recurrent attacks of erysipelas, and where every year numerous cases of severe type occurred in the form of epidemics, Behrend's opportunities for testing any remedy were of the best. All cases were treated at the outset solely by a vigorous bathing of the affected portions and of the adjoining healthy skin with ninety per cent. alcohol. The result was in every case without exception an immediate checking of the local affection with its total disappearance within from three to five days, and in the course of the two years during which this treatment was carried out, there was a great falling off in the number of days on which the prisoners were unable to work. It was impossible to judge of the effect of this remedy on more advanced cases, on account of its certain effect in the early stages. In a private patient subject to frequent attacks, Behrend has been able, by means of prophylactic applications of alcohol twice weekly, to ward off a recurrence up to the time of writing.

ARISTOL IN SKIN DISEASES.

Since Eichhoff introduced this drug into dermatological therapeutics, its praises have been sung so loudly that we are encouraged to believe that it will prove to be more valuable than the average new preparation. Its place has, however, not yet been determined, and reports of its efficacy do not entirely accord.

In estimating the value of any new dermatological preparation, reliance is to be placed chiefly on the statements of those who, having control of beds in hospital wards, are enabled to watch the results of treatment from day to day in a series of cases, and to compare them closely with those of other methods. Neisser of Breslau, a careful and accurate observer, has not been able to corroborate the enthusiastic recommendations of Eichhoff and others with regard to aristol, although he considers it of considerable value.⁴ In order to test the antibacterial properties of the drug, he experimented by mixing powdered aristol intimately with cultures of eight different microorganisms. After eight days the growth was found to be unimpeded. Mixed with aristol-ether ten per cent., some varieties appear to be destroyed, but the ether may in some instances, at least, be the effective agent. Ointments of aristol proved to have no antibacterial effect whether made with vaseline, olive oil or liquid paraffine and lanolin. Cultures mixed with these

³ Berlin. Klin. Woch., 1889, No. 4.

⁴ Berlin. Klin. Woch., 1889, No. 19.

preparations grew with great vigor, with the exception of those of the cholera microbe. Animals inoculated with these medicamented cultures promptly died. These results were not very encouraging, yet the previous experiences with iodoform, of undoubted efficacy, must warn against conclusions drawn from test-tube experiments, as to the action in animal organisms. His therapeutic attempts, which were made with the drug in powder, in ethereal solution, and in ointments of ten per cent., give the following results:

(1) Ulceræ mollia were in seven instances thoroughly treated with aristol powder, and with aristol-ether. The result was absolutely negative.

(2) No influence could be detected upon the gonococcus.

(3) A case of chronic eczema was not benefited.

(4) In lupus, the ulcerations were very favorably influenced, healing promptly and smoothly. On lupus nodules and surfaces not previously scraped no effect was observed, and he therefore regards it as not influencing the lupus process, *per se*, acting only to cause quick healing of the ulcer which has lost its lupoid character.

(5) Ulcers generally, as gummata, ulcerated scrofulodermata, abscesses that had been curetted, etc., healed rapidly and well.

(6) Lichen ruber in two cases was unaffected.

(7) Psoriasis. While aristol was found to have little effect primarily, the action of chrysarobin after its application was more speedy, and it should be accorded a place among the remedies for this affection.

No unpleasant results were experienced and but one instance was encountered, a case of psoriasis where it was not well borne.

TREATMENT OF KELOID BY QUADRILATERAL SCARIFICATION.⁹

In 1881, Vidal proposed to treat these obstinate growths by means of quadrilateral scarifications, and although his method has not been very universally adopted, he claims that it offers the best known means of alleviation. This writer states that keloid is often confounded with the hypertrophied scar, which resembles it in its external characters, but differs in its course and termination. The hypertrophied scar never spreads beyond the area of the loss of substance that gives rise to it, often undergoes resolution, and does not recur when it is wholly excised. Keloid, on the contrary, almost always recurs and resolution is exceedingly rare. Keloid is subdivided into spontaneous or primitive keloid (true keloid of Alibert) and cicatricial or false keloid, which has its starting point in a cicatrix, but extends beyond the area of the destroyed tissue. A mercurial plaster in the form of the *Emplastrum de Vigo*, he considers of some value, having twice seen cicatricial keloids disappear under prolonged application of this agent. Hypertrophied scars can be almost surely reduced by this method. In endeavoring to find a means for mitigating the suffering of a patient afflicted with spontaneous or true keloid, he was led to try the method of quadrilateral scarification, and from the first sitting the relief produced was very great. Observing that the keloid was disappearing, the treatment was continued, with the result of completely obliterating the growth. When the tumors are of recent growth six or seven repetitions of the scarification will suffice, but in larger

tumors the treatment must be continued for a long period, and the patients are prone to become disengaged. The scarifications should be made at right angles or obliquely, forming squares or lozenges: they should extend almost to the base of the growth, and overlap its edges by two or three millimetres only. The operation is done under local anesthesia produced by painting the part two or three times with liquified chloride of methyl. The loss of blood is trifling. The part is then dressed with cotton soaked in a solution of boracic acid, and the following day a bit of *Emplastrum de Vigo* applied, which is changed twice daily.

DURATION AND METHOD OF TREATMENT IN SYPHILIS.

Professor H. Leloir, the head of the dermatological school in Lille, this describes his customary method of treating syphilis.¹⁰

The primary lesion is locally treated by mercurial preparations, and constitutional measures are not resorted to until the appearance of secondary lesions, when daily treatment by inunction of from two to four grammes of mercurial ointment is begun, and continued for ten months. During this period attention is paid to local treatment also, mercurial plaster being applied to the lesions of the skin, ointments and lotions of mercury to those of the mucous membranes. In certain rebellious skin lesions, general baths, with about seven grammes of sublimate, are prescribed. The hygiene of the mouth is, of course, carefully considered, and the endeavor is made to strengthen the patient as far as possible. Where practicable a vacation in the country or by the sea is advised.

After from six to ten months of inunction, a period of rest is allowed for from three weeks to two months, and in this manner the treatment is kept up until the end of the second year. During this time an occasional diaphoretic or laxative is given, to avoid accumulation of the drug in the economy; and in exceptional cases, when there are violent pains in the head and in the bones, iodide of potash, to which bromide of potash is added, is prescribed for a short period. After the end of the second year he proceeds according to the severity of the case. If the patient has been for sometime free from syphilitic symptoms, inunctions for a period of ten days once in three months are given, together with two to three grammes iodide of potash daily for several weeks after the inunctions.

After the third or fourth year, provided his patient has been for more than a year free from specific appearances, inunctions are made twice yearly for a period of ten days, together with two grammes of iodide of potash daily for three weeks after each of these cycles of inunction. If the patient appears after the lapse of the fourth year, he is counselled, as a matter of precaution, to still continue the last method prescribed. Leloir avoids internal administration of mercury as far as possible, as he considers that unfavorable constitutional effects may be thus produced, and limits this method to those cases where concealment is necessary, or the skin very irritable, or where it is found impossible for any reason to carry out the inunction method. Subcutaneous injections of mercurial salts he employs very sparingly, and solely in hospital practice.

Clinical Department.

A CASE OF ENLARGED SUBCUTANEOUS BURSA IN FRONT OF THE TUBERCLE OF THE TIBIA.¹

BY G. H. MONKS, M.D.

A LARGE-FRAMED man, with a large bursa on his right knee, came under my care in the Surgical Out-Patient Department of the City Hospital some two or three months ago. He was by trade a floor-layer, and had therefore spent a large part of the time during his work upon his knees. The location and appearance of the bursa suggested that it was entirely in front of the tibia and palpation confirmed this. In other words it was a case of enlargement, *not* of that bursa which is between the ligamentum patellae and the tubercle of the tibia, but of that one which is entirely in front of (anterior to) the tubercle.

The figure is an outline drawing taken from a photograph. The view represents the outer aspect of leg. The case is interesting as showing that the practice of long-continued kneeling *may*, in certain cases, cause the enlargement of this bursa (in front of the tibial tubercle) instead of the prepatellar bursa, the enlargement of which is so often seen in the common affection "known as" "housemaid's knee."

VALUE OF CYSTOSCOPY IN THE DIAGNOSIS OF SURGICAL DISEASES OF THE KIDNEY.

BY OTIS K. NEWELL, M.D.,
Surgeon to Out-Patients Massachusetts General Hospital, Boston.

THE accumulating evidence from those who are accustomed to frequent use of the cystoscope, is clearly demonstrating its great value under certain conditions in making the differential diagnosis of surgical kidney diseases. At first thought, one might not imagine that there were many ways in which the cystoscope could thus be of value, but on considering certain points its usefulness will readily be seen. Nitze in a communication before the Berlin Medical Society on October 29, 1890, on this subject, brought out some very strong points, most of which he illustrated by the report of cases. His remarks may be briefly summarized as follows:

¹ Reported at the meeting of the Surgical Section of the Suffolk District Medical Society, November 8, 1890.

"In the first place we are enabled to determine with the cystoscope whether or not two uretal orifices are present, which is of great importance in those cases where a second kidney does not exist. We are enabled to see whether or not both orifices empty fluid into the bladder, and further we can observe by extended observation whether the fluid comes in equal quantity from both sides, whether it is clear or cloudy, and in the latter case whether the cloudiness is due to the admixture of pus or blood."

Nitze substantiated his statements with the report of six cases. They were in brief as follows:

CASE I. Patient, an elderly man who had repeated attacks of haematuria. All of the ordinary methods of physical examination gave negative results. Examination with the cystoscope revealed a healthy bladder wall, thus showing the disease to be in the upper urinary tract. The autopsy six months later showed the existence of a sarcoma of the kidney.

CASE II. A woman in whom, aside from profuse haemorrhage, physical signs were entirely negative. Cystoscopy revealed a healthy bladder, excepting that the very peculiar condition was noticed of a prolapsed ureter on the right side, just as is seen in prolapsus ani. This was undoubtedly caused by the profuse flow of blood which, in its passage through the ureter, had distended it, and thus brought about the prolapse. Post-mortem examination established the existence of a renal carcinoma.

CASE III. Likewise one of very profuse haematuria. The bladder was found to be healthy but during the examination it was noticed that the blood was poured out from the left ureter. Operation was refused. Later the tumor became palpable, which was not previously the case.

CASE IV. In this young patient, who had been crushed for stone in several hospitals, it was found that there was no stone in the bladder. It was, however, shown that immense quantities of purulent matter mixed with urine were poured into the bladder from the left ureter. The diagnosis of severe pyelo-nephritis of the left side was thus established, and the operation of nephrotomy safely performed.

CASE V. A patient who had suffered for years from severe pains in the right renal region, at times intermittent, and at times continuous. On account of a journey over a rough road haematuria was started and a cystoscopic examination while this was still present showed that the bleeding came, not as was supposed from the right, but from the left side. The case is not yet explained as it has not come to operation, but the presumption is, either that the patient had not correctly located the pain, or that calculus exists upon both sides.

CASE VI. Woman, eighteen years of age, had repeated attacks of severe haematuria. Digital examination of the bladder gave no satisfactory indication of the source of the bleeding. By cystoscopic examination it was found that the bladder was sound, but that from the right uretal orifice stream of blood was being steadily poured. On the ground of the diagnosis thus established, nephrectomy was successfully performed.

I have had four similar cases where the existence of the disease was proved to be above the bladder,—one in particular examined for Dr. Maurice D. Clark of Haverhill, where, in an elderly woman, with no positive physical signs other than profuse haematuria, the bladder was found to be free from disease. The right

uretal orifice was especially prominent. The other cases also gave only the evidence of absence of bladder source for the symptoms, and presented no such striking points of suggestion as those quoted from Nitze. None of them have yet come to operation or post-mortem examination.

In cystoscopic examination of the bladder one of the first and easiest things to distinguish, after the vessels in the vascular wall, is the uretal orifice on either side. When the distension fluid can be kept clear long enough for an examination of a few moments, any flow of blood or cloudy urine from the uretal orifices can be readily seen. Clots over points on the bladder wall from which hemorrhage has previously come are frequently noticed.

In the conclusion to be drawn from these facts I decidedly agree with Nitze that the cystoscope furnishes a most valuable means of aid in the diagnosis of renal affections and that through it the prognosis of cases may be improved by bringing them earlier to the surgeon for operation.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

GEORGE H. MONKS, M.D., SECRETARY.

REGULAR Meeting, Wednesday, November 5, 1890,
DR. E. H. BRADFORD in the chair.

DR. R. W. LOVETT read a paper on

HYDROCELE IN CHILDREN, WITH A REPORT OF CASES.¹

DR. M. H. RICHARDSON said: Dr. Lovett has not spoken of a common method in use, at the Massachusetts General Hospital. I dare say it is spoken of in all the books, though I do not remember having seen it; — that is the very successful method of tapping by means of a glover's needle. Numerous punctures through the skin and the tunica vaginalis allow the fluid to escape from the sac into the surrounding tissues, and in large drops through the skin. I have tapped a good many in that way with excellent results. My last case, however, was not successful, and the fluid returned, and there was quite a large collection of it. The question of a radical operation was considered, but it was finally decided best to wait a while till the child got older to see if the fluid would not disappear ultimately after a second tapping. This case I have not seen since. I should certainly agree with the writer, that any very severe operations were not justifiable, in view of my experience with the glover's needle treatment, and I certainly should not like to inject into the tissues of a child any irritating substances as we do in adults.

DR. G. H. MONKS showed photographs of a patient with

ENLARGED SUBCUTANEOUS BURSA IN FRONT OF THE TUBERCLE OF THE TIBIA.²

DR. RICHARDSON said: The bursa involved here is in front of the insertion of the ligamentum patellae, and I remember a case where this bursa was enlarged to the size of an orange. It gave no inconvenience

whatever, but acted as an efficient pad in kneeling, and the man demonstrated this by suddenly dropping with all his weight upon his bent knee, and resting on this bursa as on a cushion. I saw this case a number of years ago, and it made quite an impression on me. The sac must have been thick and strong. The bursa usually enlarged is that over the patella. There is another between the ligamentum patellae and the top of the tibia, and thirdly, this one — I don't know how constant it is — directly in front of the insertion of the ligamentum patellae into the tubercle of the tibia.

DR. MONKS also showed a patient, a man of fifty or thereabouts, upon whom he had operated for the relief of that

ENORMOUS HYPERSTROPHY OF THE NOSE,

which is occasionally noticed in connection with acne rosacea hypertrophica. Before the operation the skin was red and filled with comedones and pus. Union by first intention was, therefore, out of the question. The forehead and cheeks were covered with acne pustules. Four times the nose was operated upon, twice with ether. The skin of each ala was dissected back, and the excess of underlying tissue removed, and the skin flap replaced, its edges having been trimmed off. When healing had taken place, a large, wedge-shaped piece of tissue was removed from the end of the nose and the edges brought together. The incision, when stitched, formed a straight line from the root of the nose to its tip. Subsequently a large amount of tissue was removed from the bottom of the nose around the nostrils.

The nose of the patient had been greatly reduced in size by the operation. Before operating it measured three and one-eighth inches transversely from ala to ala, and after the operation this was diminished to one and three-quarters inches. The size of the nose was correspondingly diminished in its other diameters. The acne pustules had been successfully treated with sulphur ointment.

DR. F. B. GREENOUGH: I think this is a very successful, and more than that, a wonderful result. It is not only that a satisfactory nose has been made, but the enlarged sebaceous follicles, which must have existed, are apparently in a comparatively normal condition now.

DR. E. G. CUTLER: Dr. R. M. Hodges once operated on a case like this, apparently quite as bad, if not worse. He did two operations, and got a very successful result. I was present at the operations. There was a good deal of hemorrhage in the first one, not so much in the second. He took out elliptical portions of skin and drew the edges of the wound together. He had arranged to do three operations, but the patient thought he looked well enough as he was after the second operation, and, therefore, refused a third one.

DRS. E. G. CUTLER and M. H. RICHARDSON presented a paper on

A CASE OF DIGITAL DILATATION OF THE PYLORUS FOR CICATRICIAL STENOSIS.³

DR. NEWELL: I should like to ask Dr. Richardson what would be the objection to excising the pylorus in a case where the patient could have stood the operation.

DR. RICHARDSON: I think the objection to that

¹ See page 584 of the Journal.

² See page 591 of the Journal.

³ See page 581 of the Journal.

procedure is very obvious. Resection of the pylorus is one of the most formidable of operations. The mortality is large. Gastro-intestinal anastomosis is better. If you use silk and substances in the stomach that are not quickly digested, you have a very safe method of establishing communication. Abbe has shown a number of specimens in which he established communication between different parts of the intestine and the opening is a beautiful one. It can be made as large as desirable; the communication is good and the danger slight. In some of these cases the anastomosis between the stomach and the intestine is more dangerous than between different parts of the intestine on account of the digesting power of the stomach, and the extravasation of the stomach contents. I think, however, that it is very much less dangerous than resection of the pylorus.

DR. A. T. CABOT: I have been very much interested in the complete report of this case in which I was interested at the time, as well as in another which I saw with Dr. Cutler in the wards of the hospital the previous year. I was particularly interested in seeing the demonstration Dr. Cutler was able to make of the dilated stomach, the fluid flowing into the greater curvature of the stomach, and being perfectly demonstrable as it gradually filled it during the washing process.

In regard to the operation, enough time has elapsed since the first cases were done to give us some idea of the permanency of the results, and unfortunately they are shown to be not permanent. The cases are frequent in which there have been recurrences. I had letters from Dr. Huntington at the time of his first operation, and subsequently he wrote me he had had to do it again, and five or six months after that, if I remember correctly, he said the patient continued well, so that the patient has had already a long immunity. What Dr. Richardson has said about the recurrence of the stricture where cicatricial tissue has been stretched and not divided, is very true, and I have for some time been doubting whether a gastro-enterostomy would not be the best for these cases. It seems to me that an operation which entirely switches the pylorus off, and establishes a communication below the pylorus so that the food gets around it, promises something. The disease does not kill except by starvation, and anything which restores the capacity for alimentation cures the patient. All of the cases that have been successful I think have shown their success by great increase of weight. It is a very different condition of things from the malignant stricture. I think that for use in the stomach I should be inclined to choose rather than either Senn's plates or Abbe's rings the rubber ring of Brokaw, of St. Louis, that having more permanence, if held together with something a little more insoluble than catgut, something like Dr. Marcy's favorite tendon or possibly fine silk. One of these rubber rings gives very little disturbance afterwards in the passing. I agree with Dr. Richardson that the operation was, so far as it went, perfectly successful. I do not think the patient died because he had let it go for about two months too long. He put off the operation for three weeks after I first saw him, although he was then strongly advised to have it done at once.

DR. CUTLER: In April, 1880, there was held in Bologna, the Sixth Congress of the Italian Society of

Surgery, and during that meeting a gentleman in the course of his speech took occasion to say that after division these cases did not contract, but there are not a sufficient number of cases given for another to draw a like conclusion. He simply made this statement without giving any details. Robert Hazard in the *British Medical Journal*, of December 21, 1889, says of his case: "I am pleased to state that it is now just four years since I performed the operation. My patient is still in perfect health, showing no signs of any pyloric recontraction." There are, it seems, two English cases not included in Dr. Bull's report which appear to have been successful. I agree with Dr. Richardson that gastro-enterostomy appears to present a more favorable outlook than any other operative procedure.

DR. R. H. FITZ reported a case of

PERFORATING GASTRIC ULCER; CIRCUMSCRIBED PERITONITIS; DEATH ON THE FIFTEENTH DAY:⁴

and showed the specimen.

DR. M. H. RICHARDSON: I saw this woman Sunday night as she entered the hospital, and she presented then the symptoms which I saw in a case of perforation of the colon some years ago, where I opened the abdomen and found fecal extravasation. It was a good case it seemed at the time, and especially a few days later, for an exploratory operation, and we were anxious to do it, but the woman refused entirely.

DR. CUTLER: I saw the patient with Dr. Fitz, and there seemed to me to be no question whatever as to the diagnosis. The case presented all the clinical features which belong to a case of that sort. I did not see the patient after the first day.

DR. E. H. BRADFORD reported

A CASE OF CONGENITAL HYPERSTROPHY OF THE NOSE.⁵

A resolution relative to the death of Dr. HENRY J. BIGELOW was offered and accepted.⁶

DR. A. T. CABOT was by acclamation chosen Chairman of the Section for the year next ensuing.

**THE NEW YORK ACADEMY OF MEDICINE.
SECTION ON THEORY AND PRACTICE OF
MEDICINE.**

STATED MEETING, November 18, 1890. FRANCIS DELAFIELD, M.D., Chairman.

DR. J. C. MINOR read a paper on

THE INDICATIONS FOR TREPHINING IN EPILEPSY.

By the administration of drugs and the careful regulation of diet, exercise, and general hygienic measures, he said, we might hope to cure about one-half of all cases of epilepsy, which experience had shown was not an affection that disappears spontaneously. It was among the other half that surgical procedure had its field. While, however, all epileptics were subjected to medical treatment, only a small proportion of those unrelieved by such treatment came under the observation of the surgeon. Of these, a majority were rejected, as not appropriate subjects for operation; but of those who were operated on, more than one-half

⁴ See page 583 of the Journal.

⁵ See page 586 of the Journal.

⁶ See page 474 of the Journal.

were cured, over one-sixth were relieved, about twenty per cent. died, and about three per cent. were neither better nor worse for the operation. Within the last ten years the mortality had been largely decreased by the application of antisepsics to brain surgery, and the favorable results had increased in equal proportion.

The conclusions reached by Dr. Minor from his study of the subject were as follows:

There are three main indications for trephining in epilepsy that hold good, provided medical treatment or the removal of peripheral irritation by other methods fails to cure or relieve.

(1) In the distinctly traumatic epilepsies following depressed fractures and other lesions of the skull.

(2) In the traumatic epilepsies in which the only visible lesion consists of a scalp wound that is sensitive or tender, and upon which pressure develops either an aura, vertigo, or an epileptic seizure.

(3) In all epilepsies, whether traumatic or not, in which the character and development of the seizures is such as to indicate a definite motor area as the seat of a cortical lesion.

The contra-indications, he went on to say, were in brief, those that might be applied to cases of such long duration as to lead to marked mental degradation, to cases in which from the first the seizures had been general and sudden, to cases where the general symptoms indicated an extensive cerebral degeneration, and to cases where, in addition to any or all of these conditions, there was nothing in the symptoms or history of the case to indicate a definite or circumscribed lesion of the cortex that could be reached and removed.

As regards the whole subject of trephining in epilepsy, while there was no reason for satisfaction with the results of surgical treatment in these cases, he was quite sure that one of the plainest lessons taught by all this experience, was that of the added dangers and difficulties that arose from unnecessary delay in resorting to surgical treatment. Certainly in traumatic epilepsy it was unwise to wait until the increased frequency of the seizures had reduced the patient to an imbecile or idiotic condition before adopting surgical methods of relief. Long before this stage had been reached, any competent physician could determine with sufficient accuracy the prognosis of a case of epilepsy under medical treatment; and the proper time to operate began as soon as it became evident that other methods were ineffectual. While it was unwise to advocate undue haste in operating upon these cases, it was equally wrong to defer the operation to such a degree as to materially diminish the chances of recovery.

Surgeons themselves had been led to delay the operation, because the mental symptoms were not very marked, because the seizures were not repeated every day, because the progress of the disease was not very rapid; and, finally, after all this had been reversed, the mind impaired, the seizures frequent, and the progress of the disease accelerated, so that the patient's chances of recovery had been greatly diminished by these complications, then the failure of the operation to relieve the condition, had contributed to the very prejudice and conservatism that distinguished the treatment. There could be no question, he thought, that the best results follow the earliest operations, and these results applied not merely to cure or relief, but also affected the question of mortality. It was, therefore, important to bear in mind that the persistence of

the primary lesions has a marked influence in determining later and graver symptoms, and that if an operation was needed at all, the sooner it could be done the better for the patient.

DR. ROBERT F. WEIR said that nothing could be added to the rules for surgical interference laid down by Dr. Minor in his paper. The indications thus presented would, he thought, be accepted as just as by all the principal authorities at the present time, and were in entire accordance with those given by Bergmann in his last lectures. While he had had quite a number of cases himself, he did not feel at all justified in speaking on this subject from his own experience, and he did not think that any one, not even excepting Horsley, had met with a sufficiently large number of cases to enable him to arrive at any positive conclusions from such experience alone. There was one point which was somewhat discouraging, and that was the fact that the mortality from operation still remained so high, ranging from twenty to fifty per cent. It must be remembered, however, that brain surgery was as yet a comparatively new field, and that many of the fatal results occurred under the hands of those who were operating for the first time. Even among the more experienced operators he thought more violence than was necessary was not infrequently employed. But these were errors which would be corrected, at least to some extent, as time went on; and he had no doubt that in the future better results would be reported than had as yet been attained.

DR. ROBERT ABBE, who was to have taken part in the discussion, was unable to be present and sent a letter in which he said: My experience is limited to two trephining for traumatic and two for idiopathic epilepsy. The cases of idiopathic trouble were victims of degenerating mental state, both being boys of about twelve years. One was often violent after his attacks. I operated less than a year since upon him. The attacks ceased, and his mental state improved. After six months there was a return of his malady, and he required restraint in an asylum. At the operation I opened the dura and found the meninges in a condition of engorgement, and also edema, suggesting a low grade of inflammation, or at least one of irritation.

The second case I operated on only three weeks since. There were half-a-dozen attacks daily. The meninges were also in much the same condition as in the former case. The attacks ceased at once. Primary union of the wound occurred, and the lad was taken to Nova Scotia by his father, who is a physician. No recurrence has yet been reported.

I feel strongly conservative in regard to the operation for functional epilepsy; but believe it may be and should be tried, with expectation of temporary relief, at least, in cases of a severely progressive or degenerative type.

DR. E. D. FISHER said that many of these traumatic cases occurred in children affected with spastic hemiplegia. Although in so many of the cases there was a one-sided lesion, the attacks for the most part were general in character, not being in any way localized. He had himself seen thirty or forty such cases. When a scar was present it was generally found that no change whatever was produced by pressure on the scar. It was a question, therefore, whether the removal of this scar would be warranted or would be a good thing to accomplish. In these cases of epilepsy

with spastic hemiplegia in children it had been advised to trephine, and reports had been published to the effect that as a result of the operation the mental condition had improved, and the seizures had disappeared.

There were two questions which he said he should like to put to Dr. Minor. In the first place, when a scar was present, but when no irritation apparently resulted from it and the attacks were general in character, would he advise operation? In the second place, he should like to ask whether trephining irrespective of any local seizure would be warranted. This he knew had been done, and if the operation was performed with ordinary care and adequate antiseptic precautions he did not think it was attended with any special danger. It seemed to him that in these extreme cases we were justified in trying to do something for the relief of the patient.

He then mentioned a case that he had met with where the epilepsy resulted from the kick of a horse. In such a case, he said, we would naturally expect to get good results from operation. Yet after a few weeks subsequent to the trephining, the patient was as bad as ever, and there had been no improvement since. The point of chief interest to him about this whole matter, was whether in idiopathic epilepsy without a localized seizure we were warranted in resorting to operative interference. His experience would certainly teach him that in instances where blows or other injuries apparently lie at the bottom of the trouble, the cases are apt to go on to general epilepsy.

Dr. Fisher said that it had always seemed strange to him that while injuries to the brain frequently caused epilepsy, surgical operations upon it were not followed by this affection. He had never seen epilepsy produced as a result of experimental investigations upon the brains of animals, such as dogs, monkeys, etc.

DR. LANDON CARTER GRAY said that like Dr. Weir he thought that Dr. Minor had presented the subject with good judgment. But still the question arose at the very outset, What is epilepsy? We knew very well that it was merely a symptom, just as fever and cough were. We might search through the whole range of neurology, however, without being able to find out what it was a symptom of. This was a point that had never as yet been determined. Another question of importance was, Whether when a reflex, peripheral, or other cause had been removed, the epilepsy would not continue.

In the third place, it had been found that epilepsy was apt to be relieved by any operation upon any part of the body. In fact, any strong impression upon the peripheral nerves would be likely to have this result. This being the case, we were not in a position to judge of the permanency of the cure or relief in a vast majority of cases of operation, because the subsequent histories of the patients were not given for a sufficient length of time following the operation. It was, moreover, a well-established fact that many cases of epilepsy would go spontaneously for months and years without a fit. The trouble practically ceased for these long periods. At the time when phimosis was considered of so much importance he had seen the operation, for the relief of this condition, do quite as much good in epilepsy as had ever been reported from trephining. In the same way, he had seen the removal of a piece of skin from the buttocks, have a most beneficial effect. When these things were taken into consideration, therefore, it could be seen that

there was considerable room for doubt as to the real efficacy of trephining.

Many of the cases of epilepsy dated back from infancy or early childhood when lesions were produced by porencephalitis or meningitis which it was utterly impossible to remove. In adults some cases were called idiopathic simply because no one had been able to determine what the pathological changes were. As to traumatic epilepsy, of course, if you could find a cicatrix and remove it, you might perhaps do good; but it was well to bear in mind that just as much good could be accomplished by the operation for phimosis. Even where there had been depression of bone the epileptic habit might continue after this condition was removed. In the brain we could now localize for a certain number of things, such as the extremities, speech, etc., but beyond this all was pure speculation.

In any case of epilepsy, however, it was certainly desirable to know whether the lesion was within reach or not. If the growing doctrine that cortical lesions alone give rise to epilepsy should prove correct, it would be a great point gained for the surgeon, and much might be hoped for the future. There was a certain amount of ground for this opinion, and that subcortical lesions do not produce any loss of consciousness. As he had said before, the histories of the cases of operation were, as a rule, sadly lacking in completeness. He had seen cases of idiopathic epilepsy go for ten years without a fit, and others had reported cases which had no fit for twenty years. This whole question of operation in epilepsy must, therefore, be regarded as still distinctly *sub judice*, and any advance that might be attempted must be made very carefully and slowly.

DR. MINOR said, in closing the discussion, that the indications for trephining as he had given them had been drawn, not from any special theory as to the nature of epilepsy or its forms, but simply from the records of clinical cases. By judging from clinical experience he had tried to avoid any discussion as to its nature, and he had not consulted tables of statistics (all of which were imperfect) so much as the original reports of cases, as far as he could get at them. As to the matter of a scar, trephining, of course, caused a scar, and several cases were on record where the operation itself had been the cause of a reproduction of epilepsy.

In reply to Dr. Fisher's inquiry as to whether it was justifiable to operate in cases of idiopathic epilepsy when the convulsions were general and no scar was present, he said that he had trephined in one such case, and the patient was at all events no worse than he had been before. The place selected for the operation was over the fissure of Orlando, and he did not go below the dura mater. This was now over ten years ago. The question of cerebral pressure, due to a disparity between the skull and its contents came up, and the case was supposed to be one of too early ossification of the cranial bones. He thought that he was warranted in trying to relieve the patient by operation, but this was not followed by any result, and he was now in a lunatic asylum. After that he gave up the doctrine of cranial pressure, which certainly did not hold good in the case of the Flathead Indians, who he had never heard were especially subject to epilepsy. As to the presence of a scar being an indication for trephining, he thought that in his paper he had given about all the data that were warranted by clinical experience.

Recent Literature.

The Principles of Psychology. (American Science Series, Advanced Course.) By WILLIAM JAMES, Professor of Psychology in Harvard University. In two volumes. New York: Henry Holt & Co. 1890.

In his "Principles of Psychology," Dr. James treats his subject as a natural science, and to the exclusion of metaphysics proper, claiming originality, as he says, only in his strictly positivistic point of view, adding that his book is chiefly a mass of descriptive details running out into queries which only a metaphysician alive to the weight of his task can hope—perhaps centuries hence—successfully to deal with. The author brings to his task a fine enthusiasm, a wonderfully alert and original mind, great knowledge of facts, facility of expression, and a charm of language in which he has few equals. It would be impossible within our limits to adequately review fourteen hundred pages so compact with thought and learning. We desire especially to call the attention of physicians to the chapters on the functions of the brain, as being the best statement of that now absorbing subject. By judiciously skipping according to their several needs, to quote the author's words, many sorts of readers will find the book an interest to them and of use; and no physician is likely to put it down without a feeling of thankfulness that it has been written.

A System of Obstetrics by American Authors. Edited by BARTON COOK HIRST, M.D. Vol. II. Philadelphia: Lea Brothers & Co. 1889.

The second volume of this standard work has been for some months in the hands of the profession, and is already well known. It would seem that, however valuable the first volume, the second, from the nature of the subjects treated, will prove of even greater value and interest. The space at our command will not permit a critical notice of the different sections of the book; but a simple enumeration of authors and subjects will bespeak for them the interested study of the profession, even if on specific points the reader may not agree with the author.

Parvin writes on the diseases and accidents of labor; E. P. Davis on the forceps and on embryotomy. Cameron, of Montreal, treats version and the premature induction of labor. The Cesarean operation, symphysiotomy, laparo-elytrotomy, and laparo-cystectomy are very naturally treated by Harris; and Garrigues writes exhaustively and well on puerperal infection, and on inflammation of the breast and allied diseases connected with childbirth. The etiology of puerperal fever is learnedly treated by Ernst. The editor, Dr. Hirst, covers the complications of the puerperal state independent of septic infection; and Lloyd, of Philadelphia, writes on insanity and diseases of the nervous system in the childbearing woman.

The value of the work is much increased by the chapters on the management and the diseases of the new-born infant by J. Lewis Smith, the surgical diseases of infancy and early childhood by Stephen Smith, and the congenital anomalies of the eye by De Schweinitz.

We congratulate Dr. Hirst on the happy completion of his work.

ETIOLOGY AND TREATMENT OF PLEURISY.

At the Third Congress of the Italian Society of Internal Medicine, held at Rome, October 20-28, 1890, the subject of the etiology and treatment of pleurisy was up for discussion: Patella, referee, and Luzzato, co-referee.

The first-named speaker stated that ten years ago but three kinds of pleurisy were distinguished: rheumatic, traumatic, and secondary (that is, supervening by propagation of an inflammatory process in the lung).

To-day we know that there are pleurisies of infectious, microbial origin. But sero-fibrinous pleurisy is still considered as rheumatic, and we cannot yet explain its pathogenicity without hypothesizing a pathogenic agent other than cold and chilling. It is probable that the chilling only prepares the soil for the microbial infection by modifying in some way the circulation in the blood, vascular and lymphatic system. But how do the pathogenic germs penetrate to the pleura? This is a question which is quite difficult to answer. At the same time, Fraenkel has shown that one of the microbes of purulent pleurisy, the encapsulated, lanceolated micrococcus, is found in the tonsils, whence, by the intermediation of the lymphatic channels, it may gain access to the pleura. We may, then, admit this same way of penetration for the microbes of sero-fibrinous pleurisy.

Although, in many cases of sero-fibrinous pleurisy, bacteriological researches have remained unfruitful, we should be on our guard against concluding that this affection is not of microbial origin. These researches should, on the contrary, be extended and care should be taken to puncture very low down, for the microbes are often deposited at the lower part of the exudation.

According to Ziemssen, there are pleurisies which are not of bacterial origin as, for instance, the pleurisy which comes on in the course of acute rheumatic polyarthritis. The reader did not believe that the cases where the negative result of bacteriological researches cast

doubt on the microbial origin of the disease were really cases in which microbes had no causal agency, and he reminded his audience that it was often impossible to detect the presence of tubercle-bacilli in pleurisies with abundant effusion, the tuberculous nature of which, was, at the same time, indubitable. This fact is explained by the peculiarities of the anatomical structure of the tubercle, which, till it becomes softened, does not allow the bacilli to escape.

Maragliano has shown that a tuberculous pleurisy may engender a serous effusion, and Patella affirms that he has seen in tuberculous patients, pleurisies not tuberculous, which were due to Fraenkel's diplococcus.

The following conclusions sum up what the reader had to say respecting the etiology of primary pleurisy: (1) There exist sero-fibrinous pleurisies due to the encapsulated micrococcus of Fraenkel; (2) There are also pleurisies with abundant effusion, of exclusively tuberculous origin; (3) In tuberculous individuals, a pleurisy may sometimes take on a simple non-tuberculous form; (4) There exist also pleurisies of chemical origin, which are still insufficiently known; (5) It belongs to clinical rather than to bacteriological researches to determine the causes and nature of primitive pleurisies.

As for the pleurisies which develop secondarily to an acute pulmonary affection (meta-pneumonic pleurisies), their etiology is evidently that of the pneumonia. Their prognosis is generally more favorable than that of primary pleurisies.

Patella asks the question: Whether the spontaneous reabsorption of a purulent effusion is possible? He says yes, when the empyema is produced by the diplococcus of Fraenkel. In all cases where bacteriological researches indicate the presence of this microbe, we may hope for the spontaneous resorption of the exudation.

Luzzato, of Padua, co-referee, said that among the pleurisies incontestably microbial the purulent forms have the first place. These often accompany puerperal fever epidemics. In regard to simple pleurisies (rheumatic pleurisy), he had nothing to add to what the previous speaker had said. But as far as the sero-purulent pleurisies are concerned, he remarked that in several cases he had noted the presence of the diplococcus. He had also found in the exudation certain granules, sometimes united in masses, which allow themselves easily to be impregnated by coloring matters. At the same time, attempts to cultivate these granules have always given negative results. Besides, he had been convinced that the serosity of pleuritic effusion is not a good culture medium. Lastly, he recalled to mind the researches of Salvio, which showed that the presence of the pneumococcus of pneumonia in the pleura may provoke sero-fibrinous effusions. The following are the conclusions which he believes to be deducible from all the facts known thus far respecting the etiology of pleurisy: (1) The pathogenic agents of purulent pleurisy are the staphylococcus, the streptococcus, the bacillus of tuberculosis, and also, though

very rarely, the bacillus of typhoid fever. (2) The sero-purulent pleurisies are rarely associated with tuberculosis.

Passing now to the treatment of pleurisy, Luzzato would, first of all, reject bleeding and mercury, those two old means still much in vogue in Italy. In fact, mercurial preparations, he says, have never given him any favorable result; as for blood letting, its pernicious influence on the effusion, of which it augments the quantity, is well known.

Medicines have generally little action during the febrile period of the disease. But the salicylates and antipyrrin, as well as flying blisters and cataplasms, may render some service. When the fever has ceased, active or passive movements, pure air, and pulmonary gymnastics, are of great utility.

Thoracentesis, done with the necessary antiseptic precautions, presents no danger. It is indicated when the effusion reaches in front the third rib and is slow to undergo resorption; he would never tap during the febrile period. A prominent indication for thoracentesis is excessive frequency of the pulse. When pyogenic microbes are the causal agents, thoracentesis should be replaced by thoracotomy. During the first days which follow this latter operation, it is well to abstain from frequent lavages of the pleural cavity.

Bozzolo, of Turin, observed that the microbe of typhoid fever provokes pleurisy oftener than one would suppose. He has seen cases whose diagnosis was doubtful till thoracentesis revealed in the pus of the pleuritic effusion the presence of the bacilli of typhoid fever.

The question of the treatment of purulent effusions is still much discussed, especially in Germany, where physicians are generally opposed to the operation for empyema, while surgeons favor it. He affirmed that in his experience, simple puncture for empyema has always failed to cure; here, costal resection is indispensable. The lung will often regain its primitive volume after resection, especially in recent cases, and where adhesions have not yet formed; but in inveterate cases with adhesions and perhaps pulmonary lesions, expansion of the lung is not likely to be obtained.

Maragliano, of Genoa, had found pleurisy very frequent in fibrinous pneumonia; in fact, pneumonia hardly ever exists without a pleuritic exudation supervening between the third and fifth day of the disease. The quantity of this effusion is generally insignificant; it is ordinarily thick and sero-fibrino-purulent. He advocates the early evacuation of these effusions between the second and third week of the disease. The exudation is rarely reproduced, or if reproduced it is always in minimum quantity. Resort to paracentesis enables one early to obtain a reduction of volume of the thorax, and saves the lung from the dangers of prolonged compression. As for purulent effusions, he has known them to undergo spontaneous resorption; he has faith in the simple puncture, repeated every eight or ten days until pus

ceases to be generated; this succeeds well in some cases.

Bacelli, of Rome, would limit simple thoracentesis to the treatment of sero-purulent exudations (pyo-thorax), while costal resection is indicated in empyema, where the exudation is frankly purulent and encapsulated.

Renzi, of Naples, said that in his bacteriological researches he had become convinced that pleurisies were caused, according to the prevalent epidemic constitution, sometimes by the diplococcus of Fraenkel, and sometimes by the streptococcus. Thus, during the last epidemic of influenza, streptococcus pleurisies predominated. He admits the curability of tuberculous pleurisy. Thoracentesis often causes the fever to cease immediately, and this result is sometimes obtained by the evacuation of a small quantity of the exudation. According to his observations, when pleurisy develops on the side of a lung affected with tuberculosis, it may have a salutary influence, though detrimental when occurring on the side of a sound lung, the other lung being tuberculous; in the former case, the morbid symptoms in relation with the tuberculous process often for the time disappear after evacuation of the pleuritic liquid.

Mya, of Sienna, has seen two cases of pleurisy with hemorrhagic effusion due to bacillus of typhoid fever.

Tomaselli, of Catania, had some faith in wet cups in the treatment of acute pleurisy. He employs also blisters and milk diet, and resorts to aspiration or thoracentesis only when the quantity of the effusion is large, or if resorption is slow.

Marino, of Messina, spoke of the benefits of compressed air in the treatment of pleuritic effusions; this agent he thought should be reserved for the sequelae of pleurisy; while Fazio, of Naples, thought inhalations of compressed air should be resorted to early to favor resorption of the exudation.

KOCH'S TREATMENT OF TUBERCULOSIS.

THE treatment of tuberculosis by Koch's method has now reached a stage in which our future knowledge of the subject and judgment of its merits must be of slow growth, founded upon the results of clinical experience, except that before very long we may expect to hear how the material is made. Those who have had the best opportunities for watching the results of the injections seem to have retained their enthusiasm for the wonderful effects produced in cases of lupus and surgical tuberculosis, whereas how much can be expected in tuberculosis of the lungs remains doubtful. There seems to be a growing feeling among them that for advanced pulmonary lesions, even disregarding the danger of the injection itself, little or nothing can be expected.

During the past week some of the fluid has been received in America, and the profession here will soon be able to record clinical results for themselves. In New Haven a small quantity had been previously received by Professor Chittenden and used by Dr. J. P.

C. Foster. The first injections were made in New York on Tuesday last, by Dr. Allan McLane Hamilton at the Hospital for Ruptured and Crippled, and later by Dr. F. P. Kinnicutt at St. Luke's and Dr. A. Jacobi at the Mount Sinai and German Hospitals. About twenty cases in all were injected, some of them normal, some with a doubtful diagnosis and others with different tubercular lesions. It is, of course, too early to study results in these cases, but the reaction seems to be about as described in Berlin. A non-tubercular subject shows sometimes a slight, sometimes absolutely no reaction after the injection of a small quantity of the material, whereas a tubercular patient exhibits a more or less severe constitutional reaction a few hours after treatment, and a characteristic local reaction in the neighborhood of the diseased tissue.

In some instances exceptional effects, observed elsewhere, have again been noted. Thus, in the case of a male adult patient at the German Hospital, suffering from pulmonary tuberculosis, the temperature rose to 105° two or three hours after the injection, though this marked elevation of temperature was of comparatively brief duration. On the other hand, in a young woman in the same hospital the subject of lupus, the temperature fell to 97°, after the injection, although marked local changes were produced by it. The same result as regards temperature was observed in a consumptive patient at the Mount Sinai Hospital. In the latter case, however, the fall of temperature was soon followed by the usual febrile reaction noted in tuberculous patients, and on the following day when the injection was repeated there was no reduction of temperature resulting.

The daily press and some medical papers continue to abound in articles on Koch's so-called "lymph," a word which, considering that the composition of the fluid is not known, is, to say the least, premature. From another point of view it would be unfortunate that this word "lymph" should be permanently fastened upon Koch's fluid; as it perpetuates the early and erroneous idea that the process is one of preventive inoculation, such as results from the introduction of the vaccine virus or "lymph." For the same reason the use of the word "inoculation" would seem to be contraindicated by our present information as to the character of the process which follows the injection of the fluid. The word "injection" is better, because non-committal. Although no advertisements have appeared, to our knowledge, claiming that Koch's material is used, a few of the advertising medical fraternity are making good and often ingenious use of the popular excitement on the subject to bring their consumption cures into prominence.

REPORTS ON RECENT PROGRESS IN MEDICINE.

As it is impossible for a medical periodical to take notice of all interesting and important articles published in the medical literature of the world without a system of reviews contributed by different men in the

subjects in which they are themselves working, such a system, which this JOURNAL was one of the first to adopt, has been employed by several of the leading medical papers, in order that nothing new or important should escape their readers.

The *British Medical Journal* has recently added a supplement of eight pages to its regular issue, devoted entirely to short reviews.

The *University Medical Magazine*, of Philadelphia, has up to this time made it a rule to take no abstracts from other journals, but in its editorials to give a short *résumé* of the more important recent advances in medicine. These have been justly appreciated by the readers of this excellent journal, but the *Magazine* feels that it is impossible in this way to offer even a satisfactory summary of recent progress, and has decided to add a new department devoted to several of the most important divisions of medical practice.

Judging from the appreciation of this department which our readers have accorded to us, we have no hesitation in predicting equal success in this venture of our contemporary.

MEDICAL NOTES.

— It is reported that the republic of Guatemala is besieged by small-pox. The disease has made fearful progress recently. In seven weeks there were 1,200 deaths throughout the country, and the number at last accounts was on the increase.

— The Berlin police have ordered that all hotels or apartments taking consumptives to board or lodge, for the purpose of being treated by the Koch cure, shall be disinfected in the same manner as those occupied by diphtheria patients. A new police regulation provides that all patients shall be registered at the nearest police station.

— There is said to be a law in Bulgaria to the effect that, if a patent medicine which is advertised to cure a particular disease fails to do so, the vendor is liable for damages, and may also be sent to prison for a time for publishing a false statement whereby the public may be injured in purse as well as in health. Bulgaria is not usually regarded as being in the van of civilization, but its careful regard for the bodily welfare of its citizens might, with much advantage, be imitated by many more "advanced" nations.

NEW ENGLAND.

The thirty-eighth annual announcement of the medical department of the University of Vermont has just been issued. The preliminary term of the medical college, which began October 30th, will continue until next March. The attendance is unusually good, pointing to a large class. The regular course of lectures for 1891 will begin Thursday, February 26th, and the session will continue twenty weeks. With this course the new requirements for entrance and graduation will go into effect. Applicants will be required to pass an entrance examination in arithmetic, grammar, geogra-

phy, orthography, American history, English composition and elementary physics, before they may be regularly enrolled as students in good standing. But applicants who may have failed in one or more branches at these examinations may be enrolled as conditioned students; they must make up the deficiency, however, during the first year. Such entrance examinations will not be required of those who are not candidates for degrees, or those who have passed certain examinations at other schools, received certain degrees, or received diplomas or certificates from the regents of the State of New York, or from any similarly constituted authority in other States. These requirements are enumerated at length in the announcement. Candidates for the degree of doctor of medicine, before presenting themselves for examination for graduation, must have attended at least three full courses of lectures of twenty weeks duration each, the last at this college. The candidates must have studied medicine three years, must have attained the age of twenty-one years, and must present full certificates of the time of his study, of age, and of moral character.

NEW YORK.

— At a meeting of the American Association for the Cure of Inebriety, held at the Academy of Medicine Building, December 10th, Dr. D. D. T. Crothers, of Hartford, read a paper on "Alcoholic Inebriety and Life Insurance," in which he expressed the opinion that the use of alcohol in any quantity was of necessity conducive in a degree to the shortening of life, and that insurance companies were too lax in the matter of "moderate drinking risks." On the same occasion Dr. J. B. Mattison, of Brooklyn, read a paper on "Opium Addiction as Related to Life Insurance," in which he stated his belief that the insurance companies, which invariably refuse opium risks, might with safety accept an applicant, otherwise in good health, who had abstained from the use of opium for three years.

— Upon the completion of the thirty-fifth day of his abstinence, Succi, the faster, had lost 36.92 lbs., and his temperature was 98 $\frac{1}{2}$, pulse 72, respiration 22, dynamometer register 50 k., and spirometer 1,500 c. c. During the day he took nine ounces of ordinary water, four ounces of Kaisir water, six ounces of Vichy water, and 24 drops of his elixir. On the same day of his fast Dr. Tanner had lost 31 pounds. In other respects his condition was as follows: Temperature 98 $\frac{1}{2}$, respiration 15, dynamometer 53, water drank, 16 ounces. In comparing the two fasters at this period, one of the physicians having Succi under observation remarked: "The test in the case of Signor Succi is not as severe as in the case of Dr. Tanner, because the elixir which the former employs certainly quiets the nervous irritation, and from its reported composition must diminish the destruction of tissue; while the mineral waters he drinks, supply the waste of earthy materials. Dr. Tanner took nothing whatever to deaden his sensibilities, and drank only pure water; but, as the statistics show, he was in much

better condition on this day of the fast than Signor Succi is." By the thirty-seventh day Succi's weight had become reduced to 110½ pounds (from 147½ pounds), and his grasp of the dynamometer to 48 kilos.

— A large plot of ground on Second Avenue between 91st and 92d Streets, belonging to the Rhinelander estate, has been offered free of rent for the use of the New York Society for Parks and Playgrounds for Children for an indefinite period. It is proposed to flood it for a free skating pond, and to provide a suitable structure for sheltering the children if the money needed for the purpose can be raised. In the spring it will be covered with sand and used as a common playground. Gymnastic apparatus will also be provided, as well as free instruction in gymnastics by competent teachers.

— At a meeting of the Section on Theory and Practice of the Academy of Medicine held December 16th, Dr. Charles E. Quimby, of the Medical Department of the University of the City of New York, who went to Berlin last month to make a personal investigation of Koch's inoculation treatment, gave a report of his visit there.

Miscellany.

THE BOSTON CHILDREN'S HOSPITAL.

WITHIN a few weeks the managers of the Boston Children's Hospital have opened a new series of wards in this institution, thus completing the plan originally proposed by them. When the present hospital building was occupied, some ten years ago, the administrative building and the west wing alone were put up; but the increasing demands upon the accommodations and the desire to enlarge the field in which the institution has been so eminently successful, encouraged the officers of the hospital to add still another wing to those already built. The out-patient building, erected two years ago, with its capacious and excellently ordered apartments, its museum of appliances, its operating rooms, lecture room, photograph room and workshop for the manufacture of apparatus, completes a hospital for sick children which has no superior.

The new wing is in the same style as the other parts of the building. It is substantially constructed, finished in ash, with hard-pine deadened floors, hard painted walls, open fireplaces, and the most approved methods of heating and ventilation. The older portions of the hospital will now be devoted to surgical cases, the new wing has been divided into smaller wards and single rooms and will be allotted to medical cases. A large part of the upper story is devoted to a recreation room, and is fully provided with means for amusing the patients while temporarily absent from the wards.

The managers desire that members of the medical profession should recognize the fact that this is a medical as well as surgical hospital. The physicians as well as the surgeons, have been chosen from those who, by positions in the medical school, or otherwise, are our authorities in the diseases of children. The Sis-

ters of St. Margaret, so well known for their devoted work, have the oversight; and abundant nurses keep watch and ward by day and night. If parents could be taught that sick children, as well as injured or deformed ones, need hospital care, and would grow up stronger and better for it, it would be the better for the children and the parents, at any rate, the Children's Hospital now throws open its *medical* wards, as well as its surgical, to any child between the ages of two and twelve, living in Boston and, at a very small price, to any one from elsewhere. Contagious cases alone are refused.

THE SEVENTIETH BIRTHDAY OF PROFESSOR VIRCHOW.

As announced in the JOURNAL of December 4th, there is a movement on foot in Germany to celebrate the seventieth birthday of Professor Virchow. A special committee, of which Professor Waldeyer, of the University of Berlin, is chairman, has issued the following circular:

"On the 13th of October, 1891, Rudolf Virchow will attain his seventieth birthday. There exists a desire and a determination to offer to the renowned scholar and master, on that day, a testimonial, in appreciation of his contributions to science. In the first place it is proposed to strike a golden portrait-medallion, of large size, designed by a noted artist; for nothing but an exceptionally appropriate gift would be worthy of the occasion. A copy, in bronze, of this medallion will be given to each member of Virchow's family, and in case the funds are sufficient, to certain scientific societies. Considerable expense will necessarily be incurred; and the committee look to the wide circle of Virchow's scholars, friends and admirers, in the firm belief that all will gladly unite in contributing to the successful fulfilment of the memorial. Any surplus will be given to Professor Virchow, in order that he may use it in any way that he sees fit, by endowing an institution or some similar object. The committee will from time to time publish the results of their endeavors."

In this country Dr. John S. Billings is endeavoring to bring the matter of this proposed festival to the attention of the admirers of Professor Virchow. Any funds may be sent, with the names of the donors, to Dr. Billings in Washington, to be forwarded with other contributions from the United States, or, if preferred, may be sent direct to the treasurer, Herr Adolf Meyer, Königgrätzerstrasse 48, Berlin, S. W.

THE DIAGNOSIS AND TREATMENT OF CYSTS OF THE PANCREAS.

In a lecture on the subject, Dr. Karczewski¹ said that in the majority of instances cyst of the pancreas had been mistaken for one of another character. In nearly all the cases reported, the tumor was large and filled the abdomen. Out of twenty-one cases recorded the diagnosis of cyst of the pancreas had been made in ten only. In all the cases described, the same train of symptoms was present: colic-like pains, marked emaciation, symptoms of indigestion in consequence of narrowing of the gastric space, and a feeling of pressure. If, on examining such a case, an intumescence was felt, which could be localized in the site of the

¹ Medical Press, November 12, 1890.

pancreas, the possibility of a cystic formation should be borne in mind. Moreover, the position and shape of the tumor was quite characteristic. It was bounded above by the stomach, on the left by the spleen, on the right by the liver, and below by a tympanic zone. It was convex below, and was prolonged backwards. Its movability was slight, but to a certain extent it participated in the respiratory movements.

Early diagnosis was important as it became still more difficult when the tumor filled the whole of the abdominal cavity, and by that time the exhaustion was sometimes so great that operation was no longer of any use.

Treatment consisted solely in radical operation. This had been carried out in three forms. Extirpation of the cyst, opening, by double operation at two periods, and drainage, and simple opening and drainage. Extirpation had been performed five times, in three the operation was fatal, and the two that recovered were operated on under specially favorable conditions. The double operation could only be performed when the tumor was very large, when small it was impossible. Free opening and drainage was the most rational; escape of some of the contents into the abdomen did no harm, under aseptic conditions. The fluid should first of all be withdrawn by puncture by a trocar, and then the wound be stitched to the abdominal opening.

AFRICAN SLEEPING SICKNESS.

A CASE of this remarkable disease, in which interest has recently been renewed by Stanley's book, was recently exhibited at the London Hospital by Dr. Stephen Mackenzie.¹ The patient was a young male negro from the Middle Congo. This is an entirely different disease from the so-called *noma* of the Italians.

Negro lethargy is practically confined to pure-blooded negroes; only in rare instances have persons of mixed blood been affected, and Europeans living in the affected regions have, so far as is known, never been victims of the malady. It is only known to occur over a large part of the West Coast of Africa between the Senegal and the Congo, and when it has been observed beyond these regions it has only been in negroes who have been imported from the West Coast. It is most common between the ages of twelve and eighteen, though no period of life is exempt, and the two sexes appear to suffer about equally. The disease manifests itself insidiously, by a tendency to fall asleep at irregular times, which gradually increases to an irresistible degree. It is progressive in its course, but not uniformly so; intermissions, and apparent recoveries even, succeeded by relapses, sometimes take place, and the duration of the complaint varies from about three months to as many years. In nearly all cases it eventually terminates fatally, the patient sinking into a completely comatose state before death. The nutrition is preserved in the majority of cases until the close, the vegetative functions not being interfered with. But though patients take and digest food when given them, they are incapable of attending to their own wants, and in the late stages the tendency to sleep is so overpowering, that they may drop and break a vessel they are carrying to their lips, or fall off to sleep with the half-masticated food in their mouths. When aroused,

their intellectual powers do not seem impaired, except that mental processes are slow. The village from which the patient shown at the Clinical Society came has suffered severely from the disease, and numerous members of the patient's family on both sides have died of it. So fatal has it been in this village that many of the inhabitants have deserted it.

The etiology of the disease is still in doubt, although many theories have been advanced in regard to it.

OBITUARY.—O. W. DOE, M.D.

THIS death of Dr. Doe removes a familiar figure from the ranks of Boston physicians in active middle life. His career was uneventful, but was marked by an even course of progressive success. He was born in South Newbury, Vt., in September, 1843. He fitted himself for college at the Boston Latin School, and graduated from Harvard with the Class of 1865. He received his medical degree from Harvard in 1869, and entered at once upon medical practice in Boston. In 1875-6, he spent a year in study at Vienna, devoting his attention chiefly to obstetrics, of which he was especially fond. Throughout his professional life he has been identified with the Boston City Hospital; he was house physician in 1868-9, physician to outpatients from 1870 until he was appointed visiting physician in 1875, and for fifteen years he has served in the latter position, up to the time of his death. In connection with his hospital work he was clinical instructor in gynaecology in Harvard Medical School. For several years he did acceptable service in connection with the Boston Dispensary and St. Luke's Home, and the latter institution included him, in recent years, upon its consulting staff. He was a councillor of the Massachusetts Medical Society, and an active member of the Boston Society for Medical Improvement and the Obstetrical Society of Boston. His death occurred on the 10th instant, from double pneumonia following an imprudent exposure to cold while answering professional calls at night.

Dr. Doe carried in his large frame a spirit that was singularly open and guileless. His temperament was sensitive and sympathetic. His life was exceptionally pure, and his reputation was without a flaw. The temptations of early manhood never touched him to do him harm. His ideal was high. He had no time or taste for conventional society, but he loved his friends loyally. He admired music, and found in this his chief recreation. He was of a generous nature; and recalling the help which a kind word or act from his elders had afforded him in the beginning of his career, he took much pleasure in extending similar recognition and aid to young men just starting in life.

In his professional work Dr. Doe was successful and prosperous. He was not a ready writer or an easy speaker, and he therefore was not widely known through contributions to medical transactions. It was at the bedside and in the homes of his patients that his medical skill and judgment found their most congenial exercise, and here he was conspicuously successful. He was untiring in his fidelity, gentle and sympathetic in manner, skilful in treatment. He inspired confidence by his presence and bearing. He was a typical illustration of the good family physician, and his death is mourned in many domestic circles where his loss seems almost irreparable.

¹ British Medical Journal, November 29.

TRIBUTE BY THE OBSTETRICAL SOCIETY OF BOSTON UPON THE DEATH OF DR. O. W. DOE.

RECOGNIZING the great loss which its fellowship has sustained in the death of Dr. O. W. Doe, the Obstetrical Society of Boston places on its records this cordial tribute to his memory :

Taken from us in the prime of his life and in the full maturity of his physical and mental vigor, his death touches us, his associates, with peculiar sadness and regret. We recall his generous disposition; his loyalty to his profession; his manly, unostentatious bearing; his unstained life. He was conscientious and true to his high ideal. He despised all that was low or mean. In his relations with his professional fellows he was courteous and square.

But it was in the daily round of his duty as the medical attendant in a wide and ever-widening circle of homes that his characteristics found their most congenial activity. To be a good family physician was his aim, and that aim was accomplished. In the execution of the peculiarly delicate and responsible obligations which this Society represents, he was gentle, skillful, devoted and successful. The circumstances which attended the beginning of his fatal illness attest the self-abnegation which marked his conduct in the care of others, his patients. A great company of people who have relied upon him in seasons of distress, and have confided in his devoted skill and sympathetic counsel, mourn him as one truly endeared to them. A single word will describe his life and his character, — he was faithful in every relation.

F. W. DRAPER,
JOHN G. BLAKE,
C. ELLERY STEDMAN.

DR. HENRY J. BIGELOW.

RESOLUTIONS OF THE MEDICAL BOARD OF THE MASSACHUSETTS GENERAL HOSPITAL.

AT a meeting of the Medical Board of the Massachusetts General Hospital, December 5, 1890, Drs. Homans, Beach and Cabot, a Committee appointed by the Surgical Staff, submitted the following remarks and resolutions:

Dr. Henry Jacob Bigelow was for forty years one of the visiting surgeons of this hospital. He was a man of wonderful mechanical skill and touch. Inheriting a remarkable intellectual power and coolness from his father, well taught by opportunities for observation and cultivation, of which he made the most, he entered on the practice of surgery perfectly equipped. Hampered in no way, neither by want of means nor by serious ill-health, and endowed with an almost intuitive perception of what was the proper course in every case, he never hesitated. No other result but success in his profession was possible. It was assured by his natural abilities, his unfailing instinct, and his cultivated judgment.

In the mechanical execution of his preconceived and thoroughly thought out plan of operation, he was superior to other operators, and was as certain as he was graceful, brilliant and daring.

Dr. Bigelow's life was coincident with the discovery of anesthesia by ether, of which he was one of the leading advocates. He himself contributed one of the greatest discoveries of all, that of a knowledge of the mechanism of the hip-joint, a knowledge which enables us to reduce a dislocation rapidly, painlessly, mercifully and intelligently. This discovery alone was enough to immortalize him, but in his later years he added another practical benefit to surgery and humanity, namely, his method of relieving those suffering with stone in the bladder. And it will be noticed that all his inventions, achievements and improvements were practical, and, one might say, manual.

How thorough he was in perfecting a mode of procedure before he introduced it! He never published until he was absolutely certain, and could demonstrate his method in an almost off-hand way. And then how concise in his writ-

ings! Not an extra word; every sentence concentrated down to its alkaloid, as one might say. And it must always be remembered that it was in this hospital that the intelligent reduction of the dislocation of the hip by Dr. Bigelow's method was first done, and that it was in this hospital that the crushing and removal of a stone from the bladder at one sitting was first practised, an operation to which Dr. Bigelow gave the name of "litholapaxy."

The code of ethics he submitted to the Massachusetts Medical Society, and which was adopted, is simply to be a gentleman, to treat others as we would be treated; that is the sum and substance of it.

His familiarity with the science of mechanics, with the use of tools, and with the engraver's art supplemented his tactical skill as a surgeon, and rounded out and perfected the clear, concise and brilliant articles he published. His native city and country are proud of him, and suffering humanity will forever be relieved by the inventions of our late associate visiting surgeon as long as the world shall exist.

It was *Resolved*, That the hospital has lost a friend, whose interest in its success as a great charity was ever active and devoted;

That, through his extraordinary skill in operating and teaching, and the rare, judicial character of his investigations in weighing the evidences of disease, standards of work have been established at the hospital that have contributed much to the advancement of the art of surgery and the comfort of the afflicted;

That his accomplishments in the art of treating hip-joint dislocations and stone, now adopted throughout the civilized world, distinguished his name among the leading surgeons of his time;

That the entire surgical staff, who have without exception been his pupils, tender this acknowledgment in grateful remembrance of one whose first instinct was to save.

"Si monumentum queris circumspice."

Resolved, That a copy of the resolutions be transmitted to the family of Dr. Bigelow, and to the *Boston Medical and Surgical Journal*.

Correspondence.

PARAFFO-STEARINE: A SUBSTITUTE FOR STARCH, PLASTER-OF-PARIS, AND SUCH MATERIALS, FOR BANDAGES AND SPLINTS.

FORT WARREN, BOSTON, December 12, 1890.

MR. EDITOR: — Some time ago I used what appears to me to be an inexpensive, useful, cleanly, elegant and efficient desideratum in the treatment of all maladies or injuries where rest, equable support, and solidity of the parts affected, are required. This consists in immersing the common bandage or felt in a combination of equal parts of rock paraffine and stearine, as used for candles, which, if necessary, may be colored to a flesh tint with alkanet root, and liquefied to a little beyond the melting point (160° F.) so as to render the composition of a temperature that may be readily manipulated without injury to the hand, or part on which it is applied. Roller bandages, or felt cut into the shape of the splint required, are to be saturated with the above melted composition, and applied whilst warm and flexible to the limb or joint; when, if needed, further strength and solidity may be given by varnishing a portion of the melted composition over the splint or bandage with a painter's brush, and afterwards smoothing the whole with the palm of the hand until it assumes the surface of ivory, or the well-known appearance of a candle. A fold of linen dipped in cold water is finally to be passed round the bandage or splint, which instantly solidifies the melted paraffo-stearine; the application is then complete, and the wet linen may be continued as an evaporating lotion, if desired. Into this bandage or splint openings may be readily cut by means of the common plaster-of-Paris scissors, the melted composition being afterwards applied over the cut edges of

the opening, so as to form a complete solid case, allowing the escape through such openings of discharges, and the application of dressings. It will be perceived, that, by dividing the paraffo-stearine bandage and removing say half an inch, or separating it into halves, and trimming the edges in the usual manner, splints will be formed having the exact configuration of the part to which they are to be applied, and that these splints can be lined with flannel, etc., and strengthened with the melted paraffo-stearine to any extent required.

The whole of the appliances before described can be readily extemporized by the aid of a pound or two of candles, such as are issued by the Commissary Department; a jug or jar in a saucepan of boiling water, for melting the same; a rolled flannel or other bandage; and a shaving brush; or should a splint and not bandage be preferred, a strip of felt cut into the required shape, and also rolled together, so as to be immersed in the melted candle composition in the jar.

I may observe that all the bandages and splints may, by remelting, be used a second or third time, thus rendering them the most economical of applications; and, it may also be well to mention that when the removal of a bandage is required, it may be at once softened and taken off by brushing it over with any kind of benzine.

This composition, I think, may be found most useful in the field as a temporary dressing. Candles are issued to troops by the Commissary in lieu of oil when in the field, and there would therefore be no difficulty in obtaining the amount required, and it could, as I have before mentioned, be used over and over again. It is by no means so heavy or cumbersome as plaster-of-Paris, and dries instantly on the application of cold water, thereby rendering unnecessary the tedious waiting that always takes place for the plaster bandage to dry. It will, I think, be found most useful and economical for troops in the field, and at first-dressing stations in time of war. Very truly yours,

H. GRAHAM, Hospital Steward, U. S. A.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 6, 1890, TO DECEMBER 12, 1890.

By direction of the Secretary of War, Captain MARCUS E. TAYLOR, assistant surgeon, is relieved from further duty at Boise Barracks, Idaho, and will proceed, at the expiration of his present sick leave of absence, to Vancouver Barracks, Washington, and report in person to the commanding officer of that post for duty, reporting also, by letter to the commanding general Department of the Columbia. Par. 17, S. O. 287, A. G. O., Washington, December 9, 1890.

By direction of the Secretary of War, Captain CHARLES M. GANDY, assistant surgeon, now on leave of absence, will report in person without delay to Colonel Eugene M. Carr, 6th Cavalry, at Rapid City, South Dakota, for duty with troops in the field, reporting also, by letter to the commanding general Department of Dakota. Par. 14, S. O. 287, A. G. O., Washington, December 9, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 13, 1890.

DELEYAN BLOODGOOD, medical director, ordered to Charles-ton, S. C., to represent the Medical Corps, U. S. N., at meeting of American Public Health Association.

H. E. AMES, passed assistant surgeon, ordered as delegate to Charleston, S. C.

D. N. BERTOLLETTE, surgeon, detached from Naval Hospital, Philadelphia, and ordered to special duty in connection with World's Columbian Exposition.

S. H. DICKSON, passed assistant surgeon, from the "Atlanta," and granted two months leave of absence.

A. R. WENTWORTH, passed assistant surgeon, to U. S. S. "Atlanta."

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, December 22, 1890, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M. Papers: Dr. F. H. Hooper, "Transillumination of the Air-Cavities of the Head and of the Larynx, with Demonstrations"; Dr. J. C. White, "Leprosy, with Lantern Illustrations." G. G. SEARS, M.D., Secretary.

OBITUARY. JAMES L. STEWART, M.D.

Dr. J. L. Stewart of Erie, Pa., died on December 6th, aged sixty-five. He was a graduate of the Medical Department of University of Pennsylvania in 1848. In 1850 he moved to Erie City, where he remained until 1855, with the exception of four years' service during the War of the Rebellion with the Union Volunteers, having charge a portion of the time of one of the large hospitals in the vicinity of Washington. He was a bold and successful operator. He had been connected with the Erie County Medical Society since 1849, acting successively as secretary and treasurer, and repeatedly as president; was vice-president of the Pennsylvania State Medical Society in 1867-68, and for six years senior member of the judicial council of the Society; member of the American Medical Association, member

of the executive council of the International Medical Congress, which met in Philadelphia in 1876. He also held the position of examining surgeon for the pension bureau from 1865 to 1876, and for seven years of that time was president of the Board of Examining Surgeons.

Address.**EARLY DIAGNOSIS OF SOME SERIOUS DISEASES OF THE NERVOUS SYSTEM; ITS IMPORTANCE AND FEASIBILITY.¹**

BY E. C. SEGUIN, M.D., PROVIDENCE, R. I.

THERE are several serious diseases of the nervous system, and others which, at an early stage present chiefly nervous symptoms, that are held to be incurable, or nearly so.

One reason for this dismal prognosis is that in the present state of medicine the diagnosis of these afflictions is usually only made when organic changes are far advanced, or, in the case of epilepsy, when the functional disturbance has become firmly fixed as a habit of the nervous system. Such cases almost never reach nervous specialists on the first appearance of symptoms; the patients consult their family physician or any general practitioner. When special advice is sought the affection is still further advanced, more deeply rooted, and consequently less amenable to treatment.

We will probably all agree that if we are ever to be able to successfully treat these diseases—to arrest or cure them—it will have to be by improved methods of treatment applied at the earliest possible moment; as near to the beginning of organic changes as possible, or before a functional disease has become fixed. The latter condition I hold to be a *sine qua non*, and improved therapy will avail but little if it can be applied only to well-developed disease.

Consequently, gentlemen, I have long held it to be a duty of specialists to endeavor by every means in their power to furnish to their *confrères* in general practice the elements for the earliest possible diagnosis of the diseases to the study of which they have devoted all their energies. Nine years ago I read two papers on this subject, one relating to organic nervous diseases,² the other to epilepsy,³ and I have reason to believe that they produced some fruit. The essay which I have the honor to read this evening embodies in a briefer form the subjects of those earlier essays, differently arranged, and with some new points and suggestions.

I beg that you will excuse the positiveness of the statements I shall make. All are the result of experience, some of my own mistakes, and every one has been well considered. Besides, the necessity of condensation of so much important matter, renders a terse and rather imperative form unavoidable. In concluding these prefatory remarks, allow me to say that I wish that our masters in other special departments of medicine would give us the results of their experience in a similar way and for the same purpose, that is, to furnish to the general practitioner the means, clearly and logically arranged, of making a correct diagnosis of serious chronic diseases at the earliest possible moment.

Before entering upon the special part of my paper, I wish to make a few remarks upon *diagnosis*, as regards its degree of certainty and its kind or form logically considered. I shall assume that the attempt at diagnosis is preceded by a thorough and exact exami-

nation of the patient as well as by the recording of a complete history of the case.

First, we have an ordinary *positive diagnosis*. Most, if not all the cardinal symptoms of a chronic organic nervous disease are present and properly grouped. The case is one of spinal sclerosis, of acute dementia, of cerebral tumor, or of actual cerebral hemorrhage or local softening, etc. In such a case it rests with the physician's conscience, his knowledge of his own capacity, whether he shall treat the case himself and be able to do all that can be done to arrest the disease or prevent new lesions.

Second, there is a *diagnosis of probability*. Some of the capital symptoms are present, though perhaps not marked; by exclusion you reject the diagnosis of various diseases presenting similar or analogous symptoms. To your mind it is probable (in varying degrees of probability) that one of the lesions above mentioned is present at a tolerably early stage of its development. In such a case is it right to wait, to allow new symptoms to develop before instituting a course of treatment? Have you the technical requirements necessary to determine the condition, static or dynamic, of all the patient's nervous organs? In other words, are you able to search for and recognize *every* symptom of the affection you suspect? Here is where the experience of specialists, freely laid before you, may be of use. In the present state of therapeutics it may be that you can do as much for your patient as a specialist could; but are you on safe ground, are you justified in warning your patient of the probably rebellious course of his ailment, and in obliging him to make the sacrifices necessary to a thorough treatment? In such cases consultations are, I believe, desirable, and equally satisfactory to the patient and to the practitioner. In many such cases the accumulated experience of the specialist will readily clear up what uncertainty may exist. Occult symptoms may be discovered, confirming the diagnosis; or seemingly positive symptoms may be shown to have no serious meaning. I could quote many cases confirmatory of the utility of a consultation under such conditions.

Third, there is, not rarely, a degree of diagnosis which I term a *diagnosis of possibility*. The anomalous course and grouping of symptoms, each one not serious in itself; the absence of elements for the diagnosis of other diseases; the inutility of prescriptions based on less serious lines of thought; all these lead you at once or gradually to suspect that you are face to face with the initial stage of one of the diseases which I shall consider analytically further on. In such a case it is, I believe, an imperative duty to hold a consultation. The specialist may be able to dispel your fears, or to advance the diagnosis to the second degrees, yes, in some instances, to the first.

It is for the perfection of diagnosis at and from this stage that I now plead, for the reason already given, that, if we are ever to be successful in curing sclerosis, inflammation of the neuroglia, decay of nervous elements, primary or secondary to arterial changes, neoplasm, etc., it will have to be by energetic treatment, including hygiene, applied at this stage. I need not tell you how dismal and discouraging is the prognosis of the above lesions at the present time; usually, making a correct diagnosis (of the second or first degree), is equivalent to pronouncing the victim's death-warrant.

Besides these three *degrees* of diagnosis, we should

¹ Delivered before the Providence Medical Association, December 1, 1880.

² New York Medical Record, February 26, 1881.

³ New York Medical Record, August 6 and 13, 1881. Both in *Opera Minora*, pp. 457 and 540.

bear in mind that the complete study of a given case of nervous disease requires several *kinds* of diagnosis, to be reached by different modes of reasoning. In organic diseases we should clearly establish in our own minds three separate diagnoses :

(1) The diagnosis of the *symptom or symptom-group*. This is arrived at by the history of the case and by a careful examination for the determination of the alterations presented by the patient's functions and external (or accessible) tissues. Physiology is our chief guide here.

(2) The diagnosis of the location or seat of the lesion. This is arrived at by a purely anatomical and physiological reasoning. We trace the symptom (that is, disordered function), to its source or anatomical substratum. I need hardly remind you of the remarkable advances made in this form of diagnosis (so-called localization diagnosis) in the last twenty years. Many small lesions can now be located in the brain and spinal cord with almost geometric exactness.

(3) The diagnosis of the *nature of the lesion*. This is often difficult, and is made by applying deductions, the accumulated results of experience as embodied by pathological anatomy and statistics. In nervous disease we cannot hope for a direct demonstration of the nature of the lesion, as we have it in pulmonary phthisis by the presence of bacilli, or in Bright's disease by the discovery of albumen and casts. In nervous diseases the third diagnosis is one purely of inferential or deductive reasoning.

In functional nervous affections, we are limited to two diagnoses :

(1) The diagnosis of the *symptom or symptom-group* made in the same manner as for organic diseases.

(2) The diagnosis of the patient's *general condition and predispositions (heredity)*.

The latter is often made impossible by the silence or deliberate deception of the patient and her relatives. The former is to be obtained by a thorough personal examination : including a study of the state of the blood, of the urine, of the condition of the heart and the arterial tension, the state of digestion and assimilation, and by an examination of those organs which we know are capable of being the starting point of exhausting irritations ; for example, the eyes, ears, and sexual organs more especially.

There is, we now believe, no true lesion (that is, gross organic change), in the nervous organs in these cases, yet there must be some delicate alterations underlying the perturbation of functions. In a good many cases of epilepsy, however, a very thorough search may reveal a lesion. What I have just said of forms of diagnosis, as to kind and degree, implies the giving of much time and patient care to the investigation of each case. But I am convinced that you will never have occasion to regret having studied your nervous cases in this way.

Here allow me to say that long before I became a specialist (having been a general practitioner fourteen years before becoming one) I had a very definite contemptuous idea of consultations as ordinarily managed. Some years ago, in all departments of medicine, the advice of a specialist or consulting physician was sought rather to confirm the serious or wholly unfavorable diagnosis of the family physician, and to enable the family to "feel that everything had been done." Consultations *pro forma* were the rule then and they are not unknown now. Is this course in accord with the

highest conception of a physician's duty, in that he is bound to do everything in his power for his patients' welfare ? - If the diagnosis has been correct, and the inevitable fatal issue is approaching, where is the utility of the consultation, and how are we justified in entailing the additional expense upon our clients ? If our diagnosis has been wrong from the start, is it not usually too late for the consultation to result in any good for the patient ? I leave out, of course, those mortifying cases, of which we all have had our share, when we had believed, and so informed the patient or his relatives, that he had a serious or fatal disease when such was not the case. Here, of course, the consultation serves to dispel the dense cloud resting on a family, and the new diagnosis and plan of treatment are followed by relief or cure : but what are the feelings of the unfortunate physician who had allowed himself to be so positive ? In this connection I need hardly remind you of such instances as hysterical irritation of organic disease, emotional paralysis, cardiac murmurs, etc.

At the present time, consultations are being more and more held for what I take to be their legitimate logical purpose, namely, to enable the practitioner to recognize serious disease of unusual occurrence at the earliest possible moment, and to determine the proper line of treatment.

I shall speak only of a few nervous diseases, but I would like to impress you with my own belief that the above remarks apply with equal force to serious diseases of other apparatuses ; to medical and surgical conditions. How can we count the victims of the late diagnosis of Phthisis, of Bright's Disease, of Perityphilitis, Intestinal Obstruction, Pernicious Malarial Fevers, Glaucoma, Cirrhosis of the Liver, Ulcer of the Stomach, etc., whose lives might have been saved or prolonged, by an early positive diagnosis, or by a strong diagnosis of possibility ?

Excuse me if I again state that one of the chief ways in which we may hope to improve our therapy and prognosis will be by the recognition, from the presence of a few carefully ascertained and reliable symptoms, at the earliest possible moment.

However, I do not wish to be understood as claiming that such an early diagnosis can be arrived at only through consultations. The purpose of this, and of my former papers, is to enable the general practitioner to make early diagnoses by becoming possessed of the knowledge and resources of the specialist. Of course, he cannot communicate his maturity of judgment nor all his knowledge of exceptional cases and conditions which sometimes modify an apparently clear case, or throw light on an obscure one, but he can and should diffuse a knowledge of the elements and logic of diagnosis, with far more detail than can be put in textbooks or treatises.

L. POSTERIOR SPINAL SCLEROSIS (TABES).

In spite of the enormous mass of literature relative to this disease which has been distributed to our profession in the last twenty years, this disease is yet, I regret to be obliged to say, often — very often — unrecognized in its first stage, the neuralgic or pre-atactic stage. Patient after patient comes to the specialist with the same story, namely, that he has been told he had rheumatism or neuralgia, and has been treated accordingly.

Leaving out non-typical cases of tabes, which are

highly-interesting and often really difficult of diagnosis, there ought not to be any uncertainty attending the very early recognition of sclerotic changes in the posterior root-zones of the spinal cord. The two difficulties in the way of a correct positive diagnosis are (1) the lax and unscientific determination of the symptoms by the physician, and (2) his feeble faith in the fatal significance of the few symptoms presented by the patient. To many a practitioner it seems the height of presumption for another to say that a man who complains of occasional sharp pains in the legs, whose patellar reflex is low or lost, and who has had temporary diplopia, is doomed to be ataxic and then bedridden in the course of a few years. Yet, gentlemen, it is true, ninety-nine times out of a hundred — as true as that a given comet shall return to our limit of vision at a given time.

Allow me treat of the first source of error in some detail, as it is fundamental. It is a result partly of the faulty clinical teachings in our medical schools, where the science of semiology is not tested as it deserves: for on it hangs all diagnosis; and partly to hurry and loose habits of questioning of physicians. The patient's statement that he has "neuralgic" or "rheumatic" pains in his legs is allowed to stand as a finality. No cross-questioning is applied to elicit a recollection of past diplopia; no objective examination is made; and two previous symptoms (loss of knee-jerk and of pupillary reflex) are not discovered. The patient goes away with a prescription directed to the relief of rheumatism or neuralgia.

I am one of those who believe that if physicians exercised proper care in the questioning and cross-questioning of patients, and made it a rule always to make a physical or objective examination of every patient, posterior spinal sclerosis would be detected by all practitioners at a very early stage of its development, at that period when possibly we may, by improved therapeutics, some day cure this dread disease.

What are the cardinal symptoms which may serve to justify a positive diagnosis of this disease in the first stage (barring non-typical cases)?

First, and chiefly, the peculiar pains which almost always precede all other symptoms, and may be almost the only symptom for many years.⁴ But to fully appreciate the significance of these pains, and to be confident enough to base a diagnosis on them, it is necessary to study the symptoms carefully and minutely. The adult patient⁵ who complains of sharp pains in his legs should be at once suspected of having tabes; and most closely questioned; first, by being asked to fully describe the pains in his own way; then, if necessary, to ask a few direct questions tending to bring out sharply the peculiarities of these pains.

The pains of tabes are pathognomonic, if the observer obtains a clear concept of their characteristics, which are:⁶

(a) Irregularity of distribution. The pains appear about always, first in the lower limbs; then in both; they strike in the heel, calf, thigh, toes, instep, anywhere and everywhere. So true is this that, after a few months, many patients will be unable to say where they have not had pains below the groins. In some

⁴ I have made an autopsy in a case, which for twenty-nine years presented only two symptoms, namely, fulgurating pains and fixed dilatation of one pupil.

⁵ I have never remembered that posterior spinal sclerosis never occurs under twenty years of age, and very rarely under thirty.

⁶ I arrange these characteristics in no logical order; all are nearly of equal importance.

cases the pains for the first few months affect perhaps half a dozen localities, but always in both legs. A secondary characteristic of this group is that pains never occur simultaneously in the two legs, though the succession may be very rapid. In double sciatica the pain is constantly present along the two sciatic nerves.

(b) Location of the pains. Usually cutaneous, appearing in rounded or ovoid spots or areas; occasionally in streaks of short length; sometimes radiating in a star-shaped way from a given point. Never do the pains extend along a nerve trunk and its branches as in true neuralgia. Occasionally the pains are deeper, in muscles, bones or joints, with somewhat different characters from cutaneous pains.

(c) Nature of the pains. This is perhaps their most important characteristic. The pains are almost always sharp, lancinating or piercing, rarely (in joints and muscles) tearing or crushing. A most valuable criterion is that these sharp pains are repeated in one spot or area every few seconds for hours or days (occasionally for weeks). The patient, if properly interrogated, without leading questions, will say that the sharp pains strike the place for so long a time, minutes or hours. This is a peculiarity presented by no other pain that I know.

(d) Hyperesthesia of the spots or areas which are the seat of pain. The affected places present these peculiarities; a slight contact with the finger, clothing, or even a sheet in bed causes suffering, whereas (usually) a firm pressure does not prove painful, or may relieve.

Let me here point to a contrast between fulgurating and truly neuralgic pains. In the former the tenderness is met with exclusively at the seat of pain; in the latter there are tender points where the nerve-trunk becomes superficial or escapes from an aponeurosis or foramen (*points douloureux* of Valleix). The tenderness of neuralgia is confined to the nerve-trunk or large branches, whereas that of tabetic pains is limited to the skin where the darting pains recur.

(e) The degree of pain is of no special value for diagnosis, though I may remark that the suffering in tabes is very much greater than in sciatica.

With these characteristics well-established in a given patient, I believe that we have in hand irrefragable evidence of beginning posterior spinal sclerosis. Yet there are imitations of the pains, to which I think I was the first to call attention. First, some gouty persons have sudden sharp pains here and there, which they compare to the stab of a needle, in legs, arms, trunk, or even scalp. This extreme extension alone serves for differential diagnosis; but more important is the fact that the pains occur only once or twice in one spot, and the spot is never hyperesthetic. Second, in dementia paralytica we occasionally hear complaints of sharp, pricking pains in various parts of the body, much like those of gout, that is, simple and not severe or large. In appreciating the value of such pains in dementia paralytica, it must not be forgotten that in a small proportion of cases the posterior columns are more or less diseased. Third, I should add that I have twice received excellent descriptions of fulgurating pains, "terrible" in degree, from victims of the morphine habit. These men said that the pains occurred everywhere, which is almost unknown in early tabes; and their knee-jerks were too strong. I suspected that these patients, having read about or been

told of fulgurating pains, had described their vague pains accordingly, to justify the continued use of morphia.

Barring these three imitations, I repeat that the pains I have endeavored to describe, are, when exactly determined, of pathognomonic value. But other symptoms are seldom wanting, even in their early stage.

Second., diminution or loss of the patellar tendon reflex. You all know about this important negative symptom, and how to obtain it. Perhaps all of you may not be aware that where the jerk is absent to ordinary tests, it may still be demonstrated to a feeble degree by diverting the patient's⁷ attention by making him count or read aloud, or better, by making him grasp an object strongly while you tap the tendon. If the knee-jerk is absent, you obtain quite a corroborative sign. But let me warn you that this negative symptom is not in itself (and the same may be said of ataxia which appears in the second stage of tabes) of absolute value. This is because the knee-jerk is absent in a variety of affections and conditions, such as old age, diabetes, multiple neuritis, diphtheritic paralysis, lead paralysis, poliomyelitis, etc. It is only a corroborative symptom.

Third. Pupillary immobility or spasm. This is, perhaps, next to the fulgurating pains, the most valuable symptom of beginning tabes; yet, after all, it also ranks only as a corroborative sign. Perhaps it may not be out of the way for me to describe the symptom, which, by the way, must be sought for, as it escapes the patient's observation. The pupils, variable in size, usually contracted, often unequal, present this peculiarity, namely, that, while they contract under the effort at accommodation (looking at your finger at less than eight inches), they neither dilate nor contract under the influence of the strongest contrasting light and shade (tested in a dark room with a mirror, or at a brightly lighted window). This condition of the pupil is often designated as Argyll-Robertson pupil, from the Scotch physician who first described it. I regret to say that its value falls below that of fulgurating pains, as it is also present in some cases of cerebral syphilis and dementia paralytica (and after fifty years of age the "pupillary reflex" is sluggish or almost lost).

Fourth. Transitory or permanent diplopia, either from paresis of an internus or of an externus rectus muscle. This may be present under your observation; but usually it has to be elicited by questioning, having occurred years or months previously. A ready means of determining which rectus muscle was paralyzed, is by asking the patient whether his diplopia was for objects within two feet of him or for them farther away. An adult who has or has had acute strabismus or diplopia should at once be suspected of posterior spinal sclerosis or of intra-cranial syphilis, and a careful inquiry made along these two lines. Of course, there are so-called rheumatic paralyses of ocular muscles, and this diagnosis is arrived at by exclusion.

As I am not speaking of refined or "fancy" diagnosis I need go no farther into the semiology of the first stage of tabes. There are cases in which atrophy of the optic nerves, with fulgurating pains; of mono-arthritides, with fulgurating pains; of vesical paralysis with fulgurating pains; of gastric crises, with fulgurating pains (always in the vast majority of cases, I beg you to remember, with fulgurating pains) characterize

⁷ In my experience, after considering all variations in the mode of onset of tabes, and studying all my cases of "abnormal tabes," I hold to the opinion that these pains fall least often of any single symptom.

the onset of the disease. Then there are non-typical or abnormal cases of tabes in which paresis or ataxia or vesical paralysis or gastric and other crises may precede pains; but these are phenomenal cases, each one worthy of record.

(1) In my opinion the determination of the existence of fulgurating pains with one or more of the four symptoms I have referred to in detail, occurring in a subject over twenty years of age, not only justifies but renders imperative the diagnosis of posterior spinal sclerosis. Any other diagnosis should be held as betraying ignorance or want of scientific courage. Excuse the force of this remark, but my memory is so filled with recollections of neglected and maltreated patients that I must cry out loudly in behalf of an early diagnosis of tabes.

(2) The existence of fulgurating pains alone, in a subject over twenty years of age, warrants a diagnosis of probability, and justifies the ordering of a special treatment.

(3) The occurrence of transitory or permanent diplopia (strabismus), especially if the subject be over thirty years of age, should at once arouse a suspicion of the beginning of tabes, and other symptoms should always be sought for diligently.

(4) The existence of Argyll-Robertson pupils alone should lead the physician to anticipate posterior spinal sclerosis or dementia paralytica.

(5) The absence of knee-jerk is not in itself of specific value; but it is abnormal, and should cause a careful full search to be made for other symptoms.

(To be continued.)

IS THE UNITY OF PHthisis AN ESTABLISHED FACT?¹

AN IMPORTANT CONSIDERATION IN REGARD TO THE CURE OF THE DISEASE BY INOCULATION.

BY HENRICH GIBBS, M.D.,
Professor of Pathology, University of Michigan.

We are now anxiously waiting the development of Dr. Koch's cure for consumption and the announcement of the composition of the lymph he employs for that purpose. While in this state of doubt it seems to me that we may profitably examine into the pathology of the disease which Dr. Koch proposes to cure, and see if, with our existing knowledge of the clinical features and morbid processes, we may reasonably expect any lymph to cure all or any of our patients. Until the discovery of the tubercle bacillus, a large number of skilled physicians held the view that phthisis pulmonalis and tuberculosis were distinct diseases, but the bacillus from its intimate association with lung diseases is now generally considered to be the virus of the disease, and as a necessary consequence the terms phthisis and tuberculosis have become interchangeable. The latest works on Pathology adopt these views, and head the chapter with, "Phthisis or Tuberculosis." The latest work to which I have access is "Fowler's Dictionary of Medicine," published this year; and under the head of "Phthisis" is given the following definition: "Phthisis, a tubercular disease of the lungs characterized by the occurrence of lesions, partly

¹ Read before the Medical and Library Association of Detroit, Michigan, December 8, 1890.

specific and in part inflammatory, which tend either to caseate or soften or to become fibrous. . . . This definition emphasizes the view, now held by most pathologists, that pulmonary phthisis is a single disease, and that it is invariably attended by the appearance in the lungs of the pathological product known as tubercle."

This statement puts in plain language the views held by the majority of pathologists at the present time, and is based on the fact, as they state it, that tubercles and inflammatory foci occur in the same lung at the same time. The only recent statement differing from this by any one believing in the bacillary origin of phthisis, is one found in the December number of the *American Journal of the Medical Sciences* over the initials "H. C. E." It occurs in a review of Dr. Arthur Ransome's Milroy Lectures on "The Cause and prevention of Phthisis," and is as follows: "It is unfortunate, however, for the sake of exactness in diction, that the author has made the common mistake of using the words phthisis and tuberculosis as interchangeable; a fault the more to be regretted for the reason that it is upon such errors as this that all the opposition there is to the specific nature of the bacillus of tuberculosis is mainly based. Of course it is known that there may be phthisis which is not due to the activity of the bacillus of tuberculosis, but so little stress is laid upon this fact by clinical writers, that the subject is still in some confusion from that cause."

Da Costa ("Medical Diagnosis," Seventh Edition, 1890) says: "and although we recognize a non-tubercular form, I shall, unless otherwise specified, use the term phthisis as implying tubercular disease."

Jaccoud in his work on "The Curability of Phthisis," says: "Phthisis, in fact, is invariably tubercular, and the anatomical unity of this disease is established by histological analysis."

He also says: "The conclusion acknowledged today in favor of the unity of tubercle regards merely its anatomical structure . . . while its clinical duality is not called into question."

These conclusions as to the histological unity of phthisis and tuberculosis were drawn from theses published by Charcot in 1860 and Grancher in 1872.

Dr. McCall Anderson published a paper on the curability of acute phthisis in the *British Medical Journal* of November 8th this year, in which he mentions seven cases of galloping consumption, five of which were cured. He says there are two forms of acute phthisis: (1) Acute tuberculosis; (2) acute pneumonic phthisis. In the first there is an infiltration of the lungs with tubercles. In the second a more or less extensive consolidation, and he states further that the two fatal cases were tubercular.

It will be seen from what I have said that there is a considerable variation in the opinions of the latest writers on this subject.

It seems to me we ought to have some definite ideas as to the morbid processes in these diseases; and in view of the possibility of curing them, this is imperative, for if there are two distinct lesions which do not occur together in the same lung, we can hardly expect one remedy will be effectual in both cases.

The first thing to be considered is, What is a tubercle?

Referring to Payne's "Manual of General Pathology" we find it stated that acute miliary tubercle is now considered the essential type of the disease. On

section a tubercle is found to be composed of lymphoid cells, of epithelial cells and of large cells containing many nuclei, called giant cells; and there is sometimes a fine reticular stroma; in the centre is a caseous mass. This is the latest definition of a tubercle of the reticular kind that I am aware of. Turning, however, to Da Costa's "Medical Diagnosis," this year's edition, we find this statement: "Tubercle is an unorganized substance, the deposits of which are at first isolated, then accumulated."

How are we to reconcile these two absolutely different appearances with the unity of phthisis, and with its cause, the tubercle bacillus? Turning again to Payne's "Pathology," we find that there are two forms of phthisis, the catarrhal and the infective; and we are told that this latter agrees with acute miliary tuberculosis, which we have already been informed is the essential type of the disease. Then comes this statement: "We have thus two chief forms of tuberculosis of the lungs: (1) ordinary phthisis, (2) infective tuberculosis. These forms may be combined, the latter being developed out of the former, and even vice versa." Now I would ask you to say whether it is within the limits of possibility that the reticular tubercle (Payne's infective form) could be developed out of the mass of broken-down material constituting the caseous tubercle; and yet this is what Dr. Payne says takes place, and he sees nothing extraordinary in such a metamorphosis. He also says the two forms are combined in the same lungs. This statement is necessary to prove the unity of phthisis; and the unity of phthisis is necessary if the bacillus tuberculosis is the virus of the disease.

I will now give some of the results of my own investigations during the last nine years. The two forms of tubercle are perfectly correct, and they are best seen in acute miliary tuberculosis, as the progress of the disease is rapid, and, especially in children, death takes place before there is any breaking down of the tubercles. But these two forms never occur in the same lung. They are absolutely and entirely separate, and their commencement and progress is totally unlike. In the caseous form the process is an inflammatory one from the beginning, and does not differ in the least from any other acute inflammatory condition starting from a small focus; while the reticular is reticular from the beginning, and does not show any signs of a necrosed centre until the process is well-advanced. Although I have used specimens from cases of acute miliary tuberculosis to illustrate my argument, the processes are exactly the same in those cases of pulmonary phthisis and tuberculosis where the disease exists for a much longer time. The lesions are then much larger. I have had, during the last eight years, a large number of students in my practical classes, and I have always given them sections showing these two forms. During this time I have examined many hundreds of sections myself, and never in any case has there been the slightest doubt as to the lesion belonging to one or the other form; there has never been one doubtful specimen.

Now, if Dr. Payne's statement is correct, mine must be wrong. Will not some one take the matter up and see who is right? From my experience in the morbid histology of these diseases I am convinced that the duality of phthisis is an established fact, and our best clinicians are well-satisfied that it is also established clinically. Admitting this to be the case,

we have to consider, first, whether the bacillus tuberculosis can be the virus of two distinct diseases; and, secondly, whether the same cure is likely to be applicable to both cases.

In the first place, one form of lesion is distinctly inflammatory in character, and it is with this lesion that the bacillus is always associated. Take the caseous form of acute miliary tuberculosis: every one of the tubercles contains a large number of bacilli in its centre. In the more chronic forms with this lesion, that is in pulmonary phthisis, we always find numbers of bacilli in the sputum and in the lungs. But in the tubercular form many cases occur where no bacilli can be detected, either in the sputum or lungs; and when the bacilli are found, they do not occur in the necrosed centre of the reticular tubercle, but scattered about in the reticular tissue, and then singly in small numbers. We find that on inoculating animals with tubercular matter, or cultivation of the tubercle bacillus, we produce in a susceptible animal a somewhat similar disease. This fact has established the bacillus in its present position; and it has been stated that the induced disease is identical with that occurring in the human lungs. This is not the case. The induced lesion in an animal is different from that in a human lung, in that there is never reproduced the typical reticular tubercle with giant cells.

But I have found that there is a marked difference in the lesion produced in an animal, if the inoculated material be taken from a case of tuberculosis, from that produced by the inoculation of material from a case of caseous phthisis. In an animal (monkey), inoculated from a case of caseous phthisis, the induced disease is similar to that which is found in pulmonary phthisis. There is no organization, merely inflammatory breaking down. In another (also a monkey) killed eleven days after inoculation with material from a case of tuberculosis, the change is just commencing in a malpighian corpuscle in the spleen, the only organ affected; and this change is of a totally different character, consisting in the formation of large cells, which resemble those found in scrofula. Then, again, the relation of the tubercle bacillus to these forms is important: it is not found until the lesions begin to caseate. We have, therefore, two distinct diseases which reproduce themselves in susceptible animals in a distinctive manner. One of these diseases is of an inflammatory character, and with it are always associated tubercle bacilli, generally in large numbers. The other is a disease producing a new growth of a fibroid character, prone to break down; and the bacilli, when found, are few in number, and their position is different; some cases also occur without any bacilli.

Before proceeding to discuss the cure of consumption, it will be as well to tabulate the different lesions found in this disease as it is surely necessary that we should know the morbid condition of the organ we are trying to cure.

Under the head of the generic term "Consumption," I would include the following: Acute miliary tuberculosis, pulmonary phthisis, pulmonary tuberculosis.

Acute miliary tuberculosis, as I have shown, must be divided into two forms, according to the lesions found in the lungs, inflammatory and tubercular. In the first form the lungs are full of minute nodules caused by inflammatory action, and in each nodule are found a number of tubercle bacilli in the centre. Hamilton, in his work on "The Pathology of Bron-

chitis," gives a very good description of this form, which he calls, "disseminated catarrhal pneumonia"; and he says that recovery is by no means uncommon. The tubercular form consists in the infiltration of the lungs with minute nodules which are indistinguishable from the first form by the naked eye, but which, on examination with the microscope, are found to be reticular tubercles.

Pulmonary phthisis, in its typical form, is found when the consolidation produced by the inflammatory action of catarrhal pneumonia has not cleared up, but has lost its vitality and undergone caseation. There is no attempt at organization, no structure anywhere, merely a mass of broken-down tissue.

Pulmonary tuberculosis is characterized by the formation of new growths throughout the lungs, which consist of fibroid tissue and giant cells, and, in their later stages, possess a necrosed centre. In acute miliary tuberculosis, the nodules are small, as the patient dies before they have time to grow. In the more chronic form large aggregations of tubercle are found, which have this peculiarity; they are very prone to necrose in the centre, and break down.

At first sight this description would seem to necessitate the divisions of the morbid lesions into three classes: the inflammatory form of acute miliary tuberculosis; pulmonary phthisis; tuberculosis, acute and chronic. But if we consider that the inflammatory form of acute miliary tuberculosis is sometimes found associated in children with measles, and that a common sequela of measles is capillary bronchitis, I think we have an explanation which will meet the difficulty.

Children do not, as a rule, expectorate, and consequently their bronchial tubes must contain more or less of the inflammatory product of capillary bronchitis. We know, that, if this inflammatory condition extends from the bronchioles into the alveoli of the lungs, a condition of catarrhal pneumonia is produced. It is not, therefore, straining a point to imagine, that, if the products of the inflammatory action in capillary bronchitis are sucked into the lungs during a fit of coughing, they would be distributed into a number of alveoli and produce inflammatory action wherever deposited, the result being the inflammatory form of acute miliary tuberculosis or Hamilton's disseminated catarrhal pneumonia.

In this way we reduce the lesions of consumption into two forms, the inflammatory and tubercular. And this classification is fully borne out by the morbid histology in every case; and the two forms are absolutely and entirely distinct, and do not occur in the same lungs.

I presume no one will doubt that Dr. Koch has entire belief in the unity of phthisis and its bacillary origin. It is, therefore, with some surprise that we read the statement that his lymph does not kill the tubercle bacilli but the tuberculous tissue, that it can influence living tuberculous tissue only, and has no effect on dead tissue, as, for instance, necrotic cheesy masses. This at once removes from its action all cases of pulmonary phthisis, and leaves only tuberculosis to be acted upon.

As I have already pointed out, we have in tubercular tissue a new formation of low vitality, which is shown by its proneness to break down. We have a somewhat similar tissue in the lesions of syphilis; and we know that under the influence of certain drugs, these lesions will soften and caseate. But the tissue

found in syphilis is of a much softer, less organized, and more unstable character than that found in tuberculosis. Koch's remedy is said always to cause a feverish reaction accompanied with rigors, when inoculated in a patient, the subject of tuberculosis; and this symptom is absent when the case is one of syphilis, cancer or any other disease. The most marked success, so far, seems to have been obtained in cases of lupus; and here the parts affected showed a reaction to the remedy by becoming red and swollen. Whatever may be the future of Koch's cure, one thing seems to be certain, and that is it will not help cases of pulmonary phthisis. This will necessitate our making a careful diagnosis in every case, as fortunately we are able to cure pulmonary phthisis in the early stage by ordinary remedies, and, as Dr. McCall Anderson has shown, even cases of galloping consumption, provided they are not tubercular.

One of Koch's statements is difficult to understand; it is, that his lymph destroys the tubercular tissue in which the tubercle bacilli are situated. Now, given a lung studded with tubercles, all of which are suddenly killed by the action of the curative lymph, it does not seem clear what is to become of the necrotic material. We know that a syphilitic gumma, after it has been destroyed by the action of a drug, will still remain as a foreign body in the part, and set up chronic inflammatory action; in this manner forming a fibrous capsule and isolating itself from the surrounding healthy tissue. The same thing may be done by a tubercle or a nematode worm. The centre is a mass of caseous material having no structure to show what it originally consisted of; it becomes, however, completely isolated by a fibrous capsule formed by the chronic irritation of its presence. The central portion may undergo calcification.

If Koch's lymph kills the tubercles in a diseased lung, what change will take place in them? If they are to be softened and absorbed, the place they occupied will be left vacant and the lungs full of holes, as they were formed at the expense of lung tissue. If, on the other hand, they are simply killed, and dry up like a dead gumma, the lung will in time be filled with numbers of small fibro-cystic masses. We need more light upon this subject; but before all things, it seems to me, we ought to have a clear idea of the actual lesion in the lungs to enable us to appreciate the action of the cure.

It may be of interest to the Society to hear a short account of the work that Dr. Shurly and I have been doing during the last two years on this subject. We came to the conclusion that the lesions in the lungs must be formed by some morbid product circulating in them; and it seemed to us that the only way, if our views were correct, in which this disease could be checked was by the introduction of some substance which would enter into chemical combination with the morbid product and render it inert. We have never made any attempt to destroy the tubercle bacilli.

It is now more than two years since our first experiments were made, and they have been continued ever since. After trying a number of different substances we found that with iodoform we could entirely check the tubercular process in an inoculated animal. We inoculated monkeys and guinea pigs with tubercular material; and we found that those treated with iodoform developed nothing further than an abscess at the seat of inoculation, with numerous tubercle bacilli

in the contained pus, while the control animal, in each series, left untreated, invariably died of the disease. But we found that the use of iodoform brought on fatty changes in the liver, of a peculiar character, consisting of an infiltration in patches and not like that found in ordinary fatty liver. These patches were not confined to one or more lobules; but at the edge of the patch, in many cases, only a part of a lobule was changed.

While Dr. Shurly was treating the inoculated animals with various drugs, I made a series of experiments on pure cultures of the tubercle bacilli; and I found a number of drugs which would render them inert, as far as their power of producing artificial tuberculosis was concerned. Among these, chloride of gold and sodium exerted a marked influence when used in very small quantities; and Dr. Shurly will tell you what a striking effect it has when used on cases of consumption. As soon as we found that we could prevent the development of the disease in inoculated animals, Dr. Shurly directed all his attention to finding a substance which could be used on human patients without deleterious effects; and I investigated the results of the various inoculations with a view to proving that tuberculosis and pulmonary phthisis reproduced themselves in a different manner in susceptible animals. In both these lines I think we have been successful, although it will require further investigation before we can consider the matter definitely proved.

I should like to call attention to the effect of Dr. Shurly's treatment of patients on their sputum. He has kept me regularly supplied with sputum from all cases under treatment; and I have found that those cases treated with substances that produced a marked amelioration of the disease had little or no effect when inoculated in animals. I have a number of guinea-pigs inoculated with sputum from undoubted cases of consumption; and these guinea-pigs are now none the worse for the operation, which was done some months ago.

That a marked change has taken place in these consumptive cases is shown by the total disappearance of bacilli in most of them.

I feel convinced if the members of this Society will take up this subject, and work it out on the lines we have indicated, some most important results will be obtained. But I also feel convinced that the duality of phthisis must be recognized to render the work of lasting good.

TWO CASES OF RELAPSING APPENDICITIS; OPERATION BETWEEN ATTACKS; REMOVAL OF APPENDIX; RECOVERY.¹

BY CHARLES B. PORTER, M.D.,
Surgeon, Massachusetts General Hospital; Professor of Clinical Surgery, Harvard University.

The literature of the last few years upon the medical and surgical treatment of appendicitis is probably more voluminous than upon any other subject. The greater interest in, and better understanding of, the pathological conditions present, are due largely to the able monograph by Dr. R. H. Fitz in the *Journal of Medical Sciences*, October, 1886. Dr. Fitz has shown that successive attacks occur in eleven per cent. of the cases. In the cases which I have been able to collect there seems to have been a tendency to increasing severity in

¹ Read before the Boston Society for Medical Improvement, November 24, 1890.

each successive attack, and in some to a state of chronic invalidism between attacks. In all who were intelligent enough to appreciate their situation there was a great dread of renewal of symptoms. The intervals between attacks may vary from a few weeks to a few months, and in some the interval is much longer. The surgical mind has been gradually coming to the consideration of operation between attacks in recurring appendicitis, and it is in support of this operation, in suitable cases, that the following two cases are reported. Case I was operated upon November 14, 1889, and Case II on December 20, 1889.

CASE I. W. G. R., aged nineteen, was brought to me for consultation by Dr. R. L. Hodgdon, of Arlington, Mass. The patient's family history was excellent, and his personal history good, having never been sick except with the present trouble, the history of which is as follows:

Nine months previous to my seeing him he had the first attack, which came on in the early morning with sharp, colicky pain in the abdomen, most severe in the umbilical region, not relieved by a natural movement of the bowels. This pain lasted all day, attended by nausea and vomiting. Towards night morphine by the mouth and subcutaneously was given with some relief.

On the next day the pain was localized in the right iliac region with tenderness, but no tumor or caking. These symptoms gradually ameliorated, and in two weeks he went to business again. From this attack until I saw him, period of nine months, he had eight similar attacks, varying in severity and duration, so that he had only about two weeks of each month in which he was well enough to be about. He did not dare to leave his home to spend the night for fear he might have an attack. He had lost flesh and spirits, and lived in a state of constant dread. Upon physical examination, nothing abnormal could be found, except in the right iliac region, a small finger-like mass could be felt, which, as it rolled from beneath the finger-tips in palpation, caused him pain. The probable cause of his trouble was explained to him and his parents, and operation for excision of the appendix was advised. Two days later Dr. F. C. Shattuck saw the case and confirmed the diagnosis.

The patient entered the ward for abdominal surgery at the Massachusetts General Hospital, and the operation was done November 14th, as follows:

An incision parallel to the linea alba and half way between it and the right anterior superior spinous process of the ilium was made, three inches in length, and extending to within one and one-half inches of Poupart's ligament; all hemorrhage was controlled by hemostatic forceps. On opening the peritoneum and turning up the omentum, a much thickened appendix was found with the omentum adherent to its tip. The adhesions were ligated and divided. The mesentery of the appendix was treated in the same manner. The appendix was ligated one-quarter of an inch from the cecum, and cut off. The lumen of the stump was cauterized with the Paquelin cautery; the omentum was stitched to the cecum in such a manner as to cover the stump. The edges of the peritoneum were united by a continuous silk suture, and the muscles and skin closed in the ordinary manner. Dry antiseptic dressing applied with swathe. An enema of black coffee was given immediately after the operation, and again in four hours. There was some nausea but very little

pain. Wound healed by first intention, and the stitches were removed on the eighth day. The temperature rose to 100° on the second day, and fell two days later to normal, where it remained. Thirteen months have now passed, and there has been no return of former symptoms; he has gained in flesh, is in excellent spirits, and attends to his business.

Examination of appendix by Dr. W. F. Whitney, Curator of the Warren Museum, Harvard University:

"The outer part of the appendix, about four centimetres long, attached by its tip by a firm adhesion to a portion of the omentum. The external surface rough; the mucous surface perfectly smooth, and showed no cicatrices or other evidences of ulceration. It contained a few drops of thin mucus. Microscopic examination showed the thickening to be in the sub-mucous, muscular and peritoneal coats. The mucosa was normal. Diagnosis, chronic peri-appendicitis."

CASE II. Frank B., age twenty-six. Entered the Massachusetts General Hospital, December 7, 1888. Four days previous to entrance was taken with severe pain in umbilical region; violent nausea, retaining nothing on the stomach except brandy or cracked ice. There was tenderness in umbilical and epigastric regions and also in right iliac fossa. General but not marked tympanites. The vomitus was green and bilious in character at times, at others brownish like coffee grounds. Temperature had not risen above 99.8°. Morphine was given subcutaneously and nutritive enemata. Hot fomentations to the abdomen.

On the second day, after admission a small lump could be felt in the right iliac region, and, by the rectum on the right, a hard mass crowding the anterior wall just above the prostate. A small area felt soft, and in its centre a spot so soft as to suggest pus.

On the next day the mass in the iliac region was larger, and it was decided to operate. An incision two inches long was made over the outer portion of Poupart's ligament and an inch above it. This was carried down to the tumor, which was aspirated, but no pus found. An assistant then, with finger in the rectum, pressed the mass upwards and outwards, and with my finger protecting the iliac artery behind, I again introduced the aspirator, and about two ounces of pus was withdrawn. This cavity was opened, and drainage-tube inserted. The case progressed favorably, and was discharged from the hospital about five weeks after operation. Wound closed.

In little less than a year from his discharge he entered the hospital again, in the middle of another attack. When asked how many attacks he had had during the year, his answer was, "So many that I have n't kept count." His condition was as follows: Pain severe, and localized in right iliac fossa. Tenderness there, but only slight resistance on palpation. Above the old cicatrix, however, there was a slightly elongated mass, size of a small plum, tender on pressure. His condition was not such as to demand any active treatment, and in ten days he was practically convalescent.

In view of his numerous attacks and his invalidism therefrom, the operation for the removal of the appendix was explained to him, and he was asked to consider it. The next day he requested it to be done if there was any hope of his recovery.

On December 20, 1889, the operation, as described in Case I, was done. The appendix was firmly bound down by adhesion, and was with difficulty brought up

to the incision. A stitch was passed through its tip to control it, while the omental adhesions were ligated and divided. The proximal end of the appendix for about an inch was firmly adherent to the cæcum, and its walls so thin that in separating the adhesions it ruptured. A ligature was tied between the opening and the cæcum, and the appendix cut off. The other steps in the operation were as in Case I. He made a rapid recovery with no complications. The temperature on the day following the operation rose to 100.8°, and on the next night fell to normal and remained there.

Examination of the appendix by Dr. Whitney: "The outer part of the appendix, 3.25 centimetres long, attached to a bit of omentum by strong adhesions. Generally thickened. The outer surface rough; inner surface smooth. Thickening was shown by the microscope to be in the sub-mucous, muscular and peritoneal coats. The mucous coat normal. Chronic periappendicitis."

Both these cases, from their relapsing character and the severity of the symptoms in some of the attacks, seem to me to have been such as to demand surgical interference, and the operation which was done. Both were fortunate in the result. Case II was most interesting, from the fact that a year prior to the radical operation for removal of the appendix he had been operated upon for abscess due to peri-appendicitis, from which he recovered in the ordinary manner.

ANOTHER SUCCESSFUL CASE OF URETERO-LITHOTOMY.¹

BY A. T. CABOT, A.M., M.D.

In the *Boston Medical and Surgical Journal* for September 11, 1890, I reported a case of operation for the removal of a stone lodged in the middle portion of the ureter.

At that time brief reference was made to another case in which a stone was removed from the lower portion of the ureter in a woman. As this stone was reached and removed in a manner not hitherto employed, so far as I can learn, I will give a more complete report of the case.

Mrs. S., a rather stout woman of thirty-nine, was seen by me, May 15, 1890, in consultation with Dr. J. L. Williams and Dr. W. A. Morris. She had for fifteen or sixteen years been subject to attacks of renal colic, always on the left side, and almost always followed by the passage of stones.

The last severe attack was in December, 1888, but since that time she had had a number of slight attacks during which she had passed twenty or more small stones. The attack in which I saw her began five or six weeks before my visit, and had continued ever since, with pain of varying intensity.

The urine was at times much diminished in quantity, and for several days before the consultation had been very scanty (from four to six ounces a day). It had, during this time, been loaded with urates. On that day it had become more abundant and less thick.

The patient had a good appearance, with moist tongue, quiet and steady pulse and normal temperature. She was perspiring rather freely.

The pain in the region of the left kidney, and run-

ning down towards the bladder, was intermittent and spasmodic in character.

In the left lumbar region was a distinct tumor about as large as two fists, which was sensitive to pressure. There was also a point of tenderness deep in the left side of the pelvis. By vaginal examination, a little hard mass was found in the left broad ligament close to the cervix uteri. This felt about as large as the last joint of the forefinger, and it was very sensitive to pressure. The palpation of it during the examination started a spasmodic pain in the left side, that had bearing-down or expulsive character.

A sound introduced into the bladder could be carried to within about three-quarters of an inch of this little hard mass, but could not be brought in contact with it by the most careful bimanual manipulation.

Dr. Williams had examined Mrs. S. a few days before, and was sure that at that time this hard mass could not be felt. It therefore seemed that the calculus must have moved some distance down the ureter during the time that had elapsed since that examination.

In view of this fact, and also encouraged by the increase in the amount of urine in the preceding twenty-four hours, we decided to wait and see if nature, aided perhaps by manipulation with the finger per vaginam, would not be sufficient to propel the calculus into the bladder, from which it could be easily removed. Soon after this the husband of the patient was taken suddenly sick and died, and owing to the disturbance on this account, nothing was done or thought of for some time. Finally, towards the end of June, the patient entered the Massachusetts General Hospital for operation, if such seemed desirable.

On July 1st, the calculus could be felt in exactly the same place where it had been detected by examination in May.

On July 4th the patient was etherized for operation. An incision was made over the calculus through the vault of the vagina just to the left of the cervix uteri. The calculus was easily reached, the grating of the knife upon it being distinctly felt during the first incision.

After the end which presented had been thoroughly uncovered, it was found that the rest of the calculus was so tightly grasped by the tissues above that it could not be easily extracted. In fact, the presenting end broke to pieces under the grasp of the forceps with which extraction was being attempted. After trying many manipulations in vain, a blunt hook was passed up alongside of the calculus into the ureter behind, then turned and hooked over the upper end, and traction with this, aided with the finger pressing the tissues aside, finally accomplished the removal of the stone.

The moment it came out there was a rush of pus from above. This pus was of ordinary thickness, apparently not much thinned by urine. Probably from ten to twelve ounces escaped. A T-shaped rubber tube was introduced into the ureter through the opening made. After the pus had fully escaped, the tumor in the abdomen was found to have disappeared. The patient made a good recovery, and the urine, which was very scanty just after the operation, gradually increased in quantity until it became sufficiently abundant. Drainage through the fistula was kept up for some time, and finally, when the drainage-tube was removed, there seemed to be no tendency for the open-

¹ Read before the Boston Society for Medical Improvement, October 27, 1890.

ing to close, there being a constant, moderate discharge of pus through it. She recovered strength slowly, as is usual in those cases where the kidneys are seriously involved. She left the hospital on the 25th of July. She continued to gain strength after getting home, and finally was able to be about as usual, doing her ordinary work.

She was last heard from in November, 1890, and at that time there was still a fistula in the vagina, discharging a small amount of pus. No urine ever came through the fistula, showing that the long distension of the kidney during the complete stoppage of the ureter had sufficiently destroyed the cortex, to stop excretion. If at any time the escape of pus into the vagina becomes a serious annoyance, it can be stopped by the removal of what remains of the kidney.

The stone that was removed weighed one hundred and ninety grains. It was elongated, and evidently made up of two stones which had become attached together, as there were two nuclei, one at each end of it. This case shows that a calculus lodged in the lower part of the ureter in a woman can be safely reached through the vault of the vagina without injury to the peritoneal cavity. This is an important fact; for this lower end of the ureter, where it narrows just before entering the bladder, is a not uncommon point for the lodgement of a calculus.

REPORT ON DISEASES OF CHILDREN.¹

BY T. M. BOTCH, M.D.

MITRAL STENOSIS IN CHILDREN.²

THIS paper on the pathological anatomy and mode of development of mitral stenosis was founded on forty cases clinically observed and nineteen post-mortem examinations, all in children under twelve years of age.

Mitral stenosis in its least pronounced degree was evidenced by a ring of granulations around the mitral orifice on its auricular aspect. The subjacent structures were firmer than normal and formed a thickened ring. In more pronounced stenosis the mitral curtains were fused to form a funnel, the ventricular aperture of which might be of varying degrees of patency to the dimensions. The right chambers were almost invariably dilated. Mitral stenosis was not a congenital malformation. It might be considered invariably the result of endocarditis. In every case examined post-mortem there was an association with endocarditis, pericarditis, or both these affections combined. In regard to etiology, the cases showed a very strong association with rheumatism. In the more severe forms of rheumatism mitral insufficiency was a far more frequent result than mitral stenosis, while in the slighter forms the proportion of the latter to the former greatly increased. The author considered that mitral stenosis was the result of a limited and slow endocarditis, while mitral insufficiency was due to the retraction of the mitral curtains, the result of a more widely spread and more intense inflammation. A probable initiatory cause was fright. In such cases a temporary arrest of the heart's action was followed by violent palpitation; and in the disturbed condition of blood-pressure, violence might be done to the delicate valve-structures of the child. So a limited endocarditis might be initiated at the valve edge, the first lesion, perhaps, being mi-

nute hemorrhages such as have been experimentally produced in animals by increasing the blood-pressure in the aorta. The question of prognosis is a difficult one. Taking the ages at death of the published cases, the average was a shorter one than that of regurgitation. Mitral stenosis developed in children may disappear later in life.

PERICARDITIS IN CHILDHOOD.³

Ten cases of this disease in children are reported. Three were under one year of age, three between one and two, and the others between six and ten. Among the causes of the disease during the nursing period of life are mentioned septic-pyemic processes, proceeding either from the mother or the umbilicus; also chronic diseases, especially tuberclosis. It may be due to inflammatory processes in the pleura, lungs, ribs, sternum, vertebral column, bronchial or mediastinal glands, thymus and oesophagus; likewise to inflammation in the abdominal viscera and peritoneum. It is impossible to explain the origin of diffuse pericarditis. In six of the author's cases, it occurred with inflammation of the pleura and lungs; in one, with chorea; in two with scarlatina; and in one it was the only lesion. While in adults and older children pericarditis is manifested by weakness of the apex beat, the latter sometimes being entirely imperceptible, and the heart being forced over toward the left side with its base turned downward, a friction murmur being also perceptible, in very young children all these symptoms are absent. In seven of the author's cases the result was fatal; and the autopsies revealed only a moderate quantity of exudation, not enough to effect the sounds of the heart, its position, or its relation to neighboring organs. The exudation was moderately thick in consistency, contained no fibrin, and was not sufficiently abundant to cause friction sounds. Though the physical signs referred to are often present in older children, they vary as to their appearance, so that great care and watchfulness are necessary lest pericarditis be overlooked. A case is narrated in which such was the case until the symptoms became so urgent that a careful examination revealed the actual condition. The treatment may consist of local applications of ice, and the use of large doses of digitalis. Should the pericardial folds become agglutinated, the condition would be a very dangerous one, the heart muscle becoming more or less paralyzed, and dropsy from stasis becoming more or less extensive. The symptoms which are the most dangerous in this disease, are a small, rapid pulse; subnormal temperature; edema of the cheeks, eyelids, and lower extremities; and slight albuminuria.

TWO CASES OF EMPYEMA TREATED BY ASPIRATION: RECOVERY.⁴

CASE I. A girl, aged eight, admitted to hospital, October 24, 1888, with signs of fluid at base of right chest. Two days later five ounces of pus were removed by aspiration. Four days after this she expectorated a quantity of pus with manifest relief of symptoms, and no fluid was found by hypodermic needle. After two weeks fluid again accumulated, and two ounces were drawn off. From this time she steadily improved, and was discharged, cured, on January 14th.

CASE II. A boy, aged eight, admitted November 1st, 1889, with signs of fluid at base of right chest. November 1890.

⁴ Carmichael: Edinburgh Medical Journal, August, 1890. Archives of Pediatrics, August, 1890.

28th, with signs of limited effusion at base of right lung. Pus was withdrawn by hypodermic needle, and again one week later. He was put upon maltine and cod-liver oil, and in two weeks no pus could be found. He steadily improved, and was discharged, cured, on January 14th.

CHOREA AND RHEUMATISM.*

The wide divergence of opinion concerning the relationship between acute rheumatism and chorea, as cause and effect, is well-known. The author has, therefore, recorded the result of an analysis of 146 cases of chorea. The following results were obtained: Of the 146 cases, only 6.16 per cent. could by any possibility be attributed to acute rheumatism as their cause. Rheumatic antecedents, not causal, existed in 35 cases, or 23.97 per cent. A rheumatic inheritance existed in 47 cases. The cause assigned by friends, in 94 cases was nervous strain (fright, distress, and school over-pressure). As regards the condition of the heart, in 20 cases a persistent systolic murmur was audible over the region of the apex; and of these twenty cases, eleven only had suffered from acute rheumatism. A murmur, constant neither in force nor rhythm, was audible over the region of the apex in 64 cases, this murmur entirely disappearing as the patient recovered. It is still commonly stated that rheumatism is one of the most efficient causes of chorea, yet several recent observations tend to results opposed to this view. So long as vague pains in the limbs are admitted as evidence of rheumatism, and the mere presence of a murmur is considered satisfactory evidence of cardiac disease of rheumatic origin, just so long will the ordinary views as to the intimate connection between chorea and acute rheumatism be maintained.

SEVERE CHOREA TERMINATING FATALLY FROM ACUTE PARALYTIC DISTENTION OF THE STOMACH.¹⁰

A girl, aged sixteen years, had suffered from acute rheumatism. Six weeks later she developed severe chorea: at the same time she became melancholic and emotional. She had had no previous attack, and the present one was attributed to anxiety about domestic matters.

There was a loud, musical, systolic bruit, and considerable constant temperature. The chorea became worse in spite of treatment; delirium supervened. The pulse became very weak. It was almost impossible to induce sleep. Then she became better as to the chorea and delirium. Diarrhea and vomiting then came on. There was slight abdominal distension. Three days latter she became profoundly collapsed. The abdomen was greatly distended. She died twelve hours later. There had been no vomiting for the last twenty-four hours, and no urine had been passed.

Necropsy. — On opening the peritoneum a cystic tumor presented itself, and on introducing the hand this was found to be a part of an enormously-distended stomach, which occupied the entire abdominal cavity, extending from the diaphragm on the left, to the right iliac fossa. The intestines were quite empty and collapsed. The wall of the stomach was very much thinned. There were several brownish-red patches in the mucous membrane, as though there had been slight

hemorrhage into its substance. The mitral valve of the heart showed beading of recent endocarditis.

Remarks. — Acute paralytic distension of the stomach causing death in a few hours, with symptoms of profound collapse, is a very rare and very interesting pathological condition. Very few cases have been recorded.

POINTS IN THE PATHOLOGY OF PARALYSES OCCURRING IN THE FIRST TWO YEARS OF LIFE.¹¹

Dr. Henry Ashby, in an article published in the *British Medical Journal*, divides the paralyses of infants into six classes:

(1) Intra-uterine lesions (meningo-encephalitis). Grave lesions may occur in the fetus, and it may continue to live and be born at term. The results of meningeal inflammation appear in the brains of idiotic children, which show atrophy, sclerosis or chronic hydrocephalus.

(2) Meningeal hemorrhage. This occurs under a variety of circumstances during early life; but the invariable immediate cause is asphyxia, the delicate vessels being readily ruptured when distended with venous blood. The most common cause of asphyxia and resulting hemorrhage is prolonged and difficult labor. It may also occur during paroxysms of whooping-cough, violent attacks of vomiting, or convulsions. The bleeding is usually bilateral and most commonly involves the parietal region. The clot separates the pia mater from the surface of the convolutions, tearing the vessels which pass from the pia to the gray matter. The result is interference with the nutrition of the nerve-centres, and more or less degeneration. In a majority of cases there are no symptoms of a surface lesion at first. An extensive haemorrhage may be present without paresis or even convulsions. This is, no doubt, due to the undeveloped state of the cortical centres at birth. Symptoms appear as the child develops.

(3) Syphilitic arteritis and softening. Disease in the brain in connection with hereditary syphilis is not common in young infants. When it does occur it usually takes the form of an arteritis.

(4) Acute cerebral paralysis. Much controversy has taken place with regard to the cause of this condition. It usually takes the form of hemiplegia, and may be due to tubercular meningitis, meningeal hemorrhage, or embolism of the middle cerebral artery. The paralysis appears suddenly, convulsions or an acute febrile disease being present at the onset. The cause of the primary illness is often uncertain and the relation of the convulsions to the paralysis, in most instances, cannot be determined. This is also true of the hyperpyrexia which is frequently present. It has been suggested by Strümpell that a polioencephalitis takes place analogous to anterior poliomyelitis. This is suggestive, but, as yet, only a theory.

(5) Acute spinal paralysis (atrophic paralysis, anterior poliomyelitis). Here the lesions are found chiefly in the anterior horns of the spinal cord, and are regarded by the author as inflammatory in character.

(6) Peripheral paralysis. These play an unimportant part in the paralysis of early life. The group includes diphtheritic paralysis and the various paralyses resulting from injury to the nerves.

Clinical Department.

DOUBLE PRIMARY AND ACTUALLY SYNCHRONOUS AMPUTATION OF THE LOWER EXTREMITIES, WITH RECOVERY.

SERVICE OF J. C. IRISH, M.D., ST. JOHN'S HOSPITAL, LOWELL, MASS., AND REPORTED BY JOE V. MEIGS, M.D., LOWELL.

CHARLES L., a Frenchman, aged twenty-eight years, of good habits, subject to epileptic seizures, and employed by the Boston and Maine System as a switchman. While in pursuit of his vocation on the afternoon of Wednesday, September 17, 1890, he was seized with an epileptic convulsion, fell upon the track, and was run over by several loaded freight-cars. After a needless delay of half an hour he was taken to St. John's Hospital, arriving there at about four o'clock.

On examination he was found to have sustained a crushing of right foot and a compound comminuted fracture of tibia and fibula in middle third, so that lower and middle thirds were hanging to upper third by few shreds of muscular tissue. The left foot, leg and lower third of thigh were terribly crushed, bones and muscles ground together into an almost shapeless mass. Shock was but hardly appreciable, and hemorrhage but slight.

It was decided to amputate and amputate at once. Patient was immediately anesthetized, ether being used, and during etherization Esmarch's bandages were applied to both members and the flat tapes secured above the bandages.

With the assistance of Dr. Wentworth I immediately amputated right leg in the middle third, by circular method; and at precisely the same time Dr. Irish, with assistance of Dr. Bell, amputated left thigh, in middle third. On account of the weakness and the smallness of the pulse, it was necessary to give patient repeated hypodermic injections of ether and brandy alternately; after ligation of vessels and insertion of drainage-tubes, the flaps were approximated, sutured, and stumps dressed with carbolicized solutions and gauze. The time consumed in the operations was about forty-five minutes.

Patient was immediately put to bed, surrounded by hot bottles and covered with warm blankets. He rallied well, but suffered with acute pain. Knowing his epileptic tendency, and rather fearing result of it, he was given hypodermically one-quarter of a grain of morphine; and shortly after, he sank into a sleep, from which he awoke in the early morning almost free from pain, and, as he expressed it later, during my daily visit, "perfectly easy."

Temperature on the second day was 99.1°. The dressings were not removed until fourth day, when drainage-tubes were removed and stumps redressed.

At the end of one week the sutures were removed. Left stump healed by first intention, right stump by second intention, as there was some sloughing of anterior flap. Patient went on, with no untoward symptom except having a convolution every other day, to a complete recovery. I do not claim that primary double synchronous amputations are at all infrequent, but I do say that primary double amputations done at actually the same moment by separate operators are infrequent, and at least worthy of some thought. I cannot remember of ever having read of a similar case, nor can I find any reported in statistics at hand.

In looking up the subject I find that Professor Ash-

hurst, in the "International Encyclopedia of Surgery," says, "Double synchronous amputations are not very rare but (except where the feet and hands only are involved) are unfortunately not usually successful."

I do not find that he reports a single case identical with the case published above; but I do find that he does not regard it as a wise procedure, for he says that the operations (double) will be more apt to be done well if only one be done at a time.

Paradoxically speaking, Professor Ashhurst is both right and wrong. Double amputations when done by one man may be done well, yet result unsuccessfully; while double amputations by separate operators done actually synchronously may not be done quite so well, that is, not so beautifully, yet result successfully.

Which should we choose? I think the latter, for by so doing we lessen the chance of our patient dying, by saving time, which is, it must be evident to all, the one element qualifying the prognosis in operations of this character. Professor Brinton says that "A powerful element in the production of shock is prolonged operation." I believe all will agree with Professor Brinton.

With two surgeons amputating at actually the same time, only about one-half the time is consumed that one man would consume; consequently the tendency for shock to appear is lessened, and the rate of mortality decreased. In conclusion I would say, that, where it is possible for two men to operate actually synchronously, it were better for our patient to sacrifice the beauty and lessen the time, than to attain the beautiful and prolong the time of the operation.

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON ORTHOPEDIC SURGERY.

STATED MEETING, October 17, 1890, V. P. GIBNEY, M. D., Chairman.

NON-UNION OF FRACTURED RADIUS.

DR. C. A. POWERS exhibited a patient in whom this condition had existed for many years, and also showed an extension-apparatus which had given relief. The first fracture occurred twenty-nine years ago, at the junction of the middle and lower thirds. A re-fracture took place eighteen years later, and united with deformity and disability. The radial nerve had become involved in the callus, and this gave rise to such intense pain, that she underwent an operation for its relief five years later, in which the bone was again fractured. All attempts to cause this fracture to unite, failed. When she came under the care of the speaker in May of the present year, it was found that the carpus had slipped upwards with the lower fragment of the radius, and caused the ulna to project very forcibly against the soft parts, giving rise to much pain in the region supplied by the ulnar nerve. As further operative measures were not deemed advisable, a simple extension-apparatus was applied, and had answered admirably.

DR. A. M. PHELPS said that he thought it had been wisely decided not to subject the patient to further operation, as fractures of the radius and of the lower third of the tibia were peculiarly prone to non-union. Out of about three hundred osteotomies, he had had

only one case of non-union, and that was after an operation for the correction of an anterior tibial curve. Operations by himself and others had failed to bring about union. Thomas, of Liverpool, claimed that such fractures could be made to unite by pounding the parts with a mallet; but, in his experience, this method had not proved successful, and he thought that where there was muscle between the ends of the bone, and the peculiar ivory-like condition of the ends of the bone, which was not uncommonly present, none of the methods heretofore proposed were likely to prove successful. He had very recently proposed and performed a new operation, which he thought might prove successful. It consisted in cutting down upon the ununited fracture, freshening the ends of the bone, and grafting in between them a part of the forearm of a dog, both patient and dog being secured in plaster-of-Paris. When the graft had united firmly, the dog's leg would be amputated, and the skin-flaps of the dog united to those of the patient.

HIP-JOINT DISEASE AFTER TYPHOID FEVER.

DR. J. McG. WOODBURY presented a girl of eleven years, who six months after a severe attack of typhoid fever was found to have some limitation of motion and pain at the right hip, with distension of the capsule. Flexion caused lordosis, and some pain. She was treated by counter-irritation over the joint, and a plaster-of-Paris spica bandage, and was allowed to walk around upon a high patten, with crutches. Now, after a period of eight months, there was no pain.

A CASE OF OSTEOMALACIA.

Dr. Woodbury also presented a case of this nature. The patient had lived in Switzerland until twenty-six years old, and had suffered considerably from exposure during the late war. On October 26, 1886, when forty-three years of age, he sustained a fracture of the surgical neck of the left humerus, and between that date and May 26, 1890, he received five other fractures, namely, two of the left humerus, two of the right humerus, and one of the left clavicle. Most of these fractures were caused by very slight falls. During the last three months, but more particularly since the first of last August, a tumor has been rapidly growing between the sites of the two fractures of the shaft of the right humerus. Two small tumors may be observed upon the clavicle—one at the point of the fracture, and the other to the inside of it. A specimen removed from the large tumor with a harpoon was sent to Dr. J. S. Ely for microscopic examination, and he reported that it contained "polyhedral cells, and occasional large spindle and giant cells." He adds, that this "speaks very strongly for sarcoma." A loud murmur, similar to that heard in aortic aneurism, is audible over the large tumor. Dr. Woodbury said that, as in cases of tumor of the middle of the spinal cord, osteomalacia due to trophic disturbances is one of the early symptoms, concurrent with disturbances of sensation, he had referred the case to Dr. M. A. Starr, with the hope of learning more about the etiology of this interesting condition. Dr. Starr examined the patient on two or three occasions—the last time, only a few days ago—and had reported that there was no central lesion of the cord. The patient had had no pain with the fractures, or upon resetting these bones, and this, together with the fact that there

had been no fractures of the lower extremity, seemed to favor the view that the condition was due to syringomyelia or tumors of the cord.

DR. POWERS said that Dr. Woodbury's case of multiple fracture with tumors, was very similar to a case of multiple sarcomata which he had recently presented to the Surgical Section.

DR. V. P. GINZER thought the pulsation in the tumor might be due to the condition of the tumor itself—in other words, it might be a pulsating sarcoma.

ANKLE-JOINT DISEASE.

DR. A. B. JUDSON presented a case of this disease which he said was interesting because the child had suffered from this condition almost all her life. The disease began at the age of one year, and she is now about seven years old. Notwithstanding that she had been under mechanical treatment only two years, she had recovered with but little disability and deformity. There was considerable lateral motion at the ankle-joint; extension was almost normal; flexion was arrested at about ninety degrees. Scars on both sides of the ankle showed where abscesses had opened spontaneously. There was a difference of one inch between the two calves, and the shortening amounted to only a small fraction of an inch. This result had been obtained by the use of a simple brace, and without resorting to any operation.

DR. JOHN RIDLON presented an astragalus which had been removed by Dr. Farquhar Curtis from a child, which had been brought to the speaker when only six weeks old. He had faithfully tried stretching, and the various retentive appliances, during a period of one and a half years. Dr. G. S. Huntington had then operated by Dr. A. P. Phelps's open method, but without improving the condition. The specimen which he presented was interesting on account of two bony prominences which it showed and which apparently had been the obstacle to flexion of the foot.

THE TREATMENT OF ANKLE-JOINT AND TARSAL DISEASE.

The paper of the evening, with the above title, was read by DR. T. HALSTED MYERS, who also presented a patient illustrative of this subject.

DR. Myers said that tubercular inflammation might attack, first, the synovial membrane, later, the cartilage, and lastly, the bone; or the primary local focus might be in the bone.

While it was still confined to the synovial membrane, a number of surgeons recommended erosion. If it had attacked the bone, many more urged operative methods, irrespective of the general health of the patient. The author considered only the latter condition.

Simple incision was of no advantage, for we had no element of tension, as in acute processes, and we only opened new channels of infection, leaving the original disease unchanged.

The usual method of treatment, curetting the abscess walls, and the sinuses, could not be expected to remove all disease, and would greatly increase the risk of absorption. The success which had been secured in some of these cases seemed to be due to the power of the antiseptic agent to render inert the bacilli which remained.

The rational method was to remove all the disease at once; but bones apparently healthy might contain

tuberculous foci, and hence, it was a most difficult problem to know when to stop, and in fact, this could not be determined at the time of operation. If all of the disease were successfully removed, the duration of treatment was less than under conservative methods. The ultimate results were, however, less satisfactory. He had seen a considerable number of misshapen and atrophied feet after operative treatment, which were weak and painful, and required support to render them able to bear the weight of the body. He had not observed such results from conservative treatment. It was confessedly difficult to ascertain the ultimate results; and although Dr. Shaffer had kindly placed the records of the New York Orthopaedic Dispensary at his service, he had not been able in the short time at his disposal to do more in most of the cases than quote the histories.

The number of cases treated before July, 1888, was fifty-five, and of these, he knew personally that at least twenty-one were cured. Five were cases of synovitis, and sixteen of osteitis. The average duration of treatment in the latter was twenty-one and a half months, the longest case being under treatment fifty-five months. The results in all were extremely good; yet under careful private treatment, still better results should be expected.

From our knowledge of the various ways in which the bacilli of tuberculosis may be spread in the body, it would seem that a primary tubercular process in a joint must be extremely rare. Drs. Prudden, Northrup, Biggs and Thacher, to whom he had written for information on this subject, all considered that these affections were generally secondary, but agreed that primary joint lesions did occur. The practical importance of this was that the danger of general infection from a joint lesion which was not interfered with surgically, was an entirely unknown, and probably extremely small, quantity.

Of the whole number treated (fifty-five) but three had died — one of diphtheria, one while tarsal disease was active, and the other, six months after a note of "nearly cured" had been recorded. In neither of the latter was the cause of death stated. However, in Dr. Scudder's report of eighteen cases of excision, six deaths occurred; three were due to the operation, or its direct effects; another might have been; and the other two were from tuberculosis, but occurred one and two years after the operations.

The treatment in synovitis consisted in absolute protection of the joint from traumatism. In children, he considers a perineal crutch absolutely necessary while walking. Ordinary crutches were invariably laid aside at times, and the joint left unprotected. In addition to this crutch, the foot should be protected by a splint to avoid local injuries, and to maintain a good position. There being no involuntary muscular spasm, while the disease was confined to the synovial membrane, traction was not necessary.

In cases of osteitis, the same protection of the joint was imperative, and if there were pain and spasm, indicating the necessity for traction, this could be applied at the ankle, by means of a Dow brace, or the apparatus of Dr. Sayre or Dr. Foster.

The application of adhesive plaster to a painful ankle required more care than a dispensary case was willing to give, especially when abscess was present. For this reason he had found it most serviceable to employ a leg brace, or plaster splint, worn constantly,

and a perineal crutch for walking, which could be laid aside at night; or the Dow brace, as modified by Dr. Shaffer, might be used.

Abscesses should be left entirely alone, and the sinuses simply kept aseptic. After the joint was considered cured, it was well to wear an ankle brace for some months, to prevent twists. The malpositions found in the acute stages, were almost entirely due to muscular spasm, and did not require tenotomy, or other operative treatment.

In the later stages, there might be bony changes, and these, if not painful or progressive, did not require treatment. However, if these conditions did exist, and yet there was no evidence of active disease, an attempt should be made to restore and preserve the normal relations of the parts.

The value of hygienic surroundings during the treatment of these cases, could not be overestimated. His observations had been made on children only, and for contrast, an extended series of cases in the adult would be very valuable. Without exception, every one of his cases of ankle-joint or tarsal osteitis in children had done well under conservative treatment, and he had yet to see the case which he would condemn to erosion or excision.

DR. N. M. SHAFFER said that his own experience led him to think that one point in Dr. Myers's paper should be particularly emphasized, that is, the necessity of absolute protection of the articulation. He had accomplished this in practice, whenever possible, by the use of a modification of Dow's brace, and had found that adhesive plaster was rarely required, as a well-fitting shoe made efficient counter-traction. He thought that the further removed the tuberculous joint was from the centre of the body, the more benign was the disease, and the less the danger of general infection; and he was inclined to speak more strongly of the conservative treatment of ankle-joint disease, than of any other articulation in the body.

DR. RIDLON thought these cases did well with the Dow instrument; but with this, as with some others, we could not secure immobilization, but only protect the joint from the jar of walking. He had seen such excellent results in cases of suppurative ankle-joint disease without any treatment whatever, that he often doubted how much of a good result could be attributed to the treatment received.

DR. H. W. BERG said that he had had such good results in the treatment of phthisis by the administration of the bichloride of mercury in doses of one-twenty-fourth of a grain, three times a day, that he was inclined to believe the old theory that tuberculosis was really a change in the syphilitic virus due to passing through several generations. He considered that splints like Dr. Judson's were imperfect, for, by taking their bearing from the outside of the foot, intra-articular pressure was increased. To diminish this pressure, the foot must be adducted and rotated inwards.

DR. PHLEPS was of the opinion that the vast majority of these cases were cured by immobilization and relief of intra-articular pressure, but in suppurative cases, he believed that the soundest and most scientific surgery demanded operative measures. If we could protect the hip-joint as well as the ankle-joint, we ought to get equally good results in hip disease. He believed that these cases were inoculations of pathogenic germs on a diseased surface, and that they were purely local.

DR. R. H. SAYRE exhibited a splint which his father had devised for an adult with ankle-joint disease. He agreed with Dr. Ridlon, that it was difficult to apply traction at this joint, but he thought this splint solved the problem. His views regarding the prognosis and treatment of this disease, were in accordance with those just expressed by Dr. Phelps.

DR. SAMUEL LLOYD said that fifteen cases of adult ankle-joint disease had been treated in the New York Post-Graduate School, by the so-called conservative method, but the relapses had been very frequent, and he thought this method was less likely to yield good results in adults than in children. In answer to questions from the Chairman, he said that several of the cases were due to injury, and a number of them were suppurative, while four were recorded as synovitis. Two of the cases had been discharged as cured before 1883, and were known to be well in 1889.

DR. JUDSON protested against the statement that cases of disease in the ankle should do equally well without treatment, although neglected cases of ankle-joint disease would have nothing like so bad a deformity as those at the hip.

DR. H. L. TAYLOR also spoke about the different mechanical conditions present at the various joints. The weight of the limb exerted great leverage upon the joint, especially in a spasmotic condition of the muscles. It is more marked at the hip than at the knee, and very much more noticeable than at the ankle. He referred to a case of ankle-joint disease occurring in a distinctly phthisical subject, where the sinuses were treated by injections of a saturated solution of iodoform in ether. The beneficial effect upon the healing process was almost magical.

DR. GIBNEY said that about ten years ago, the surgical section of the "Therapeutic Society" of this city, spent about two years collecting data relative to the comparative results obtained by the operative and non-operative treatment of this condition; and the conclusion was, that the conservative method yielded the greatest number of useful ankles, even in cases where the foot was seamed with cicatrices. There were two or three operative cases having a high degree of equinus, and a stiffened and shortened joint, and one or two flail joints were also shown. In his experience, cases of adult ankle-joint disease, relapsed again and again on the slightest provocation; later on, abscesses would appear; still later, pulmonary signs would develop, and then amputation would follow. As regards the mercurial treatment of tuberculous disease of the joint, he need only call attention to the fact that many years ago the routine treatment for these cases at the Hospital for Ruptured and Crippled, was one-twenty-fourth of a grain of the bichloride of mercury in tincture of bark, three times a day; and the results attained by this treatment were certainly far from striking.

— A Western physician is said to have received the following from a brother physician: "Dear Dock I have a pashunt whose physical sinet shewes that the windpipe has ulcerated off, and his lungs have drop into his stumick I have given hym everry thing without effectt his father is welthy honable and influenshal as he is a member of assembly and god nose I dont want to loss hym what shall I do ans by return male. Yours frat, — — —."

AMERICAN PUBLIC HEALTH ASSOCIATION.

THE Eighteenth Annual Meeting was held at Charleston, S. C., December 16, 17, 18, 19, 1890. A good average attendance was present, especially from the Northern States. Delegates were also present from Canada, and, for the first time, from Mexico.

The Association is one of the largest and most influential of its kind in the world; and its scope should extend to all American countries. It aims at co-operation between all the countries upon the Western continent so far as all matters pertaining to general sanitation, international sanitation, and local hygiene are concerned.

FIRST DAY.—DECEMBER 16TH. MORNING SESSION.

The meetings of the first day, Tuesday, were held in Hibernian Hall, a building which had suffered severely in the earthquake shock of 1886, but like many other public buildings, which were not utterly destroyed, had been so carefully repaired as to show few traces of the great calamity.

At 10 A. M. PRESIDENT BAKER, of Michigan, opened the meeting with a brief address, and introduced DR. HORLBECK, of Charleston, the Chairman of the Committee of Arrangements, who welcomed the Association to the city, and also extended invitations to the members from the various local organizations.

DR. LINDSLEY, of Tennessee, the Treasurer, reported that the Association was in a prosperous financial condition, having a balance of about \$1,100 in its treasury.

On motion of DR. GHION, a resolution was adopted welcoming the delegates from the Superior Board of Health of Mexico, Drs. Orvananos and Gomez.

About seventy-five new members were then elected to membership, representing various parts of the country.

DR. WYMAN, of Aiken, S. C., invited the Association to visit that health-resort, and the invitation was accepted by a large number of the members at the close of the week's session.

DR. ORVANANOS submitted the first paper (translated from the Spanish), entitled

THE FEDERAL DISTRICT IN THE REPUBLIC OF MEXICO, AS A SUITABLE RESIDENCE FOR PERSONS PREPARED TO TUBERCULOSIS, AND FOR THE RELIEF OF PULMONARY CONSUMPTION.

In this paper the author described very accurately the topography and climatic conditions of the country. It was shown that the prevalence of tuberculosis differs very much in the different parts of the country, and that in those parts where the disease was most prevalent, the presence of a large foreign element was a controlling factor. Even among these, post-mortem examinations had shown a considerable ratio of cured cases.

Among the conditions of the high table-land which were deemed to be unfavorable to the development of tuberculosis were cold, dryness and sunlight. At these elevations fog is unknown. Another condition which the writer believed to be hostile to the bacillus tuberculosis consists in the exhalation of the volatile oils of the abundant flora of the region.

DR. L. F. FLICK, of Philadelphia, presented the next paper, entitled

THE PREVENTION OF TUBERCULOSIS; A CENTURY'S SUPERVISION IN ITALY, UNDER THE INFLUENCE OF THE PREVENTIVE LAWS OF THE KINGDOM OF NAPLES, ENACTED IN 1782.

The paper was very largely historical in its character, and the conclusions derived from the successful application of ancient laws were applied to the prevention of consumption under modern conditions.

A paper upon

VENTILATION AND IMPURE AIR AS PROPHYLACTIVE OR CAUSATIVE OF DISEASE,

by DR. REMONDINO, of San Diego, Cal., was presented and read by title only.

DR. WYMAN, of Aiken, S. C., followed with a paper entitled

THE PREVENTION OF PHthisis,

which showed the importance of Aiken as a health-resort for consumptives.

As might be expected, these papers, all treating upon tuberculosis, with special reference to its prevention, awakened a prolonged and lively discussion. The consensus of opinion appeared to be in the direction of more stringent regulations for its prevention, especially as applied to people living mostly in closed apartments, such as hotels, boarding-houses, health-resorts, and to travellers in steamers, cars, and especially in sleeping-cars.

DR. GHION, of the U. S. Navy, offered the following resolution, which was adopted: "That a standing committee of five members be appointed by the President to formulate practical prophylactic measures, for the prevention of the spread of tuberculosis, especially looking to the protection of the healthy members of the community from tuberculous infection."

An interesting fact brought out in the discussion was that the Japanese dispose of their spouts by means of the cheap paper handkerchiefs, which they conceal in their sleeves and destroy by burning. It was also stated that the washerwomen at Aiken, S. C., are especially liable to tuberculosis.

AFTERNOON SESSION.

DR. GIBSON presented, on behalf of the author, a paper by DR. JOSÉ L. GOMEZ, of Mexico, on the

SWINE-RED DISEASE OF MEXICO,

a disease of hogs, the symptoms of which, together with the pathological appearances were so minutely and so accurately detailed by the writer as to provoke the inquiry whether the disease in question was not identical, or nearly so, with hog-cholera, to which the author replied in the affirmative.

A paper on the

SANITARY ADVANTAGES OF THE TURKISH BATH, by DR. C. H. SHEPARD, of Brooklyn, N. Y., added but little to the existing knowledge upon the subject.

PROF. F. P. VENABLE, of the University of North Carolina, read a carefully prepared paper entitled,

SOME NOTES ON CHEMICAL DISINFECTION, being a *résumé* of the present aspect of the subject of chemical disinfection.

The discussion which followed was very largely participated in by the Association, and took a different turn from that which the writer had plainly sought. The discussion was mainly devoted to the possible

harmful effects which might result from the excessive use and application of the bichloride of mercury as a disinfectant. The opinion of those who took part in the discussion appeared to be very much divided upon the subject.

EVENING SESSION.

The evening of the first day was devoted, as usual, to the President's address and to the formal reception of the Association by the city authorities. The meeting was held in the Grand Opera House; and, in consequence of the unusually low temperature, the audience was small.

DR. BAKER, the President of the Association in his

ANNUAL ADDRESS

reviewed the objects and aim of the organization, as expressed in its name, and referred briefly to the increasing geographical limits of the Association, as shown by the admission in recent years of delegates from all the British North American provinces and from Mexico.

He spoke of the thorough sanitary work and investigations of the English and German governments.

In referring to the subject of quarantine, Dr. Baker said that this was but a small part of the actual sanitary duty of the general government. It should investigate the causes and conditions of infectious diseases, especially in localities where they are known to prevail, and for such purposes a Health Department of the Interior is needed.

He favored the liberal bestowing of government aid upon all departments of sanitary inquiry, and commended the action of such State governments as had supported the work of their State Boards of Health by liberal appropriations. Congress had been given constitutional authority to attend to the general welfare of the people, and this could not be better secured than by providing means for the investigation and the prevention of disease. Economics—political questions, such as protection and free trade—were of small consequence when compared with governmental protection of life and health.

The other exercises of the evening consisted in addresses of welcome by eminent citizens, DR. BUIST representing the medical, and J. D. K. BRYON, the legal professions. Both addresses were extremely eloquent.

DR. VEDDER, the eloquent pastor of the Huguenot Church, closed the programme with a constant fusilade of wit and humor.

The speaker went on to formulate the charge against the Health Association, of seeking to find and eradicate the seeds of human malady, and thus interfering with the livelihood of our many and good and well-beloved physicians, taking the bread out of their mouths by forbidding them to put bread pills in the mouths of others. And though our doctors gave them welcome and were glad of their advice and aid in thus playing at cross-purposes with their bread and butter, yet the community would not stand silently by and see its endeared medical men thus ruthlessly immolated upon the altar of self-sacrifice; and, therefore, the community had adjudged that the members of this Public Health Association should be visited and persecuted by all forms of public and social attention and courtesy, be immured in a building where they must wrestle with bacteria, bacilli, mephitic vapors and miasmatic conditions, and like savory matters, whilst

the community looked on, uninterfering and unpitying. From time to time, to aggravate their imprisonment by contrast, they were to be taken out and around our city, to bemoan the fate that compelled them to live elsewhere, save, of course, in the favored localities, so much like Charleston, where they did reside; taken into our homes, so much sweeter than any others, except, of course, their own; to be made to get, if not "half seas over," at least "over the bay," by being taken down to the Bar; to be invited to ride in railway coaches where no dust could penetrate; and to explore our splendid system of drainage, without any drain upon their susceptible olfactorys, etc., etc.; and when they had reached the limit of human endurance, and were ready to go, to see their persecutors, so unaffected by compunctions as to be willing to endure the whole programme, and hear them giving to the Health Association the hearty send-off: "Come again, as soon, as often, and in as great force as possible." The jury of the city has been polled, and it cries: "So say we all."

SECOND DAY, DECEMBER 17TH.
MORNING SESSION.

The first regular paper of the second day's session was a report of the Committee on Diphtheria presented by Dr. ASHMUN, of Cleveland, O., the chairman of the committee. The report estimated the annual mortality from this disease in the United States and Canada at 10,000, and the number of cases 40,000. Climatic, local and contagious causes were enumerated by the Committee, as well as the probability that domestic animals may be concerned in its spread. The apathy of boards of health in resisting its spread was especially noted, and the establishment of disinfecting stations, and the isolation of diphtheria patients, advised.

A lengthy discussion followed, in which the prominent fact which was brought out was the permanence of the infection in houses and apartments once infected.

The next regular paper was presented by Dr. S. W. ABBOTT, of Massachusetts, and was entitled,

WHAT CONSTITUTES A FILTH-DISEASE?

The writer prefaced his paper by stating that the term filth-disease conveyed to the popular mind an erroneous impression, namely, that filth was an actual cause instead of a condition, and that unless this was clearly understood, the administration of local sanitary work could not be intelligently performed. Many instances were cited in support of this view.

"We may reasonably conclude," said the writer, "that a filth-disease is one in relation to which filth in some form or other, either wet or dry, plays the part of an important factor only in causation, but is not itself the direct cause; that it acts either as a favorable soil for the propagation of disease-germs (other favorable conditions also existing), or that it acts as a suitable medium or vehicle for the transmission of the *particulate contagium* from the sick to the well, as is probably the case in the inhalation of the bacillus tuberculosis in and with the dust of filthy or ill-ventilated apartments.

"We may also conclude that the filth which promotes the spread of infectious diseases is specific filth.

"The point to be emphasized in the foregoing paper is, not that the removal of filth should in the least de-

gree be discouraged, but, that when done, it should be done intelligently and with this principle in view, that filth is a condition rather than a cause, that it is the soil for the culture and transmission of infection and not the infection itself, and just so far as the principle of infection is deprived of its proper soil, so far is one of the most important conditions of its growth and propagation removed."

DR. GEORGE T. KEMP, Director of Physiology and Experimental Therapeutics at the Hoagland Laboratory, of Brooklyn, N. Y., spoke upon

THE VALUE OF MICROSCOPICAL, CHEMICAL AND SPECTROSCOPICAL EXAMINATIONS OF BLACK VOMIT, AS AN AID TO HEALTH OFFICERS IN THE DIAGNOSIS OF YELLOW FEVER FROM MALARIAL FEVER.

He had made cultures, and presented samples in tubes in illustration of his subject.

In the afternoon, the Association enjoyed a diversion from its usual programme, by taking a trip of about twenty miles out into the country, to visit an old historic building, the old church at Goose Creek, built in 1706. It is in a comparatively deserted region, surrounded by the immense live-oaks with hanging moss and other semi-tropical plants of this climate. Attached to the train which conveyed the Association was a car ventilated by a new method, the motive power for producing a current of air being furnished by the wheels of the car. The fresh air, when introduced, is deprived of its smoke and cinders by passage through water. The air passes into the car through small tubes at the sides of the car, and the foul air is withdrawn at the top.

(To be continued.)

Recent Literature.

Cyclopaedia of the Diseases of Children. Edited by JOHN M. KEATING, M.D. Vol. IV, 1128 pages. Philadelphia: J. B. Lippincott Company.

The fourth and last volume of this great work is fully up to the high standard of the other volumes. Containing much that will interest the specialist, it is evidently written with the needs of the general practitioner in view.

Part I is devoted to "The Diseases of the Ear in Children," by Charles H. Burnett. The subject is treated in a very thorough and clear manner, and special stress is laid on the treatment of such accidents as a foreign body in the ear, and of ear-ache, which frequently fall to the lot of the general practitioner. A good deal of his advice is on what not to do. Against "ear-drops" he is particularly outspoken; and he says, "There are no 'drops' which can relieve ear-ache in children."

Part II, "The Eye," contains articles by G. E. de Schweinitz, C. S. Turnbull and C. A. Oliver. The latter writer deals with the subject of "Ophthalmoscopy," in an article of nearly one hundred pages, illustrated with many excellent plates. The value of this study in diseases of the circulatory, nervous and other systems, and in general diseases, is discussed at length, and with its numerous references to papers and cases reported, the article will form for some time to come an important work of reference.

Part III, "Hygiene," to which two hundred pages are devoted, contains much of general interest; but it is impossible to more than allude here in the briefest way to this division. The article by Keating and Young, on "Physical Development," is particularly interesting, and is profusely and beautifully illustrated, some of the plates being reproductions of Muybridge's well-known photographs. The Swedish system of gymnastics is explained in detail, and the different motions are figured. The article on "Prophylaxis," by J. W. Byers, is a little disappointing; and one is surprised to find the burning of sulphur so highly esteemed as a disinfectant. The omission of everything on the question of the duration of isolation in contagious diseases is probably intentional, as this is thoroughly discussed in the article on "School Hygiene," by D. F. Lincoln, an article filled with valuable information and suggestions.

The other articles in this division are on "Massage," by Wm. A. Edwards; "Construction of Children's Hospitals," by Lindley Johnson; "Juvenile Crime," by J. P. Keating; and "Medico-legal Testimony," by Jerome Walker.

Part IV, "Diseases of the Nervous System," contains in some six hundred pages a series of monographs by well-known specialists, the mere mention of whose names would suffice to show the great value of the articles. Among these may be mentioned the Introduction by A. M. Hamilton; "Cerebral Palsies and Suppurative Meningitis," and also the article on "Epilepsy," by L. C. Gray; "Tubercular Meningitis," by A. Jacobi; "Cerebral Haemorrhage and Chorea," by B. Sachs; "Toxic Affections from Arsenic and Lead," by J. J. Putnam; "Poliomyleitis Anterior," by Wharton Sinkler; "Hereditary Ataxia," by C. L. Dana; and other equally valuable papers which space does not permit us even to mention. In a word, this volume is a worthy companion of the other volumes to which so much praise has already been given.

C. W. T.

The Medical Bulletin Visiting List, or Physician's Call Record. No 1. Arranged upon an original and convenient monthly and weekly plan for the daily recording of professional visits. Philadelphia: F. A. Davis, Medical Publisher.

The "original plan" on which this visiting list is arranged consists in the insertion of half-leaves or stubs in such a fashion that when the first week is completed, the record of the following weeks of the month is made on the half-leaves without rewriting the names. It is offered in three styles: No. 1 provides for seventy names per month, which the publishers consider will meet the requirements of an ordinary practice. It not only obviates the necessity of writing a new list of names every week, but makes a somewhat less bulky book for the pocket. It contains blank spaces for memoranda, and a list of doses of the more recent drugs copied (by permission) from Merck, with other useful information, and a fee-table with double column giving charges for city and country.

— *Sympathetic Visitor.* "Mrs. A., what do you suppose makes you suffer so?"

Mrs. A. "I don't know, I'm sure, and I believe nothing but a post-mortem will ever show."

S. V. "You poor thing! You are so weak you could never stand that!"

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 25, 1890.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersig'd.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ANNUS MEDICUS MDCCCXC.

THE past year has been a busy one in the medical world, and one in which public attention has been more than usually directed to medical matters. It opened during a world-wide epidemic of influenza, and is now closing in the midst of the excitement and hope which centre around Koch in Berlin. The intermediate months have not been without their share of interest. A most successful medical congress has attracted the attention of a large number of the profession. Cholera has left its habitat and invaded some countries and threatened others. Neither has the year been lacking in matters of more local interest nor in the steady progress of medical science.

EPIDEMICS.

Epidemic influenza, commonly known as "the grip," which for the first time since 1847 visited the greater part of the world, has been the subject of much discussion and study during the year. It may be roughly said that its general course was from east to west, occasionally turned aside by mountain systems and land divisions, but advancing, often with great rapidity, against prevailing winds. There was absolutely no regularity in time in its advance; appearing nearly a fortnight later in England than on the eastern coast of North America, it was sometimes two weeks in going from one town to another only a few miles apart. It appeared in Russia in October, 1889, and soon spread to St. Petersburg and the neighborhood of the Baltic Sea. During the first half of December, central Europe was its seat, but its advance was most marked in the last half of the month. During this time it spread over a large part of Europe, the eastern portion of North America, and became established in Great Britain. The first of the year was almost the central point of time of the epidemic in Boston, which was one of the first places visited on this continent. In towns only a short distance from us, and in cities farther west, it was at its height from one to three weeks later. After this it continued to advance generally westerly and to the south until April, with decreasing intensity, except

that it appeared in Japan in April, with a good deal of energy. It did not spare either the arctic circle or the torrid zone, isolated islands or ships at sea.

In consequence of the epidemic a vast amount of money was spent, business paralyzed and many lives lost, either directly or indirectly. The greatest damage was done in December and the first half of January. The death-rate of cities increased enormously for three or four weeks, the highest attained generally being from two to three times the usual rate. The cause assigned was seldom influenza itself, but almost universally pneumonia, broncho-pneumonia or the lighting up of a chronic lung trouble.¹

After the beginning of summer we heard but little of the epidemic until within a few weeks, when it seems to have rekindled in a few places, in October in Denmark, and in November in Hungary, some parts of Germany, Great Britain and Japan. It is, however, improbable that we shall have another general outbreak at present.

Cholera during the past year again invaded Europe, and for a time threatened the whole of the Mediterranean seaboard. At the beginning of the year it was present in Mesopotamia and Persia, and more or less in Turkish Arabia. In April it appeared in Turkey, but not to an alarming extent. On the 13th of May it broke out at Puebla de Rugat, a small village of seven hundred inhabitants, in the valley of Albaida in Spain, and in a month spread through the province of Valencia. During July, August and September it spread through five provinces, increasing in severity; it then began to decline, and is now fast disappearing. Toledo and Madrid were visited; but the greatest losses were in some small towns, which were nearly depopulated. It was in western Europe practically confined to Spain, where up to November 20th there had occurred during the epidemic 5,477 cases, of which 2,840, or 51 per cent., had been fatal. Formerly such an outbreak in Spain would have meant extension to other European countries.

In July the cholera began to spread in all directions from Mesopotamia and Persia. It broke out at Mecca in the middle of the month, and finding favorable conditions in the annual pilgrimage to that city, killed an enormous number, probably tens of thousands, of devout Mussulmen. It spread to the borders of Russia, through Egypt and along the northern shore of Africa, and also eastward. It was active in Japan early in the summer, and spread, with ever-increasing violence, until September. The extent of the epidemic in the empire may be appreciated from a report of October 2d, which said that up to that time there had been 33,863 cases with 22,560 deaths.

Small-pox as an epidemic has not appeared during the year, except in Madrid and Lisbon and recently in Guatemala. In Madrid there were 138 cases in August, 421 in September, and 654 in October. The

¹ An account of this epidemic, especially as it existed in Massachusetts, may be seen by turning to pages 49, 59 and 547 of this volume of the Journal.

mortality appears to have been about 65 per cent. The epidemic in Lisbon appeared later, and it is too early to learn its extent. Other places have been more than usually afflicted. Holland, becoming alarmed, resorted to more vigorous vaccination. St. Petersburg had a large number of cases during the past month. Milan has entirely recovered from its visitation of a year ago. Those countries where vaccination is enforced have remained comparatively immune.

Other epidemics have not been particularly noticeable during the year. Yellow fever has been present, as always, in Havana, and other places in the West Indies, but did not get a foothold in the United States. Dengue has been epidemic at Smyrna, and has attacked four-fifths of the population of one hundred and fifty thousand. In some places influenza was mistaken for this disease. Bubonic plague appeared in Turkey at Kale-Daragehan, a village of two hundred and eighty inhabitants.

MEDICAL LEGISLATION.

The tendency in the United States to pass laws limiting the practice of medicine to qualified practitioners is increasing, especially in the West. As one State after another drives medical adventurers from their borders, the neighboring States become more and more overrun by these gentry, and look with greater favor upon medical laws. The difficulty of drawing up a satisfactory statute is a great stumbling-block, and has resulted in defeat of medical legislation in several States.

Congress has enacted a law to prevent the introduction of contagious diseases from one State to another. Whenever cholera, yellow fever, small-pox, or plague exists in any State or Territory, and there is danger of the spread of such disease into other States or Territories, the Secretary of the Treasury may promulgate such rules and regulations as may be necessary to prevent the spread of such disease. The said rules and regulations shall be prepared by the Supervising Surgeon-General of the Marine Hospital Service. Any person who shall willfully violate any rule or regulation so made shall be guilty of a misdemeanor, and shall be punished.

Congress has also passed a bill to prevent adulteration and misbranding of food and drugs. The Department of Agriculture shall organize a division for examining and analyzing food and drugs, and all such found adulterated or misbranded shall, under penalty, be prevented from being imported into any State from any other State or foreign country.

A bill has been introduced in the United States Senate establishing a board of medical examiners for the District of Columbia. The bill provides that the board shall consist of ten physicians or surgeons, three dental surgeons, and in addition five homoeopathic practitioners of medicine, the term of office to be four years. The board is to prescribe rules and

regulations for the examination of all candidates for the practice of medicine appearing before it, who having passed a satisfactory examination and registered, shall then be allowed to practise.

Congress has recently passed an act for the District of Columbia requiring the notification and isolation of cases of scarlet fever and diphtheria, and providing for the placarding and disinfection of the premises. The bill is believed to be a model one for municipalities.

The New Jersey legislature passed a law regulating the practice of medicine, which requires all physicians to pass an examination before a State board of examiners before they can be licensed, and imposes a fine of from fifty to a hundred dollars, or imprisonment for from ten to ninety days, or both, for practising in the State without a license. The board of examiners consists of nine members, appointed by the governor for terms of three years, which board shall consist of five regular physicians, three homeopaths and one eclectic; and no member of any college or university having a medical department shall be eligible. Those physicians already in practice do not come under the provisions of the law. A peculiar feature of this law is that many New York and Philadelphia physicians who have been in the habit of practising in New Jersey are disqualified.

A medical law has been passed by the new State of Washington, which in the short space of six months has already developed curiosities. A law was passed that all persons, before practising medicine should be examined and licensed by a State board, appointed by the governor. The governor appointed on the board four regular practitioners, three homeopaths, a "physio-medic," and an eclectic. It is difficult to learn what a "physio-medic" is. The irregulars combined, elected their candidate president of the board, and placed such other members as they pleased in office. The board adopted rules to the effect that a general average of sixty-five must be made by all but old graduates (of at least five years' standing), who need not average as high in chemistry, physiology, or anatomy as graduates of less than five years' standing. Each member of the board was given subjects on which to prepare questions in writing. Some of these questions have gone the rounds of the medical press as jokes, as for instance one asked by the eclectic, "What is the effect of too much red blood-corpuscles in the blood?"

State medical practice bills were defeated in Maryland and Rhode Island.

In New York several bills of medical interest were passed. Among them one providing that all of the pauper and indigent insane in all the counties of the State, except New York, Kings, and Monroe, shall be cared for and maintained by the State. The number of insane affected by this bill is a little less than 2,300.

The New York anti-smoking law, which went into operation September 1st, says: "No child actually or

apparently under sixteen years of age shall smoke or in any way use any cigar, cigarette, or tobacco in any form whatsoever in any public place."

The following law also went into effect in that State on the same date: "Should any midwife or nurse having charge of an infant in this State notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty, under penalty, of such midwife or nurse so having charge of such infant to report the fact in writing within six hours to the nearest health officer or some legally qualified practitioner of medicine, of the city, town or district in which the parents of the infant reside."

EXECUTION BY ELECTRICITY.

After a long series of delays and appeals to different courts, the first execution by electricity took place in New York at Auburn Prison on August 6th. The criminal was William Kemmler, whose name has become widely known as that of the first victim of the new method of killing. The apparatus consisted of a dynamo capable of generating an alternating current of 2,000 volts, with a death-chair, and suitable electrodes, the victim completing the circuit. Only two or three minutes were consumed in adjusting the appliances. When the current was turned on, in an instant the victim was apparently driven into a shrinking, crouching, rigid mass, with the exposed features in a grin, and the muscles of the entire body in fixed and rigid spasm. He remained in this condition for seventeen seconds, when the current was interrupted and the muscles became relaxed. Seventy-three seconds after the current was turned off a slight heaving of the chest was noticed, and this was immediately followed by slow, rhythmical, stertorous breathing. By some mistake it was two minutes before the current was turned on again. Then the same phenomena were repeated, and the culprit was kept under the full power of the instrument — fourteen hundred volts — for two and one-quarter minutes, when all the unpleasant symptoms disappeared.

Many sensational accounts of the so-called electrocution appeared in the daily papers, describing the scene as barbarous; but in an official report to the governor, Dr. C. F. McDonald says that when properly understood, the first execution under the new law will be regarded as a successful experiment. In spite of certain minor defects the important fact remains that unconsciousness was instantly effected, and that death was painless. The movements were reflex, and no more than were to be expected, and occur to the same extent in decapitation. The breathing could not be considered as a return of normal respiration.

THE TENTH INTERNATIONAL MEDICAL CONGRESS.

The Triennial International Medical Congress was held this year in Berlin. It was in all respects an unqualified success. Never before has there been so large an attendance, the total number of members be-

ing 5,737, of which 683 were from the United States and Canada. The first general meeting of the Congress was held in the Circus Renz on Monday, August 4th. It was called to order by Professor Virchow, who delivered the Address of Welcome. Secretary-General Lassar then made his report. Minister von Boetticher, as the representative of the German Empire, followed with an address. Minister von Gossler welcomed the members on behalf of the Prussian State. Other addresses were delivered by Herr von Forckenbeck on behalf of the city of Berlin, and Dr. Graff, President of the German Medical Society. Addresses from the foreign members then followed. Surgeon-General Hamilton spoke for the United States. Professor Virchow was unanimously elected president of the Congress. General addresses were delivered by Sir Joseph Lister, Bart., on "The Present Position of Antiseptic Surgery"; Dr. Robert Koch, on "Bacteriological Investigation"; Dr. Boucharde, on "The Mechanism of Infection and Immunity"; Dr. Axel Key, on "The Relation of the Development of Puberty to Diseases of School Life"; Dr. H. C. Wood, "On Anesthesia"; Dr. Cantani, "On Antipyretics"; Professor Meynert, on "The Co-operation of the Parts of the Brain"; Professor Stokvis, on "Colonial Pathology."

The order of proceedings was as follows: Saturday, August 2d, opening of the Medico-Scientific Exhibition in the National Exhibition Building. Monday, August 4th, opening of the Congress in the Circus Renz; constitution of the Sections in the sectional meeting rooms in the National Exhibition Park; in the evening social reunion of members and ladies in the Exhibition Park. Tuesday, sectional meetings; in the evening reception of members in the Rathaus by the Municipality of Berlin. Wednesday, general meeting, Circus Renz; sectional meetings; in the evening sectional dinners, to some of which ladies were invited. Thursday, sectional meetings; in the evening a ball. Friday, sectional meetings; in the afternoon Court reception at the New Palace at Potsdam by special invitation. Saturday, sectional meetings; at noon final general meeting; in the evening farewell dinner to members of the Congress, given by members of the profession in Berlin.

At the Medico-Scientific Exhibition, in addition to the usual exhibit of surgical appliances and pharmaceutical preparations, there were shown anatomical, histological, and pathological specimens, models of field hospitals, conveyances for the wounded, methods of bacteriological investigation, and many other objects of interest to medical men.

Professor Virchow delivered the farewell address, and Dr. Billings spoke in behalf of American members, expressing their thanks for all the courtesies they had received.

The medical profession of France just escaped making themselves ridiculous. Their patriotic emotions combined with a doubt of their cordial reception, caused a long deliberation as to whether they should

attend a congress in Berlin. They finally decided to go, and were received by their German *confrères* with open arms.

The United States Army was represented by Drs. John S. Billings and Charles H. Alden; and the Navy by Medical Directors Albert L. Gihon and David Kindleberger.

The most noteworthy occurrence of the Congress was the reading of his paper by Professor Koch. He is said to have read it against his will, very probably anticipating what has since occurred, that a premature and incomplete announcement of his work would place him in a false position in the eyes of a large part of the world.

KOCH'S METHOD OF TREATING TUBERCULOSIS.

It was known that Professor Robert Koch in Berlin, had been engaged in experiments on preventive inoculation, and as the International Medical Congress was to meet there in August, he was practically forced by the authorities to deliver an address on the subject, consequently he said that it was not his custom to publish his investigations until they were completed, but he would make an exception this time. He had not only succeeded in conferring upon guinea-pigs, which are known to be peculiarly susceptible to tuberculosis, perfect immunity against that disease, but had also discovered means of arresting the growth and multiplication of tubercle bacilli after injection of a fluid. If he should be equally successful with tuberculosis in man, it was not too much to hope that means would be found for successfully combating other diseases.

Considering the reputation which Koch had earned, not only for great scientific ability but also for the accuracy of his statements, it is no wonder that this paper produced the most profound sensation in the medical profession, and through it in the world at large. And when two months later it was discovered that a considerable number of patients were being treated under Koch's direction, the excitement and curiosity became so intense that it was finally impossible longer to resist, and he published an account of the clinical results of treatment by a new method up to that time.

The paper appeared first in the *Deutsche Medicinische Wochenschrift*, on November 14th, and said that in spite of all precautions, so many accounts had reached the public, and in such an exaggerated and distorted form, that it seemed imperative, in order to prevent false impressions, to give at once a review of the position of the subject at the present stage. As regards the origin and the preparation of the remedy, he considered himself unable to make any statement, as his research was not yet concluded. He reserved this for a future communication. The remedy is a brownish, transparent liquid, which does not require special care to prevent decomposition. For use, this fluid must be more or less diluted, and the dilutions are liable to undergo decomposition if prepared with distilled water. He then described the different phenomena observed

up to that time after injection of this fluid. Koch did not grow enthusiastic over the possible value to medical science; all that was done for him by others and then often credited to him. He pointed out the use of the method in the diagnosis as well as in the treatment of tuberculosis, and said that as it seemed that incipient pulmonary tuberculosis was much more favorable for treatment than in a later stage, early diagnosis would in future be of importance.

Since this paper by Koch but little has been learned on the subject. The supply of the fluid has been limited, but some has now reached America. The late clinical observations have not differed materially from those described by Koch, and it will probably be some time before the exact value of this new therapeutic agent is known.

In view of the action of Koch's fluid on tubercular lungs, a fresh impulse seems to have been given to pulmonary surgery in Berlin within the last few weeks.

MISCELLANY.

The Convention for the Seventh Revision of the United States Pharmacopœia was held in the city of Washington, May 17th, and was called to order by Dr. Robert Amory, the president of the last convention. The session lasted until the 10th. There were about two hundred delegates present sent by incorporated medical and pharmaceutical societies, also representatives of the medical departments of the army, navy and marine hospital service. The committee of final revision of the last pharmacopœia presented a draft of the general principles which they recommended. These were discussed and either adapted or referred to the new committee. Dr. H. C. Wood was made president of the convention, and a committee of final revision consisting of twenty-five members was chosen.

The United States Census was taken in June. Great excitement was caused among the laity by the addition to the usual questions asked in census-taking of those relating to physical conditions. Besides the name, age, sex, color and occupation, the census enumerator was required to ascertain whether the person was insane, feeble-minded or idiotic, blind, deaf, dumb, crippled, maimed, lame, deformed, or suffering from acute or chronic disease. It is probable that the answers obtained will not be worth using for statistics, especially as a circular sent to each physician asking about his patients was very commonly not returned.

The Pan-American Congress made a unanimous report, in which it condemned absolute isolation in preventing the spread of epidemics, and recommended in its stead the disinfection of all articles from infected localities before they are permitted to be imported into healthy places.

The Johns Hopkins Medical School has agreed to take female students on the same conditions as male as soon as the sum of \$500,000 has been raised. A number of women have already raised \$100,000, and deposited it with the trustees.

The New York Academy of Medicine opened its new, magnificent building on November 20th. There was a very large attendance of members of the profession and ladies, as well as of distinguished laymen. The library is in a thoroughly fireproof apartment; the grand assembly hall and other rooms are well adapted to their purposes, with the unfortunate exception that the great hall does not seem to be acoustically perfect, it being difficult to hear in some parts of the room.

Leprosy has attracted a good deal of attention during the past year. The Indian government has been at work devising means for isolating and caring for lepers. Some new cases have appeared in Minnesota, and isolated ones in other States. The United States government has issued an order that no vessel shall be admitted to entry until the master shall produce a certificate that no person affected with leprosy was on board the vessel when admitted to free pratique, or, in case a leper was on board such vessel, that he or she, with their baggage, had been removed and detained at quarantine.

Succi, the famous fastner, completed a period of forty days in London in May, and later coming to New York, commenced a fast of forty-five days on November 5th.

Hypnotism has attracted an increasing amount of notice during the year, both from the medical profession and from the laity. Belgium has passed a law regulating its practice. What promises to be a *cause célèbre* is now on trial in France, in which a man and woman are tried for murder. The defence of the woman is that she was hypnotized by the man, and consequently not responsible for her act. The medical testimony seems to be divided.

The depopulation of France is a subject which, for some time, has agitated the French people. The question has been discussed this year at great length by the Académie de Médecine and other bodies. As causes, were given: the lack of care of illegitimate children, the military service, the pecuniary difficulties of large families, the large numbers of prostitutes, the late age of marriage and several others. Among the remedies proposed were: better care of unmarried pregnant women and illegitimate children, change in the military laws and laws of inheritance, a tax on bachelors and remission of tax on men with large families. Although the population is not now actually decreasing, the increase has practically stopped, which is not the case in most of the other countries.

Surgeon T. H. Parke, who arrived at Zanzibar with Stanley, having been through Africa with him as surgeon of the expedition, has been the object of well-deserved praise, not only from his chief, but from many high officials and societies, for his admirable conduct and his skill during his service.

The office of Surgeon-General of the United States Army was at the opening of the year occupied by

Dr. John Moore, who, in September, reached the age of retirement. The president then appointed Dr. Jedediah H. Baxter, who died December 4th. Charles Sutherland, M.D., senior medical officer, has recently been nominated for the vacant office.

The McKinley Tariff Bill has some features that will interest medical men. It allows the importation free, of books and pamphlets printed in any language but English, and of periodicals in all languages. Opium is put upon the free list. Other changes in the tariff on drugs were made, but they are not likely to affect the retail price to any extent.

The first Japanese Medical Congress was held in the early part of April in Tokio. The attendance was estimated at about three hundred, all of them being Japanese, the foreign physicians resident in Tokio taking no part.

The Longue Pointe Insane Asylum, near Montreal, Canada, caught fire, on May 6th, and was destroyed, with the loss of nearly fifty lives. The fire started in mid-day, but, despite this, the building was so inflammable and the means of arresting the flames so inadequate, that a great and shocking loss of life and a great many serious injuries resulted. The institution held about a thousand patients.

An accident at Quincy, Mass., occurred August 19th, on the Old Colony Railroad, in which about twenty persons were literally steamed to death, by being caught in a car which was thrown on top of an engine, allowing the whole contents of the boiler to escape into the car. Several were injured, mostly by steam, and removed to a new hospital recently built in the town.

A Pasteur Institute was opened in New York on February 18th, under the management of Dr. Paul Gibier, for preventive inoculation for hydrophobia. After having been open for eight months 610 persons had applied for treatment, having been bitten by dogs or cats. Of these, 480 were sent back after having their wounds attended to, it having been demonstrated that the animals were not mad. In 130 cases treatment was applied, after evidence that the offending animal had hydrophobia. All of those treated are doing well.

Among the scandals and abuses to which the attention of the medical profession has been drawn during the past year may be mentioned the early age of the girls at marriage in India, where sexual relations are often begun prior to menstruation; and the habit of ether intoxication in some parts of Ireland. Attention has also been more than usually directed to the slave trade and cannibalism in Africa, on account of the interest taken in that continent in connection with Stanley.

ANNUAL MEETINGS.

Some of the more important annual meetings of the year have been as follows:

The National Association of Railway Surgeons held its annual meeting at Kansas City, May 1st; the

Association of American Physicians held its fifth annual meeting at Washington, May 13th to 15th; the American Surgical Association held its meeting at the same place and time; the American Medical Association held its forty-first annual meeting at Nashville, Tenn., May 20th to 23d; the American Laryngological Association held its twelfth Annual Congress in the Johns Hopkins University, Baltimore, May 29th to 31st; the American Association of Genito-Urinary Surgeons held its fourth annual meeting at Altoona, Pa., June 3-4th; The sixteenth annual meeting of the American Neurological Association was held at Philadelphia on June 4th to 6th; the Massachusetts Medical Society held its one hundred and ninth annual meeting in Boston, June 10th and 11th; the American Otological Society held its twenty-third annual meeting on July 15th, at the Hotel Kaaterskill, Catskill Mountains; the American Climatological Society held its annual meeting at Denver, September 2d, 3d, 4th; the American Dermatological Association held its fourteenth annual meeting at Richfield Springs, N. Y., September 2d to 4th; the American Orthopedic Association held its fourth annual meeting at the College of Physicians, Philadelphia, September 16th to 18th; the American Gynecological Society held its fifteenth annual meeting in Buffalo, September 16th to 18th; the American Association of Gynecologists and Obstetricians held its annual meeting in Philadelphia, on September 16th to 18th; the American Rhinological Association met at Louisville, Ky., October 6th to 8th; the Mississippi Valley Medical Association held its sixteenth annual meeting at Louisville, Ky., on October 8th to 10th; the Southern Surgical and Gynecological Association was held at Atlanta, November 11th to 13th; the American Public Health Association held its eighteenth annual meeting at Charleston, S. C., December 15th to 19th; the Eighth Congress of Russian Naturalists and Physicians was held in St. Petersburg on January 9th to 11th; the First National Assembly of Japanese Physicians was held at Tokio early in April; the Seventh Italian Surgical Congress was held at Florence, March 30th to April 2d; the German Surgical Congress held its nineteenth annual meeting at Berlin on April 9th to 11th; the Ninth German Congress of Internal Medicine was held in Vienna, April 15th to 18th; the fifty-eighth annual meeting of the British Medical Association was held in Birmingham, July 29th to 31st, and August 1st; the first annual Congress of Psychological Medicine was held at Rouen on August 4th; the Congress of the French Association for the Advancement of the Sciences, was held at Limoges from August 7th to 14th; the Third International Congress on Alcohol was held in Christiania, September 3d to 5th.

LECTURES AND REPORTS.

The second report of the "Hyderabad Chloroform Commission," of which Dr. Lauder Brunton of London was president, was made in January; the Harveian Oration on "The Conditions of the Pulmonary Circulation" was delivered at the Royal College of Physi-

cians, on October 18th, by James Andrew, M.D., F.R.C.P.; the Milroy Lectures on "The Etiology and Prevention of Phthisis" were delivered before the Royal College of Physicians of London, by Arthur Ransome, M.D., F.R.S.; the Goulstonian Lectures on "Some Cerebral Lesions" were delivered before the same Society by G. Newton Pitt, M.D., F.R.C.P.; the Lumleian Lectures on "Convulsive Seizures" were delivered before the same society by J. Hughlings Jackson, M.D., F.R.C.P., LL.D., F.R.S.; the Croonian Lectures on "Cerebral Localization" were delivered before the same society by David Ferrier, M.D., LL.D., F.R.S.; the Bradshawe Lecture on the "Morbid Anatomy of Diabetes" was delivered before the same society by Robert Launby, M.D., F.R.C.P.; the Harveian Lectures on "Painful Menstruation" were delivered before the Harveian Society by F. H. Champneys, M.D., F.R.C.P.L.; the Cavendish Lecture on "Unrecognized Lesions of the Labyrinth," was delivered before the West London Medico-Chirurgical Society, by Alexander Ogston, M.D., C.M.; the first Shattuck Lecture was delivered before the Massachusetts Medical Society by George B. Shattuck, M.D., on "Influenza in Massachusetts"; the Middleton-Goldsmith Lecture was delivered before the New York Pathological Society by William Pepper, M.D., on "Hepatic Fever."

NECROLOGY.—FOREIGN.

Prof. S. Botkin, physician to the Czar, professor of clinical medicine, St. Petersburg, died December 24, 1889, aged fifty-seven.

Dr. Benedict Schulz, the first Austrian physician to place electrotherapy upon a scientific basis, died January 5, 1890, aged seventy.

Dr. Karl Westphal, professor extraordinary and medical director of the department for mental and nervous disease at the Charité Hospital, Berlin, died January 7, aged fifty-seven.

Dr. Anton Friedrich von Trötsch, professor of ear diseases in University of Würzburg, died January 9.

Victor Gautier, M.D., who is claimed by his countrymen as a precursor of Lister in antisepic surgery, died at Geneva, January 11, aged sixty-six.

M. Daniel Mollière, M.D., of Lyons, surgeon-major of the Hotel Dieu, died January 19, aged forty-one.

Sir William Gull, Bart., M.D., F.R.C.P., etc., Fulanian professor of physiology, physician and lecturer at Guy's Hospital, medical adviser of the royal family, died January 29, aged seventy-four.

Eduard von Wahl, M.D., professor of surgery at the University of Dorpat, died February 1, aged fifty-seven.

Alexander Shaw, F.R.C.S., surgeon to the Middlesex Hospital London, died February 5, aged eighty-six.

Dr. Otto Becker, professor of diseases of the eye at the University of Heidelberg, died February 7, aged sixty-two.

Marcellano Gómez Panco, M.D., one of the leading

surgeons of Spain, died at Madrid, February 6, aged fifty-five.

Prof. Marino Turchi, Dean of the University of Naples, died March 3, aged eighty-two.

Dr. Ulysse Trélat, professor of clinical surgery in the Charité Hospital, member of the Paris Academy of Medicine, died March 28, aged sixty-two.

Victor Besson, M.D., professor of pathology, St. Petersburg, died April 15, aged sixty-five.

Alessandro Tafani, M.D., professor of anatomy, Florence, died April 20, aged forty.

Robert McCormick, F.R.C.S., R.N., well-known arctic explorer, aged ninety.

William Kitchen Parker, M.R.C.S., F.R.S., etc., Hunterian professor of comparative anatomy, died at Cardiff on July 3, aged sixty-seven.

James Matthews Duncan, M.D., F.R.S., obstetric physician and lecturer on midwifery at St. Bartholomew's Hospital, London, died September 1, aged sixty-four.

Professor Gavarret, president of the Academy of Medicine, Paris, professor of medical physics at the Paris Faculty of Medicine, died September 2, aged eighty-one.

Charles Handfield Jones, M.B., F.R.C.P., F.R.S., Lumleian lecturer, physician to St. Mary's Hospital, etc., died September 30, aged seventy-one.

Ernest Hardy, M.D., head of the Chemical Laboratory of the Academy of Medicine in Paris, aged sixty-three.

Wenzel Gruber, professor of anatomy for nearly forty years at St. Petersburg, died in Vienna, in October, aged seventy-six.

Dr. Gustave Monod, sometime professor in the Faculté de Médecine, Paris, died on October 16, aged eighty-six.

Alexander Boggs, M.D., M.R.C.S. senior member of the English Medical Colony in Paris, and correspondent of several medical journals, died in October, aged sixty-seven.

Johann Nepomuck von Nussbaum, professor of surgery in the University of Munich, surgeon-general of the Bavarian army, died October 31, aged sixty-one.

Albert Vogel, formerly professor of diseases of children at the University of Dorpat, died in Munich November 9, aged sixty-four.

NECROLOGY.—UNITED STATES.

James H. Hutchinson, M.D., vice-president of the College of Physicians, Philadelphia, visiting physician to the Pennsylvania and Children's Hospital, died December 27, 1889, aged fifty-five.

Lewis Hall Sayre, M.D., assistant professor of orthopedic surgery at the Bellevue Hospital Medical College, died January 2, 1890, aged thirty-nine.

Charles S. Wood, M.D., president of the New York County Medical Association, died in February, aged sixty-five.

John W. Jackson, M.D., president of the Faculty of the University Medical College of Kansas City,

chief surgeon of the Missouri, Pacific and Wabash railroads, died March 13, aged fifty-six.

John P. Davidson, M.D., chairman of the board of yellow fever experts, died in New Orleans, March 30, aged eighty-two.

Henry H. Smith, M.D., professor of surgery in the University of Pennsylvania, distinguished army surgeon, died April 11, aged seventy-five.

William H. Byford, M.D., professor of obstetrics and gynaecology at the Rush Medical College, Chicago, died May 22, aged seventy-three.

Joseph W. Howe, M.D., surgeon in several New York hospitals, died on his way to the International Medical Congress, at sea, June 7, aged forty-seven.

Joseph P. Ross, M.D., for over twenty years professor of clinical medicine at the Rush Medical College, died June 25, aged sixty-two.

Charles L. Allen, M.D., secretary of the Vermont State board of health, died July 2, aged seventy.

R. C. Ward, M.D., professor of physiology in the Southern Medical College, Atlanta, died July 20.

J. A. Allen, M.D., dean of Rush Medical College, and for twenty-five years chief surgeon of the Chicago, Burlington and Quincy Railroad, died August 15, aged sixty-five.

Proctor Thayer, M.D., professor of surgery in the Western Reserve Medical College, Cleveland, O., noted army surgeon during the war, died October 1, aged sixty-seven.

Montross A. Pallen, M.D., formerly professor in the University of the City of New York, and St. Louis Medical College, notorious confederate surgeon during the war, died October 1, aged fifty-one.

Henry J. Bigelow, M.D., LL.D., professor of surgery at the Harvard Medical School, emeritus; surgeon to the Massachusetts General Hospital; discoverer of the Y-ligament of the hip, and of the operation of litholapaxy; died October 30, aged seventy-two.

Richard J. Lewis, M.D., formerly surgeon of the Pennsylvania and Jefferson Medical College Hospitals and of the Polyclinic, died November 12, aged sixty-three.

Jedediah H. Baxter, M.D., Surgeon-General of the United States Army, died December 4, aged fifty-three.

NECROLOGY OF MASSACHUSETTS MEDICAL SOCIETY.

Benjamin Fearing, M.D., of Wareham, died December 26, 1889, aged sixty-five.

James Griswold Shannon, M.D., of Rutland, died December 29, 1889, aged forty-six.

Arthur Quinn Phelan, M.D., of Lowell, died January 7, 1890, aged forty-two.

Francis Frederick Brown, M.D., of Reading, died January 13, aged fifty-five.

William Michael Hoar, M.D., of Lowell, died January 18, aged forty.

William Adams Winn, M.D., of Arlington, died January 19, aged forty-one.

James Emerson, M.D., of Gardner, died January 21, aged sixty-two.

James Porter Lynde, M.D., of Athol, died January 21, aged sixty-two.

George Henry Nichols, M.D., of Cambridge, died February 5, aged seventy-five.

Josiah Trow, M.D., of Buckland, died February 15, aged seventy-three.

Frederick Lysander Burden, M.D., of Attleboro, died February 23, aged forty-two.

Benjamin Franklin Seabury, M.D., of Orleans, died February 26, aged eighty-two.

George Mumford Read, M.D., of Dorchester, died March 16, aged thirty-three.

Edward Henry Weston, M.D., of Somerville, died March 28, aged seventy.

John Crowell, M.D., of Haverhill, died April 28, aged sixty-six.

Edward Evans Denniston, M.D., of Northampton, died May 10, aged eighty-seven.

Albert Sylvester Tobien, M.D., of Templeton, died May 10, aged forty-five.

Arthur Henry Wilson, M.D., of South Boston, died May 11, aged fifty one.

Bradford Leonard Wales, M.D., of Randolph, died May 13, aged eighty-six.

Perley Eben Goodhue, M.D., of Haverhill, died May 19, aged thirty-one.

John Henry Gilman, M.D., of Lowell, died June 11, aged fifty-four.

Jesse Walker Snow, M.D., of Somerville, died June 12, aged sixty-nine.

William Dandridge Peck, M.D., of Sterling, died June 29, aged seventy-seven.

Willard Everett Smith, M.D., of Boston, died July 14, aged thirty-four.

Daniel Waterhouse Niles, M.D., of Worcester, died July 17, aged sixty-three.

John Nelson Borland, M.D., of Boston, died August 10, aged sixty-two.

Herman Elvers Davidson, M.D., of Boston, died August 10, aged seventy-five.

Thomas Thurston Griggs, M.D., of Grafton, died August 11, aged seventy-two.

Moses David Church, M.D., of Cambridgeport, died August 25, aged forty-five.

Daniel Homer Batchelder, M.D., of Danversport, died September 4, aged seventy-nine.

Winthrop Flint Stevens, M.D., of Stoneham, died September 5, aged forty-two.

Joseph Murphy, M.D., of Taunton, died September 15, aged seventy-two.

John Cauldwell Sharp, M.D., of Boston, died September 26.

Charles Lyman Hubbell, M.D., of Williamstown, died October 7.

Jerome Wilmarth, M.D., of Milford, died October 7, aged fifty-nine.

Israel Houston Taylor, M.D., of Amherst, died October 16, aged sixty-seven.

Charles Edward Spring, M.D., of Holliston, died October 25, aged forty-eight.

Henry Jacob Bigelow, M.D., of Boston, died October 30, aged seventy-two.

Jubal Converse Gleason, M.D., of Rockland, died November 1, aged fifty-two.

Thaddeus Kingsley DeWolf, M.D., of Chester Centre, died November 4, aged eighty-nine.

Orlando Witherspoon Doe, M.D., of Boston, died December 10, aged forty-seven.

We are sorry to note that the average age this year of the deceased members of the Massachusetts Medical Society is only a little over sixty years, being less by eight years than in 1889.

MEDICAL NOTES.

— The President has recently nominated Colonel Charles Sutherland, M.D., senior medical officer, for the office of surgeon-general of the army, in place of Dr. J. H. Baxter, deceased. The number of petitions for the appointment of Dr. J. S. Billings was remarkably large, as might be expected by all who are familiar with his particular fitness for the position.

— Dr. Henry H. Hunt, of Portland, has resigned the chair of physiology in Bowdoin College. Dr. Charles D. Smith, of Portland, has been chosen to give the course of lectures in this branch for the next term. Dr. Smith, who is a member of the State Board of Health of Maine, gave the course on public hygiene, in the college this year, and his work was so satisfactory no doubt is felt of his success in this new field.

— An amusing instance of the kind of paternal anxiety for the public welfare which occasionally arises in the breasts of our national legislators is seen in a recent proposition of Mr. Platt, of Connecticut, to appropriate \$10,000 to enable the President to take action to obtain from the German Government a supply of the remedy discovered by Dr. Koch and the formula for its manufacture.

— The police authorities of Berlin have notified all unlicensed sanatoriums, hotels, etc., that consumptives and other patients suffering from infectious diseases, who may be stopping at such places, must depart within eight days, or the places will be closed. This action, it is supposed, will affect private clinics.

— A letter received by us from Berlin, under date of December 9th, states that there were at that time 6,000 unanswered applications on file for Koch's fluid.

— Before the recent introduction of aniline colors as antiseptics, one could often tell by their various odors what antiseptic substances a surgeon preferred; but now the hues that adorn his hands give him away. Steady elderly gentlemen may be content with a monochromatic dressing; while younger men, of more aesthetic tastes, will prefer substances more cunningly mingled, so as to produce the general effect of the patch-work quilt of our aunts and the coat of Joseph.

— A board of medical officers appointed to consider the question of disinfectants for quarantine and hos-

pital purposes have reported to the Marine-Hospital Bureau that disinfection by steam heat at 100° C. should be applied when practicable to all clothing, bedding, and textile fabrics, in such a manner as to cause a current of steam to pass through the articles, so that the same temperature is maintained for a period of not less than two hours. Solutions of mercuric chloride should be made by mixing mercuric chloride, one part; hydrochloric acid, 15 parts; water, 500 parts. This diluted one-half gives the weaker solution. The strong solution is to be used principally in the treatment of the holds, decks, and water-closets of vessels. The weaker solution (1-1000) is used for the disinfection of those articles of clothing and other fabrics which cannot be subjected to steam heat. Sulphur dioxide should be used as an auxiliary in the disinfection of the hold, cargo, and cabins, in strength of not less than 10 per cent., for 36 hours. Potass. permanganate, chlorine, bromine iodine, peroxide of hydrogen and lime, in addition to their germicidal powers, are reliable as deodorizers.

— As a theatrical performance the following is unique. The description comes from a daily paper of a city in Nebraska. "Last evening the large attendance at the People's Theatre, in addition to the usual entertainment given by the great German Polyclinic doctors, were witnesses of several difficult surgical operations that were undertaken and most successfully accomplished in full view of the packed audience, including a number of Omaha's leading physicians. They were pronounced by those who know to have been most skilfully and scientifically handled. The first case was a large tumor removed from the right cheek of William Villiers of the Millard Hotel billiard-room. One of the doctors of this staff, conducted this operation, and it was eminently successful; and the result will be, William Villiers before long will be all right. Another operation requiring great skill was relieving the little eight-year-old son of F. M. Kiger of strabismus (or cross-eyes). Cases of this kind require the greatest of care and experience, and was most satisfactory evidence of what these doctors can do. These entertainments are most instructive and pleasing. Nothing is done to which the most fastidious can take exception, ladies being always especially pleased. These notable physicians can be consulted at their office in the Barker Building. Operations and entertainment each evening at 8 p. m., at the People's Theatre. Admission free to all."

NEW YORK.

— New York physicians are arriving almost daily from Berlin now, and in consequence there is an abundance of Koch's fluid for use in the various hospitals. The first injections were made at Bellevue Hospital on December 19th by Dr. Alfred L. Loomis with material brought by his son, Dr. H. P. Loomis, who arrived from Europe the day previous. On the same date Dr. J. H. Linsley gave a report of his observations in Berlin at the Post-Graduate Medical College. Thus far, one death has been reported after

injection, but it was in the case of a child at the New York Foundling Asylum, who was in an advanced stage of tubercular meningitis, and it is not believed that the treatment had any effect in hastening the fatal termination.

— At a meeting of the Section on Theory and Practice of the Academy of Medicine held December 16th, Dr. J. West Roosevelt read a paper on the anatomy of the lungs illustrated by some very fine corrosive specimens, and, in the course of it he alluded to some points of special interest in a surgical aspect, in view of the fact that it seems probable that in the near future certain new departures in the surgery of the lungs are likely to be made. On December 17th, a dispatch was received from Berlin stating that Professor Sonnenburg has commenced to apply surgical treatment to patients suffering from cavities in the lungs, three operations, at each of which Professor Koch was present, having already been performed by him.

— The Board of Estimate and Apportionment has allotted the sum of \$404,400 for the expenses of the Health Department for the ensuing year.

— On October 1st the number of insane poor still remaining in the various county poor-houses and asylums amounted to 2,050. Since then 309 have been

removed, by order of the State Commission in Lunacy, to the State hospitals, and it is expected that by October 1, 1891, not more than 1,200 will be left to be provided for by the State institutions.

— Succi completed his fast of forty-five days at 8 o'clock on the evening of December 20th. The final medical examination was made at 4 o'clock in the afternoon, and showed his weight to be 104½ pounds (weight on first day 147½ pounds); temperature normal; pulse, 62; respiration, 90; dynamometer, 44; spirometer, not taken; general condition weak; tongue clear, moist and steady. Urinary analysis, eight ounces in twenty-four hours; specific gravity, 1.022; reaction acid, clear. Water drunk during the day, natural, seven ounces; alkaline, 20 ounces; purgative, four ounces. During the forty-five days the faster took 291 ounces of Croton water, 799 ounces of mineral waters, and 64 ounces of ice. He also took 710 drops of his elixir, which is said to be composed of morphia, cannabis indica, chloroform, sulphuric ether and alcohol. On some of the forty-five days this was omitted. During the last few days he had a hard struggle, and there can be little question that any prolongation of the fast beyond the forty-five days, would have proved fatal.

REPORTED MORTALITY FOR THE WEEK ENDING DECEMBER 13, 1890.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 13, 1890, TO DECEMBER 19, 1890.

First Lieutenant THOMAS U. RAYMOND, assistant surgeon, having been ordered to temporary duty at Vancouver Barracks, Washington, by the commanding general Department of Columbia, is assigned to duty at that post, and relieved from further duty at Fort Sherman, Idaho. S. O. 294, A. G. O., Washington, D. C., December 17, 1890.

Paragraph 17, of Special Orders, No. 287, December 9, 1890, from this office, relating to Captain MARCUS E. TAYLOR, assistant surgeon, is amended so as to direct him to report to the commanding officer, Vancouver Barracks, Washington, for duty as post surgeon, relieving Colonel BERNARD D. IRWIN, surgeon, of that duty. Captain RUDOLPH G. EBERT, assistant surgeon, will be relieved from duty at Vancouver Barracks, Washington, upon the arrival of Captain Taylor, and will proceed to Fort Hancock, A. T., and report in person to the commanding officer of that post for duty. S. O.—Par. 1, A. G. O., Washington, D. C., December 17, 1890.

By direction of the Secretary of War the extension of leave of absence granted Major STEPHENSON G. COVENDEN, surgeon, in Special Orders, No. 263, November 10, 1890, from this office, is further extended ten days on account of sickness. Par. 4, S. O. 293, A. G. O., December 16, 1890.

By direction of the Secretary of War, Captain FRANCIS J. IVES, assistant surgeon, now on leave of absence, will proceed to South Dakota, Rapid City, and report in person to Colonel EUGENE A. CARE, 6th Cavalry for duty with troops in the field, relieving First Lieutenant WILLIAM B. BANISTER, assistant surgeon, and reporting also by letter to the commanding general Department of Dakota. Par. 18, S. O. 299, A. G. O., Washington, D. C., December 11, 1890.

Leave of absence for fourteen days, to take effect on or about December 20, 1890, is granted Captain WILLIAM STEPHENSON, assistant surgeon, Par. 18, S. O. 291, A. G. O., Washington, D. C., December 13, 1890.

By direction of the Secretary of War, Captain WALTER REED, assistant surgeon, now on duty at Baltimore, Maryland, will remain without delay to commanding officer, Fort Keogh, Montana, for temporary duty at that station, and by letter to the commanding general Department of Dakota, S. O. 291, Headquarters of the Army, A. G. O., Washington, D. C., December 13, 1890.

By direction of the Secretary of War, Captain WILLIAM O. OWEN, Jr., assistant surgeon, now on leave of absence, will re-

port in person without delay to Colonel EUGENE A. CARE, 6th Cavalry, at Rapid City, South Dakota, for duty with troops in the field, and by letter to the commanding general Department of Dakota. Par. 17, S. O. 291, A. G. O., Washington, D. C., December 13, 1890.

By direction of the Secretary of War, Major CHARLES SMART, surgeon, is detailed as a delegate to represent the Medical Department of the Army, at the annual meeting of the American Public Health Association, to be held at Charleston, South Carolina, December 16 to 19, 1890. He will proceed to Charleston, accordingly, and upon the final adjournment of the Association, return to his station in this city. Par. 2, S. O. 290, A. G. O., Washington, D. C., December 12, 1890.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 20, 1890.

SHELDON G. EVANS, assistant surgeon, ordered to Naval Academy, Annapolis, Md.

CORBIN J. DECKER, passed assistant surgeon, detached from Naval Academy, and ordered to Naval Hospital, Philadelphia, Pa.
